All thermodynamic measurements are based on differences between states; there is no absolute value for any property (with the exception of entropy). To quantify thermodynamics, we choose by convention a reference state called the *standard ambient temperature*, pressure, and concentration state [temperature = 298 K (25°C), pressure = 1 bar (10^5 Pa), concentration = 1 molal (mol of solute/kg of solvent)]. The use of atmospheres as a unit of pressure is widespread, and it is so close to the value of 1 bar (1.0134 bar = 1 atm) that the reference state often used is that of 1 atm. The differences are seldom significant. Concentrations are more reliably measured in molality (amount/mass of solvent) rather than molarity (amount/volume of solvent). However, for the following reasons: 1) volume is easier to measure than mass, and 2) density of water (the most common solvent) is close to 1, the most commonly used reference state for concentration is that of 1 M (mol/L). Reference states are indicated by the superscript °, e.g., C° or P°.

The propensity for a given material to contribute to a reaction is measured by its activity, a. This describes how "active" this substance is in the reaction compared with how it would behave if it were present in its standard state. Activity scales with concentration or partial pressure:

$$a \propto C/C^\circ \text{ or } a \propto P/P^\circ \tag{7.47}$$

Generally speaking, a substance's activity increases as the amount of that substance available for reaction increases. However, because of intermolecular interactions (which increase as a substance's concentration or partial pressure increases), there are deviations from a direct correspondence as pressure and concentration increase. These differences can become very significant at very high concentrations. We then define activity as:

$$a = \gamma C/C^\circ \text{ or } a = \gamma P/P^\circ \tag{7.48}$$

Activity coefficients γ are close to 1 for dilute solutions and for low partial pressures, but they change with concentration, temperature, other species, and so on. Generally, we ignore activity coefficients for educational simplicity, but careful work requires its consideration. In the case of pressure, the coefficient used is often called *fugacity*, but it is the same thing and behaves in the same way. Activity *a* is unitless, and because activity coefficients are close to 1 for dilute solutions, the reference states for partial pressure and concentration have a numerical value of 1. Therefore, we often approximate activity by concentration (M) or partial pressure (atm). The reference state for a solid material is itself, and the same is true for a pure liquid. A solvent is usually present in huge excess (compared with the solutes); therefore, it is mostly like a pure liquid. In all these cases, $a = 1$. In other words, if we increase the amount of a pure solid, a pure liquid, or a solvent, the reaction goes on for a longer time (but it does not go any faster).

If you increase the amount of these materials in a system, it will not increase the reaction rate, but it may increase the duration of a reaction. The point is that the "activity" of the system does not change with amount of these materials, so they are always referenced to themselves.

The Nernst Equation

We now want to know what happens with the cell potential if the concentrations and pressures are not in the standard state. We first derive how the chemical potential, μ, changes with activity by integrating the expressions for the dependence of amount of material on the Gibbs function, leading to the following relationship:

$$\mu = \mu^0 + RT \ln a \tag{7.49}$$

When analyzing a chemical reaction such as aA + bB → cC + dD mathematically, we form the following reaction quotient:

$$Q = \frac{a_C^c a_D^d}{a_A^a a_B^b} \tag{7.50}$$

where products appear in the numerator and reactants in the denominator. It requires the activity of each reaction participant, where each term is raised to the power of its stoichiometric coefficient. Terms in the reaction quotient that arise from the participation of pure solids, pure liquids, or solvents are left out as they all equal to 1. If we ignore activity coefficients, then activities for solutes and gases are numerically equal to their concentration or partial pressures (because the activity is the ratio of these terms with the number 1). One often writes the reaction coefficient Q with concentration and pressure shown explicitly, but remember that we are really dealing with activities. The reaction quotient is unitless because it has only activity in its expression, and all activities are unitless. The Gibbs free energy has the same activity dependence as the chemical potential:

$$G = G^0 + RT \ln a \tag{7.51}$$

When we apply this to a reaction, the reaction quotient comes into play, which gives us:

$$\Delta G = \Delta G^0 + RT \ln Q \tag{7.52}$$

Q contains all the activities of both reactants and products, all raised to their proper stoichiometric coefficients. When all participants have unit activity (a = 1), then Q = 1 and ln Q = 0, or:

$$\Delta G = \Delta G^0 \tag{7.53}$$

The reaction proceeds and Q changes until finally ΔG = 0. At that point, the reaction stops as equilibrium is reached with the reaction quotient Q = Q*. The reaction does not stop at Q^* but simply has reached the situation where the forward and reverse reaction rates are equal. Chemical activity is still ongoing with just as much vigor as before, but it is happening equally in both directions—products are reacting to turn into reactants just as fast as reactants are reacting to turn into products. This is called a *dynamic equilibrium*, rather than a *static equilibrium*.

$$\begin{aligned} 0 &= \Delta G^0 + RT \ln Q^* \\ \Delta G^0 &= -RT \ln Q^* \\ \text{and } Q^* &= K_{eq} \end{aligned} \tag{7.54}$$

This special Q^* is renamed K_{eq}, the equilibrium constant. From the expression for the Gibbs free energy as a function of activity (Equation 7.51), we can derive an expression in terms of the cell potential by using the relation between the free energy and the cell potential E (Equation 7.46):

$$\Delta G = \Delta G^0 + RT \ln Q = -nFE = -nFE^0 + RT \ln Q \tag{7.55}$$

where n is the number of electrons transferred in the process. By rearranging, we obtain the very important Nernst equation:

$$E = E^0 - \frac{RT}{nF} \ln Q = E^0 - \frac{0.0592}{n} \log Q \tag{7.56}$$

This expression relates the dependence of the cell potential E on the reaction quotient Q. The logarithmic term tells us that if Q changes by a factor of 10, this will change the cell potential by 59.2 mV, or about 60 mV for a one-electron process (n = 1). This "rule of thumb" relationship will show up often in sensors, batteries, fuel cells, and so on.

The above equations allow us to relate measured cell potentials to standard Gibbs free energies of reaction. These, in turn, are related to a reaction's equilibrium constant (see Equation 7.54).

Example 7.4:

Consider the Daniell cell of Figure 7.35 again. What is the potential of the cell if $[Cu^{2+}] = 0.01$ M and $[Zn^{2+}] = 1.00$ M? (We will assume that the activity coefficients are = 1.)

$$E = 1.10 - \frac{0.0592}{n} \log\frac{1.00}{0.01} = 1.10 - 0.030 \log(100)$$

$$= 1.041\,V$$

Note that the cell potential is decreased by about 60 mV from the standard cell potential. This accounts for a decrease in Cu^{2+} concentration of two orders of magnitude, where our rule of thumb predicted 120 mV; however, because the reaction involves two electrons (n = 2), we obtain a 60-mV change in potential only.

Example 7.5:

The Nernst equation demonstrates that potential depends on concentration. A cell made of the same materials, but with different concentrations, will also produce a potential difference, e.g.:

$$Cu \mid Cu^{2+}\,(0.001M) \parallel Cu^{2+}\,(1.00M) \mid Cu$$

What is standard cell potential E^0 for this cell? What is the cell potential E? What is n, the number of electrons transferred? Which electrode, anode, or cathode will be in the numerator?

$$E = E^0 - \frac{0.0592}{n} \log\left(\frac{[Cu^{2+}]_{anode}}{[Cu^{2+}]_{cathode}}\right)$$

$$= 0 - \frac{0.0592}{2} \log\frac{0.001}{1.00} = +0.089\,V$$

The standard cell potential in a concentration cell clearly must be 0 for the two electrodes, because at standard conditions both are identical. The number of electrons transferred is two. Remember that we are calculating the cell potential for the cell as written in the definition. The right side is the cathode and thus refers to a reduction process. The other is for oxidation. If we write those two reactions, we see that the aqueous solution from the cathode appears as a reactant. Hence the cathode aqueous solution is in the denominator, and conversely the anode side is in the numerator.

Example 7.6:

Consider the cell:

$$Pt \mid I^-\,(1.00M),\ I_2\,(1.00M) \parallel Fe^{2+}\,(1.00M),\ Fe^{3+}\,(1.00M) \mid Pt$$

with a standard cell potential given by = 0.771 V – 0.536 V = +0.235 V.

$$\Delta G^0 = -nFE^0 = -2(96,485\ C/mol)(0.235\ J)$$

$$= -45,348\ J/mol$$

This is the free energy change leading to the equilibrium constant, K_{eq}, for the reaction as follows:

$$\ln K_{eq} = -\frac{\Delta G^0}{RT} = -\frac{(-45,348\ J/mol)}{(8.314\ J/Kmol)(298\ K)} = 18.3034$$

$$K_{eq} = e^{18.3034} = 8,8910^7$$

Exercise 7.3: A metal in contact with a sparingly soluble salt of the metal, we will see below, is called an *electrode of the second kind*. Another common name for such an electrode is an anion electrode. Examples include reference electrodes (REF Es), such as Ag/AgCl(s) and $Hg/Hg_2Cl_2(s)/Cl^-$ [saturated calomel electrode (SCE)]. These reference electrodes are often more convenient to use than the above-reviewed SHE. Consider the Ag/AgCl electrode shown in Figure 7.36. This REF E is made from an Ag wire coated with AgCl(s) immersed in an NaCl or KCl solution.

The reactions involved are $AgCl \leftrightarrow Ag^+ + Cl^-$ and $Ag^+ + e^- \leftrightarrow Ag(s)$ [$E^0_{red} = +0.80$ V]. Derive the Nernst equation for this electrode.

$$Ag^+ + e^- \leftrightarrow Ag(s) \quad E^0_{red} = +0.80\ V$$

Chemical reaction;

$$AgCl \leftrightarrow Ag^+ + Cl^- \text{ no electrons involved}$$

$$AgCl + e^- \leftrightarrow Ag(s) + Cl^-$$

$$E = E^0 - \frac{0.0592}{1} \log\frac{a_{Ag}a_{Cl^-}}{a_{AgCl}} \text{ but } a_{Ag} \text{ and } a_{AgCl} = 1$$

$$\text{or } E = 0.80 - 0.0592 \log a_{Cl^-}$$

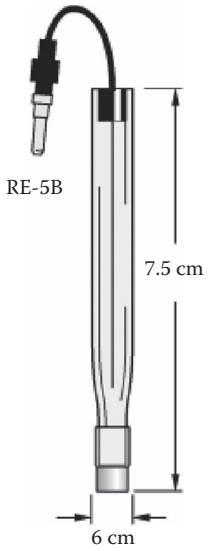

FIGURE 7.36 A typical commercial Ag/AgCl reference electrode. (From http://www.bioanalytical.com.)

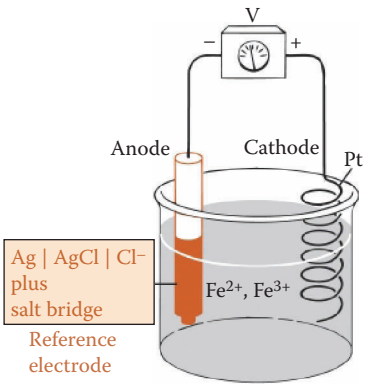

FIGURE 7.37 Potentiometric sensor in a two-electrode cell. The entire left half-cell is made into a self-contained reference electrode containing appropriate solutions and a salt bridge. The chloride concentration in the reference electrode is held constant by the fixed solubility of KCl.

From this expression, Cl^- (an anion) activity determines the potential of this electrode, and the electrode can be used as a Cl^- sensor (60-mV voltage change per decade of Cl^- concentration change). The purpose of a reference electrode is to provide a stable potential, independent of solution composition, against which other potentials can be reliably measured. Filling a glass envelope, which is equipped with a small pinhole to make ionic contact with the outside solution, with a saturated Cl^- solution that surrounds a Ag/AgCl wire produces a reliable reference electrode. The constant a_{Cl^-} in the above equation provides for a constant E (E = 0.22 V vs. SHE at 25°C). Only when enough solvent or ions from the outside solution enter the glass envelope does the reference potential start drifting. It is obvious that the larger the REF E electrolyte reservoir, the longer the reference electrode will last without need to refill the reservoir with fresh saturated Cl^- solution. This explains why miniaturization of a reference electrode is such a challenge; smaller means less electrolyte capacity and thus a shorter lifetime.

Two-Electrode and Three-Electrode Cell Configurations

There are two common electrode configurations used in electrochemistry: two-electrode and three-electrode cells. In a two-electrode configuration, an electrochemical cell is equipped with one working electrode (WE) and one reference electrode (REF E) (Figure 7.37). The electrode at which the reaction of interest occurs is called the *working electrode*. An *amperometric measurement* with such a cell occurs when current is passed between the WE and REF E by applying a potential between the two. The kinetics of the electrochemical reaction are driven by the applied potential, and we measure the diffusion-controlled current flowing across the electrode/solution interface. This current is directly proportional to the bulk concentration of the analyte present in the solution (see Equation 7.124). Passage of a significant current through a reference electrode shifts the electrode away from equilibrium and may even destroy its materials (e.g., in the case of Ag/AgCl, the AgCl could all be reduced to Ag). Moreover, a significant resistance decrease (iR) results for less conductive media (in a salt water solution, this is not a problem since R is typically 100 Ω, so with $i < 10$ μA, $iR < 1$ mV) or when the WE is very large. As a consequence, a two-electrode cell should only be used when the iR drop is less than 1 mV or when using *micro-* or *ultramicroelectrodes*. In *potentiometric measurements*, only very small currents are drawn, and a two-electrode system can always be used confidently in this case (as long as a high-impedance voltmeter is used so that a measurement of the potential difference will be accurate). In potentiometry, the electron transfer reaction is kinetically facile, i.e.,

the equilibrium electron exchange current $i_{0,e}$ (on an electron conductor) or ion exchange current $i_{0,i}$ (on an ion conductor) is large. The cell potential responds to changes in the activity of the analyte species present in the solution in a well-defined manner described by the Nernst equation. The cell potential varies in a linear manner with the logarithm of the analyte activity.

Microelectrochemical sensors are often based on a two-electrode system with a WE and a pseudoreference electrode because a real reference electrode is too complicated and expensive to implement. This is possible because the small working electrode draws so little current that a larger pseudoreference electrode (i.e., a Ag/AgCl film) is not shifted from equilibrium enough to cause large errors.

In a three-electrode electrochemical cell (Figure 7.38) one deals with a WE, a REF E, and a counter electrode (CE) or auxiliary electrode. A Luggin capillary is often used to position the sensing point of a reference electrode at a desired point in a cell close to the working electrode.

With three-electrode systems, a *potentiostat* is used. A potentiostat is an instrument that controls the voltage difference between a WE and a REF E (Figure 7.39). The potentiostat implements this control by injecting current into the cell through the auxiliary electrode or CE. In almost all applications, the potentiostat measures the current flow between

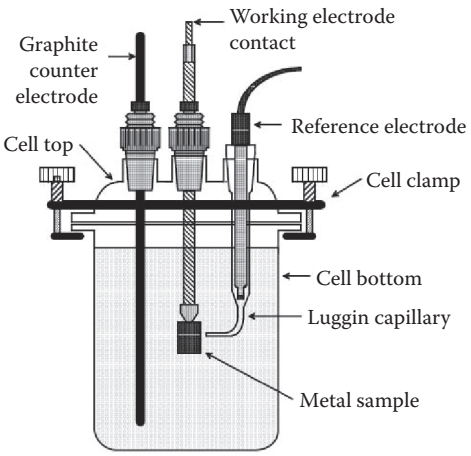

FIGURE 7.38 In this three-electrode cell, the counter electrode (CE) is a graphite rod, the working electrode (WE) is located in the center, and the reference electrode (REF E) is brought close to the working electrode surface via a Luggin capillary.

FIGURE 7.39 Solartron 1286 potentiostat and 1250 frequency response analyzer. (See also http://www.bioanalytical.com.)

the working and auxiliary electrodes. A high impedance is placed in front of the reference electrode to limit the current so that the reference potential remains constant. A cell like this avoids the internal polarization of the reference electrode and its potential degradation. The system also compensates for a major portion of the cell *iR* drop.

A potentiostat can be converted to work in *galvanostat* mode. Whereas in potentiostat mode one controls the potential and measures the ensuing current, in galvanostat mode one controls the current and measures the ensuing voltage. *Voltammetry* is an electroanalytical method in which the potential of an indicator electrode is varied in a definite manner with time, and the current flowing through the indicator electrode is measured. Voltammetric techniques are classified according to the type of voltage perturbation applied to the working or indicator electrodes, i.e., the way in which the voltage signal input varies with time. The form of the input $V(t)$ function determines the form of the resulting current response (see some examples in Table 7.12). The current/potential response curve is called a *voltammogram*. The voltammetry method relies on the fact that the current measured reflects rate-determining diffusion of the analyte species from the bulk solution to the surface of the indicator electrode, where it is readily oxidized or reduced. The solution contains supporting electrolyte, i.e., an excess of nonreactive electrolyte (e.g., KCl or NaCl), to conduct current besides the redox couple. This ensures that the redox species reaches the electrode by diffusion but not by migration. Under such conditions of diffusion control, the measured current is linearly proportional

TABLE 7.12 Voltammetry Examples

Name of Techniques	Potential Excitation Signal		Mass Transfer	Measurement	Analytical Relation to Bulk Concentration	Typical Display
Polarography (DC or normal)	Slow linear scan (or constant E)		Diffusion	i vs. E	$i_d \propto C$	AC Polarograph	Slow linear scan + low amplitude sine wave		Diffusion	i_{ac} vs. E	$i_a \propto C$	
Pulse polarography	Square voltage pulses of increasing amplitude		Diffusion	i vs. E	$i_d \propto C$	Differential pulse polarography	Square voltage pulses of constant amplitude + linear ramp		Diffusion	Δi vs. E	$i_p \propto C$	Single-sweep voltammetry	Linear scan E		Diffusion	i vs. E	$i_p \propto C$	Cyclic voltammetry	Triangular scan E		Diffusion	i vs. E	$i_p \propto C$	
to the bulk concentration of the analyte species (see Equation 7.124).

A most important example of voltammetry is cyclic voltammetry, an electrochemical method in which information about an analyte is obtained by measuring current (i) as a function of applied potential using a triangular waveform for excitation (Figure 7.40). We will detail the features of a cyclic voltammogram after we elucidate the difference between kinetic and diffusion-controlled electrochemical reactions.

In Figure 7.41 we compare two- and three-electrode systems.

Types of Electrodes

Introduction

We distinguish electrodes based on the nature and number of phases between which electron transfer occurs and/or based on the nature of the current-carrying species within them. Based on the nature and number of phases, one typically recognizes electrodes of the first kind and electrodes of the second kind. Based on the charge carrier in the solid, we can also distinguish between metals, semiconductors, insulators, solid electrolytes, and mixed conductors. As summarized in Table 7.10, different types of mobile charge carriers characterize the different types of electrode materials. Metal electrodes (e.g., Pt) feature electrons as the mobile charge carriers, whereas semiconductors (e.g., n-Si) have electrons and/or holes that play that role. Solid electrolytes

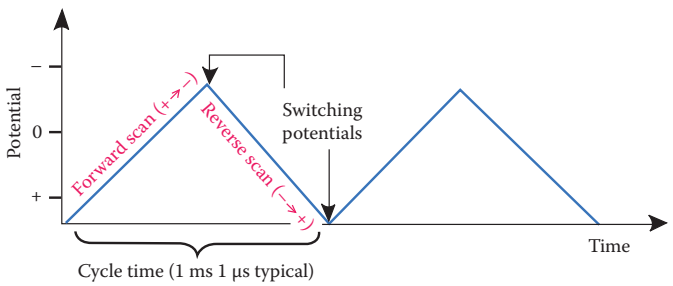

FIGURE 7.40 Triangular waveform used to register a cyclic voltammogram.

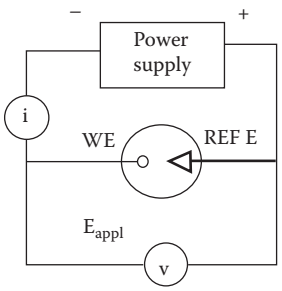
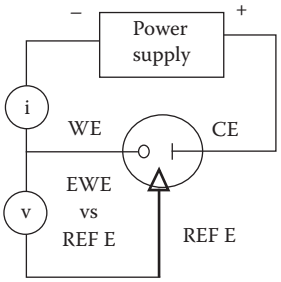


Two-electrode cell: Current passes through reference (can cause iR drop and degradation of the reference)

R in aqueous solutions is ~100 Ω so when i < 10 μA, iR < 1 mV



Three-electrode cell: Current is passed through the counter (auxiliary) electrode

Useful for high-resistance (nonaqueous) solutions

FIGURE 7.41 Two-electrode versus three-electrode system.

(e.g., LaF_3) have mobile ions, whereas insulators (e.g., SiO_2) possess no free charge carriers. Mixed conductors (e.g., IrO_x) have both ions and electrons for conduction.

We treat ion-selective electrodes (ISEs), also called *membrane electrodes*, as a separate category of electrodes. Membrane electrodes include pH glass membrane electrodes, crystalline solid electrolyte electrodes, polymeric electrodes, and membrane-based gas-sensing probes.

Electrodes of the First and Second Kind

Electrodes of the First Kind A metal in contact with its cations or a metal in contact with a redox couple in solution is called an *electrode of the first kind*. Examples include $Cu^{2+}/Cu(s)$, $Zn^{2+}/Zn(s)$, the standard hydrogen electrode (SHE) (i.e., Pt black in contact with H_2/H^+), Ag^+/Ag [nonaqueous reference electrode (REF E)], and $Cl^-/Cl_2(g)/Pt$. A working electrode (WE) (e.g., Pt) that changes potential against a suitable reference electrode and senses the redox couple concentration present in solution is an indicator electrode of the first kind. The electrode response of this type with respect to a REF E is given by the Nernst equation:

$$E = E^0 + \frac{0.0592}{n} \log a_{M^{n+}} \qquad (7.57)$$

Often these sensors respond to cations, so they also may be called *cation electrodes*. With an electrode of the first kind, the fastest electron-exchange reaction, i.e., the reaction with the largest exchange current density $i_{0,e}$ (the current at zero external current and with no net reaction), determines the potential of the electrode. Often there are different redox species involved in establishing the equilibrium potential, in which case we speak about a mixed potential: zero external current but net reaction (e.g., corrosion). The inert species in solution (e.g., 1 M NaCl), also called *indifferent electrolyte*, do not, at zero or low bias, exchange electrons with the platinum electrode. Instead, they provide solution conductivity. All redox couples have a known redox potential as measured against a standard reference electrode (e.g., SHE). Platinum is the most common metal indicator electrode to measure these redox potentials. Pt is mostly inert, does not participate in reactions, and allows electron transfer to and from solution. Gold is also an inert metal indicator electrode used for the same purpose. Carbon electrodes are often used because many redox reactions are very fast on a carbon surface (see also C-MEMS in Volume III, Chapter 5). Note that not all metals are electrodes of the first kind; metals such as Fe, Al, and W are not electrodes of the first kind because they have relatively thick surface oxide coatings that are pH-sensitive.

Electrodes of the Second Kind Metals in contact with their sparingly soluble salt are *electrodes of the second kind*, also called *anion electrodes*. Examples include Ag/AgCl(s) and $Hg/Hg_2Cl_2(s)/Cl^-$ (saturated calomel electrode; SCE). As seen from the Nernst expression for an electrode of the second kind (see also Exercise 7.3 on a Ag/AgCl electrode):

$$E = E^0 - \frac{0.0592}{n} \log a_{A^{n-}} \qquad (7.58)$$

In this case, anion activity determines potential. These electrodes make great reference electrodes because of the low solubility of their salt (potential very stable). As said before, a reference electrode is an electrode that does not change its potential with solution composition. By making the anion concentration around the sensor element constant, one obtains such a situation. Fixing the anion concentration is often accomplished by mounting the electrode in a glass envelope and putting a saturated solution of the anion in contact with the sparingly soluble salt of the metal wire, which itself is encapsulated in a very slowly leaking glass envelope. This is illustrated for a Ag/AgCl REF E in Figure 7.42.

The purpose of a reference electrode is to provide a stable potential against which other potentials can be reliably measured. Criteria for the selection of a good reference electrode include stability (time, temperature) and reproducibility. Importantly, the potential should not be altered by passage of a small current, i.e., the electrode should be perfectly nonpolarizable (Figure 7.43). The definition for an ideal nonpolarizable electrode is that there is no charge transferred across the electrode/electrolyte interface (in the case of a Ag/AgCl electrode, all the charge transfer is between the Ag and the

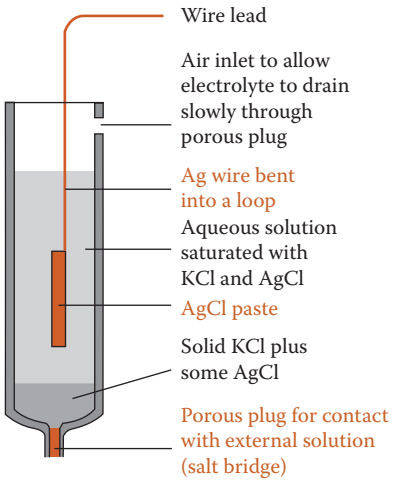


FIGURE 7.42 Construction of a Ag/AgCl reference electrode.

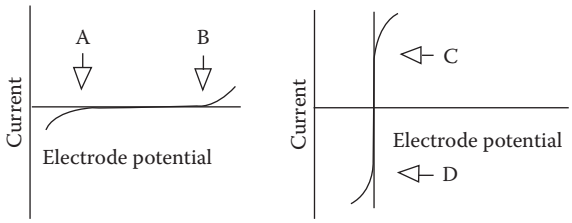
AgCl instead), and ΔV remains = 0 for a wide range of currents. An ideal polarizable electrode (IPE) is one where the charge transfer resistance is very large, so that Δi = 0 for a large range of voltages. The behavior of such an interface when the potential across the electrode is changed resembles that of a plain capacitor. An IPE follows the standard capacitor equation. The reference electrode should also be easily constructed and convenient for use. The standard hydrogen electrode is difficult to use because Pt black is easily poisoned by organics, sulfide, cyanide, and so on. Also, hydrogen is explosive, and sulfuric and hydrochloric acids are very strong acids; however, SHEs feature one of most reproducible potentials (±1 mV). More convenient reference electrodes include the Ag/AgCl and the saturated calomel electrode (Hg/Hg_2Cl_2) (which has problems with mercury toxicity though).



Ideal polarized electrode (INPE; electrode of fixed i)

Δi = 0 over a wide range of V (A to B)

Δi/ΔV = 0

Ideal nonpolarized electrode (INPE; electrode of fixed V reference electrodes)

ΔV = 0 over a wide range of i (C to D)

Δi/ΔV = finite value

FIGURE 7.43 Concept of polarization. A good reference electrode is ideally nonpolarizable.

When the above reference electrodes are used in nonaqueous media, there might be significant junction potentials. Nonaqueous media can also cause greater noise, and electrolyte precipitation may clog the electrode frit. Finally, the chemistry may be water-sensitive.

Electrochemical reference electrodes are very difficult to miniaturize, and when miniaturized they do not last very long because the internal electrolyte quickly mixes with the external solution. The development of miniature chemical and biological sensors has been hampered by this problem. Because of these problems, many researchers have chosen to implement pseudo-reference electrodes in miniature sensors. These pseudo-reference electrodes, for example, a Ag/AgCl wire without the saturated anion solution, only mimick the behavior of a real thermodynamically justified electrode. These problems will be illustrated below when introducing the ISFET.

Earlier, we pointed out that some metals with a relatively thick surface oxide coating may act as electrodes of the second kind, with the oxide coat setting up a pH response. This may be interesting as an alternative for pH glass electrodes. Glass pH electrodes have their shortcomings, such as extreme fragility, relatively slow response times, short lifetime, and very high impedance. Moreover, glass electrodes cannot be used in strong alkaline, HF, or organic solutions and are very difficult to miniaturize. As a consequence, various metal oxides have been tested as alternate, fast, robust, long-lifetime, low-impedance pH sensors that are easier to miniaturize. Most studies have focused on Sb/Sb_2O_3 (widely used for acid-based titrations or in solutions containing HF; however, voltage drift with this electrode is considerable), Bi/Bi_2O_3 (used in alkaline media), Pt/PtO_2, Ir/IrO_x, Ru/RuO_2, Os/OsO_2, Rh/RhO_2, Ti/TiO_2, and Sn/SnO_2. These oxides all represent mixed conductors with both electrons and ions (protons) exchanging rapidly at the interface. Depending on the relative magnitude of $i_{0,e}$ versus $i_{0,i}$, the electrode acts as a redox probe, a pH sensor, or both. For most mixed conductors $i_{0,e} \gg i_{0,i}$, i.e., one expects severe redox interference when used as pH sensors. Of the metal oxides listed, IrO_x holds the most promise as a very fast, stable,

low-impedance pH sensor with surprisingly small redox interference.[8] As an example, we introduce some of our own work on Ir/IrO_x as a solid-state ion-selective electrode (ISE). Whereas this oxide previously had been prepared by electrochemical growth (potential cycling), anodic electrodeposition, AC reactive sputter coating (Ir target and oxygen gas), and thermal oxidation, we showed for the first time that an electrode prepared by melt-oxidation in a lithium carbonate (Li_2CO_3) exhibits a very reproducible, fast pH response (faster than a few tens of seconds) with low redox interference. The Nernstian slope (58 mV/pH) is close to ideal. Other good characteristics of this electrode include stability, even in solutions containing F^-. The ease of miniaturization using integrated circuit (IC) techniques is an additional benefit. The world's smallest CO_2 sensor, based on thin-film IrO_x pH sensing, is shown in Volume II, Figures 4.92–4.97. An example IrO_x-based pH probe (A) and some experimental results (B) are shown in Figure 7.44. From the SEM picture of an electrode cross-section (C), the IrO_x coating on the Ir wire appears as a 20-µm-thick, nonporous film with a columnar grain structure. In Figure 7.50 we use a Ir/IrO_x wire as described here to make a CO_2 gas sensor.

SensIrOx, a private enterprise, demonstrated effective pH measurement in extreme temperature and pressure conditions using IrO_x probes as shown in Figure 7.44 (http://www.sensirox.com). For example, in food production or biological process monitoring, IrO_x probes provide a safe, nonglass solution. They are also well-suited for measurements in high salt solutions, viscous sludges and slurries, or for wide-ranging pH. A pH sensor based on IrO_x, suitable for measuring total acidity number in non-aqueous applications (e.g., engine oil), was also developed by SensIrOx.

Ion-Selective Electrodes

Introduction Ion-selective electrodes (ISEs) are membrane electrodes that exchange ions at a membrane/solution interface. Ideally, these electrodes respond to one ion only, and their equilibrium potential does not involve redox reactions. ISEs use a membrane that exchanges ions fast, where the electric potential across the membrane/liquid interface depends on the concentration of the ion with the fastest (largest) ion exchange current, $i_{0,i}$. The difference in voltage across the membrane is measured between two REF Es: an internal and an external one, as sketched for the case of F^- sensing with a LaF_3 ISE (developed in 1967 by Ross) in Figure 7.45. The ion from solution that exchanges sites within the single-crystal LaF_3 is F^-, which is mobile in the LaF_3 crystal lattice, even at room temperature.

The electrical potential difference across the membrane boundaries of an ISE can be described by:

$$\triangle E = \frac{0.0592}{n} \log \frac{[C^+]_{outer}}{[C^+]_{inner}} \qquad (7.59)$$

where n is the charge on the analyte ion (1 in the case of F^-), $[C^+]_{outer}$ is the ion concentration in the

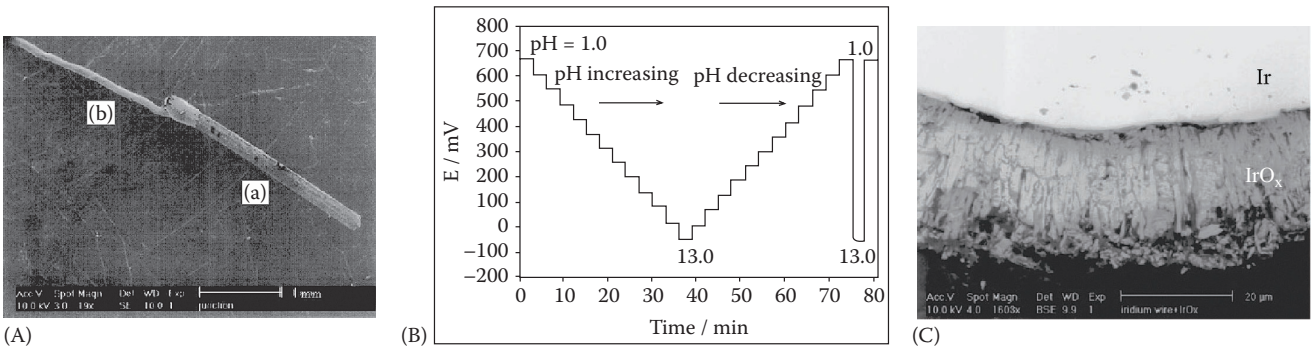


FIGURE 7.44 (A) Solid-state pH sensor: Ir wire with IrO_x coat (a) and Au wire contact (b). (B) A pH titration curve with IrO_x, no hysteresis. (C) SEM of an electrode cross-section. Note this same type of pH sensor was used to construct the CO_2 gas sensor in Figure 7.50.

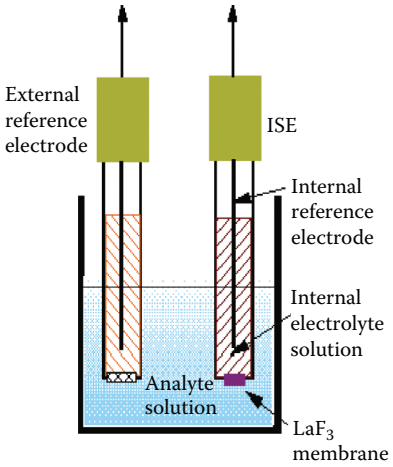

FIGURE 7.45 A F^- ion-selective electrode based on a single crystal of the solid electrolyte LaF_3 as the membrane.

unknown solution, and $[C^+]_{inner}$ is its concentration in the inner solution. Because the $[C^+]_{inner}$ is constant, the above equation can be simplified to:

$$\triangle E = \frac{0.0592}{n} \log\left[C_{outer}\right] \tag{7.60}$$

There is no change in the inner reference solution because there is no contact between the inner reference electrolyte and the unknown sample solution. Contact with the sample solution is established with the outer membrane surface and the external reference electrode, which is in ionic contact via a Luggin capillary. The potential of the whole electrochemical cell (at 25°C) is then given as:

$$E_{cell} = E_{const} + \frac{0.0592}{n} \log\, a_{M^{n+}} \tag{7.61}$$

where n is the valence of the ion that can be – (for anions) or + (for cations) and a is the activity of the ion.

For univalent ions, the slope is 59.16 mV/decade, and for divalent ions, the slope is 29.58 mV/decade. From the slope, it is possible to tell whether the electrode is behaving properly.

The selectivity coefficient describes the relative response of any electrode to interfering species and is defined as:

$$k_{A,X} = \frac{\text{response to interfering X}}{\text{response to principal ion A}} \tag{7.62}$$

The smaller the value of k, the lesser the response to X. For example, for F^- sensing with a LaF_3 sensor in the presence of Cl^-, the selectivity coefficient is $k_{F^-,Cl^-} = 10^{-4}$; in other words, Cl^- ions must be present in a concentration 10,000 times higher than F^- to set up a similar signal strength. At pH > 8, OH^- anions become a major interference for F^- measurement. At low pH, F^- exists only as HF (which this sensor will not pick up). Therefore, the sample must be buffered at a pH between 5 and 7 for reliable F^- analysis.

Some requirements that all membranes in ion-selective electrodes must meet include minimal solubility, a finite electrical conductivity, and selectivity for one ion only. The solubility of an ISE electrode in analyte solutions typically approaches zero. In general, the finite conduction of a membrane takes the form of migration of singly charged ions within the membrane (e.g., F^- in LaF_3 and Na^+ and/or Li^+ in a glass electrode). Finally, a membrane or some species contained within the membrane matrix must be capable of selectively exchanging ions with analyte ions.

The types of membrane electrodes include glass electrodes, crystalline solid-state electrodes, polymer electrodes, and gas-sensing probes.

The selectivity of a membrane electrode is linked with the uniqueness of the binding site for the intended ion from solution. Ideally, there would be only one type of binding site in the membrane with exclusive selectivity for the intended ion. In practice, surfaces are very complex, often involving fractals as encountered on the beach, trees, snowflakes, and so on, rather than atomically sharp transitions (see Figure 7.13). This implies that a binding site at the surface might find itself in a variety of energetic configurations with different associated binding constants/selectivities for the analyte. As a consequence, absolute selectivity with one sensor material cannot be achieved. In Volume III, Chapter 10 on MEMS and NEMS, we illustrate how using an array of sensors in an electronic tongue or in an electronic nose might present a possible alternative to more selective sensing.

Glass Electrodes A traditional pH (pondus Hydrogenii; literally hydrogen exponent)

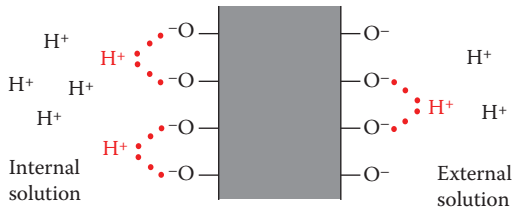

FIGURE 7.46 The Donnan potential on a thin pH-sensitive glass membrane is established on both sides of the membrane.

measurement with a glass electrode qualifies as a potentiometric ion-selective electrode (ISE) (e.g., a thin glass layer with a composition of 22% Na_2O, 6% CaO, and 72% SiO_2), and it is the most common solid-state ISE. The H^+ ion is the only one that significantly exchanges with the outer hydrated glass layer (see Figure 7.46). The proton exchange at the glass/solution interface results in a charge buildup, establishing the so-called *Donnan potential*. The Donnan potential is also established at the glass membrane/internal solution interface and is kept constant by the fixed pH of the internal electrolyte (inner reference), whereas the Donnan potential on the other side of the membrane is determined by the analyte solution pH (Figure 7.46).

Na^+ or Li^+ ions that are present in the glass carry the electrical current by migrating from one side to the other. A combination electrode used for pH measurements utilizes a combination of a silver reference electrode and a glass electrode as shown in Figure 7.47.

The pH response of a glass electrode, based on Equation 7.61 and the fact that pH = –log $[H^+]$, is given by:

$$E_{cell} = E_{const} = 0.0592 \text{ pH} \qquad (7.63)$$

A glass electrode is calibrated with several buffers close to the pH of the unknown solution. It is also important that the glass electrode be kept hydrated when not in use. If not, the hydrated gel layer of the glass dries out, and the electrode has to be reconditioned/rehydrated for several hours before use.

The selectivity of a glass electrode strongly depends on the glass composition, with a Li_2O-containing glass having a selectivity coefficient k_{H^+,Na^+} of $\approx 10^{-11} - 10^{-13}$ and a Na_2O-containing glass having a k_{H^+,Na^+} of $\approx 10^{-10}$. An "alkaline error" can result when cations other than H^+ are present in large excess in the solution. These cations can exchange for H^+ in the outer glass gel layer. However, the glass can be carefully selected to reduce the effect of interfering ions. On the other hand, by adding alumina to the glass composition, selectivity can be changed for the determination of other univalent ions such as Na^+.

The resistance (impedance) of a glass pH sensor is very high (100 MΩ to more than 1000 MΩ), which requires the input amplifier of the pH meter to be very high; the input impedance of the meter must be at least 100 times greater than that of the sensor (high-input impedance amplifier with field effect transistor input stage). However, very high

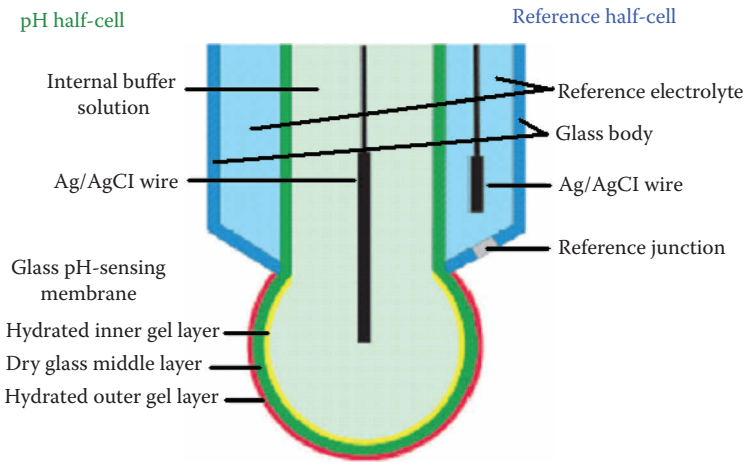

FIGURE 7.47 A combination pH sensor.

impedance can make the measurement noisy, and the smaller the sensor, the bigger this problem becomes. We will come back to this aspect of miniaturized electrochemical sensors when covering ISFETs. We saw earlier how glass pH electrodes have many shortcomings, such as extreme fragility, relatively slow response time, short lifetime, and very high impedance. We have also shown how IrO_x holds promise as a very good alternative, as a stable, low-impedance pH sensor with small redox interference (although hydrogen is detrimental).

Crystalline Solid-State ISEs Solid-state ISEs are based on inorganic crystals such as single-crystal LaF_3, as we explored earlier for F^- sensing. Doping of the LaF_3 with EuF_2 creates anion vacancies in the crystal, allowing F^- anions to jump back and forth between the solution and the vacancies in the solid. This leads to a dynamic equilibrium that establishes a Donnan potential at the crystal/solution interface (F^- has a larger ion exchange current $i_{0,i}$ than any other ion at the LaF_3/electrolyte interface). The F^- sensor cell in Figure 7.45 can be annotated as:

Ag(s) | AgCl(s) | NaCl, NaF(aq) | LaF_3 crystal | ext. soln || saturated KCl and AgCl(aq) | AgCl(s) | Ag(s)

The response of this electrode is given by:

$$E_{cell} = E_{const} - 0.0592 \log[F^-] = E_{const} + 0.0592\, pF^- \quad (7.64)$$

The solid-state membrane may be a single crystal, polycrystalline, or a mixed pellet of an ionic salt. Mixed pellets of Ag_2S (with a solubility constant k_{sp} of 10^{-31}) and AgX respond to X^-, where X = Cl, Br, I. The charge transporting species in Ag_2S electrodes is Ag^+. Ion-selective electrodes for Cu^{2+}, Cd^{2+}, and Pb^{2+} can be made by mixing CuS, CdS, or PbS with Ag_2S. All mixed pellet Ag_2S electrodes also respond to Ag^+, so this will be an interferent. Some example solid-state ISEs for anion sensing are shown in Table 7.13.

Polymer-Based ISEs Liquid- and polymer-based ISEs use a mobile carrier (also ion exchanger, chelator, or ionophore = ion carrying, from the Greek phoros, meaning "bearing") in an organic solvent or a polymer matrix, respectively, to render that liquid or polymer ion-selective. We will restrict ourselves here to the discussion of polymer-based ISEs because they are easier to miniaturize than liquid-based ISEs. The ionophore is typically a hydrophobic species that is a chelator of the species of interest. An ion-selective polymeric membrane, say for a potassium ion sensor, is made by mixing a K^+ ionophore such as 1% valinomycin (a natural-occurring antibiotic) with 33% polyvinyl chloride (PVC) and 66% plasticizer (to make the rigid plastic more flexible: plasticized PVC acts like a sponge). The valinomycin (Figure 7.48) in the membrane selectively exchanges potassium ions from the solution (with a selectivity for K^+ over Na^+ of $k_{K^+,Na^+} = -4.3$) setting up a Donnan potential at the interface. The atomic radius of K^+ is 1.33 Å and that of Na^+ is 0.95 Å. With only this difference to work with, valinomycin manages to select for the K^+ ion over the Na^+ ion by a factor of nearly 5000.

No significant amount of counterions from solution may enter the membrane phase, or selectivity will be lost. To achieve this so-called *Donnan exclusion of counterions*, counterions must also be present

Table 7.13 Examples of Solid-State ISEs for Anions

Ion	Concentration Range (M)	Membrane Material	pH Range	Interfering Species
F^-	10^{-6} – 1	LaF_3	5–8	OH^- (0.1 M)
Cl^-	10^{-4} – 1	AgCl	2–11	CN^-, S^{2-}, I^-, $S_2O_3^{2-}$, Br^-
Br^-	10^{-5} – 1	AgBr	2–12	CN^-, S^{2-}, I^- S^{2-}
I^-	10^{-6} – 1	AgI	3–12	
SCN^-	10^{-5} – 1	AgSCN	2–12	S^{2-}, I^-, CN^-, Br^-, $S_2O_3^{2-}$
CN^-	10^{-6} – 10^{-2}	AgI	11–13	S^{2-}, I^-
S^{2-}	10^{-5} – 1	Ag_2S	13–14	

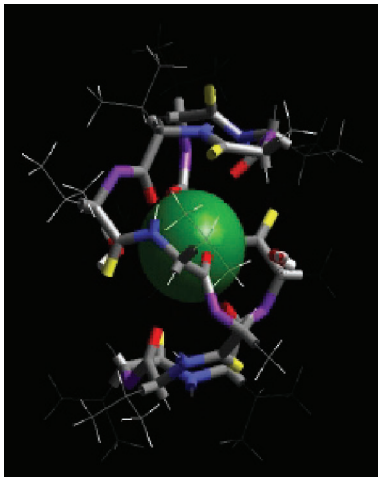

FIGURE 7.48 Valinomycin ionophore for K^+ ion.

in the membrane itself. To accomplish this, lipophilic counterions are added to the membrane cocktail [e.g., from sodium tetrakis[3,5-*bis*(trifluoromethyl) phenyl]borate or NaTFPB]. Addition of lipophilic salts to the membrane improves selectivity and also reduces the impedance of the probe. In a 3D ISE embodiment, as shown in Figure 7.49a the membrane potential is measured between an internal and an external reference electrode. Equation 7.61 gives the Nernstian response of polymeric membrane electrodes.

Ionophores for anions are harder to find than ionophores for cations because anions come in all types of shapes (e.g., SCN^- is linear but SO_4^{2-} is stetrahedral), whereas cations are mostly spherical (see Figure 7.48). Anion exchangers are typically R_4N^+ salts, and they respond according to the hydrophobicity of the anions; this is the Hofmeister series:

$$ClO_4^- > SCN^- > I^- > NO_3^- > Br^- > Cl^-$$

By using a combination of thin- and thick-film deposition techniques, one can fabricate planar ISEs on an inexpensive substrate as shown in Figure 7.49b. Thin-film silver electrodes are vapor deposited through a stencil mask on a polyimide substrate. The top layer of the Ag is converted to AgCl by dipping in a $FeCl_3$ solution. Silk screening of hydrogels with the appropriate electrolytes completes the internal and external reference electrodes. The internal reference side is now covered with the ISE membrane using a drop delivery technique, whereas the external reference side is covered with a dielectric membrane (also using drop delivery) with a small laser-cut hole for Luggin capillary. By simply changing the ionophore in the membrane, different ISEs can be fabricated. Although we show only one ISE in this figure, many planar sensors can be made in parallel (batch fabrication!). By switching from a 3D to 2D architecture, mass production of minute, polymeric ISEs (e.g., 2×3 mm per sensor) becomes possible, resulting in inexpensive (disposable), reproducible biosensors for ions such as Ca^{2+}, Na^+, K^+, NO_3^-, Cl^-, and so on. For ease of manufacturing, planar ISEs often do not use an internal reference solution. This makes the electrodes easier to handle and store, but voltage drift tends to be larger because there is no pinning of the Donnan potential on the internal reference side with a fixed reference ion concentration. The manufacturing approach sketched here is contrasted further below (under ISFETs) with an approach where the electronics are integrated. In Volume III, Chapter 1 we elaborate on the MEMS batch and continuous mode manufacture of arrays

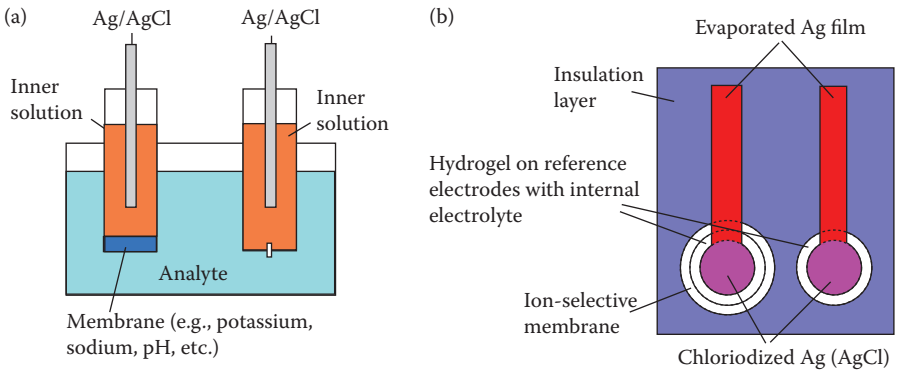

FIGURE 7.49 (a) A 3D measuring setup for polymeric ISEs. (b) A miniaturized 2D polymeric ISE.

of ISEs. In Table 7.14 we list membrane compositions and selectivities of important ISEs.

Membrane-Based Gas-Sensing Probes Gases that react with water, which causes freeing or absorbing of protons in the electrolyte, can be detected by a pH-sensitive element, e.g., a glass or an IrO_x electrode. A gas-permeable membrane (microporous), such as a 100-µm-thick Gore-Tex® film, separates the unknown sample from a pH probe and a reference electrode immersed together in a small internal solution (no ions can cross the gas-permeable membrane). The pH of the internal solution provides one with a measure of the gas content of the analyte solution. Gases that can be quantified this way include CO_2, NH_3, and H_2S. A direct proportionality exists between the concentration of the neutral gas and the measured pH. For example, in the case of the Severinghaus-type CO_2 sensor, depicted in Figure 7.50, the indicator electrode is only H^+-sensitive, and the potential of the reference is constant because of the constant Cl^- concentration in the internal electrolyte. Therefore, the potential of the pH sensor in the internal reservoir is given as:

$$E = E^0 + 0.059 \log a_{H^+} \tag{7.65}$$

The CO_2 gas penetrates through the gas-permeable membrane and reacts with the inner electrolyte,

Table 7.14 Membrane Compositions and Selectivities of Important Ion-Selective Electrodes

Analyte	Membrane Type	Membrane composition	Linear Range ($-\log a_i$)	log $K^{pot}_{i,j}$

Ag^+	Solid state	Ag_2S	1–7	Cu^{2+}: –6 Pb^{2+}: –6 to –9 H^+: –5 Hg^{2+}: –2

which contains a high fixed amount of Cl^- and bicarbonate ($NaHCO_3$) in a hydrogel matrix:

$$CO_2 + H_2O \rightleftharpoons H^+ + HCO_3^- \tag{7.66}$$

and:

$$a_{H^+} = \frac{Kp_{CO_2} a_{H_2O}}{a_{HCO_3^-}} \tag{7.67}$$

Because the activities of water and HCO_3^- are constant, one obtains:

$$E = E^{0'} - 0.059\ pH \quad \text{and also} \quad E = E^{0''} - 0.059\ pCO_2 \tag{7.68}$$

The Severinghaus sensor shown in Figure 7.50a was fabricated by the author and his team using the same Ir/IrO_x wire illustrated in Figure 7.44.[8] For the reference electrode, a Ag/AgCl wire was used. Figure 7.50a is a schematic of the CO_2 sensor, whereas Figure 7.50b is a photo of the PVC tube-based sensor.

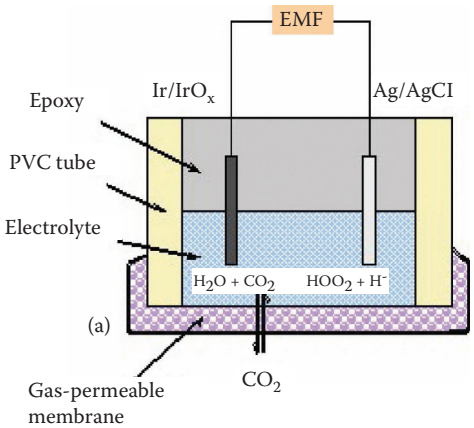
The world's smallest MEMS-fabricated electrochemical CO_2 sensor, incorporating thin-film Ir/IrO_x and Ag/AgCl electrodes, mounted in a catheter, together with an oxygen and a pH sensor, also made by this author and his team, is shown in Volume II, Figures 4.92–4.97. These miniaturized sensors are used clinically to determine blood CO_2 concentration.

Mass and Charge Transport in Solutions

As we saw in Chapter 6 on fluidics there are basically three modes of mass transport in solution: diffusion, migration, and convection (natural and mechanical). Diffusion from a region of high concentration to a region of low concentration occurs whenever the concentration of an ion or molecule at the surface of an electrode is different from that in the bulk of the solution. This will occur whenever a chemical change takes place at a surface. Convection takes place when mechanical means are used to carry reactants toward the electrode and to remove products from the electrode. The most common means of convection is to stir the solution using a stirring bar. Other methods include rotating the electrode and incorporating the electrode into a flow cell. Migration happens when charged particles in solution are attracted or repelled from an electrode that has a surface charge. The flux of material to and from the electrode surface is a complex function of all three modes of mass transport, and for most analytical techniques, one wants diffusion to dominate over migration. The reason, as we will find out further below, is that at the limit in which diffusion is the only significant means for the mass transport, the diffusion-limited current, i_l, in a voltammetric cell is simply related to the bulk concentration c_{bulk} ($x = \infty$) by:

$$i_l = nFAD_0\left[\frac{c_{bulk}(x=\infty)}{\delta}\right] \tag{7.124}$$

where n = number of electrons transferred in the redox reaction
F = Faraday's constant
A = area of the electrode



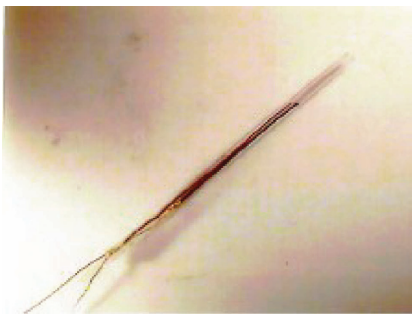


FIGURE 7.50 (a) Schematic of Severinghaus-type CO_2 sensor. (b) Photo of the sensor in a PVC tube. Notice the two wires: an Ir/IO_x wire and an Ag/AgCl wire. (By Dr. Marc Madou.)

D_0 = diffusion coefficient for the reactant or product
c_{bulk} $(x = \infty)$ = concentration of the analyte in the bulk solution
δ = thickness of the diffusion layer

For the above equation to be valid, migration and convection must not interfere with the formation of the diffusion layer around the electrode surface. Adding a high concentration of an inert supporting electrolyte to the analytical solution can eliminate migration. The large excess of inert ions ensures that few reactant and product ions will move as a result of migration. Although convection may be easily eliminated by not physically agitating the solution, in some situations it is desirable either to stir the solution or to flow the solution through an electrochemical flow cell. Fortunately, the dynamics of a fluid moving past an electrode results in a small diffusion layer, typically of 0.001–0.01-cm thickness; in this stagnant layer the rate of mass transport by convection drops to zero. Below our calculations for δ, the thickness of the steady-state diffusion layer, will reveal it to be only a fraction of the thickness of the stagnant hydrodynamic boundary layer, δ_h (see footnote on page 582).

The conductance *S* of an electrolyte, in units of Siemens (S), is given by:

$$S = \frac{1}{R} = \frac{\rho A}{l} \tag{7.69}$$

where R = resistance of the electrolyte
A = active area of contact
l = length (thickness) of electrolyte layer
ρ = conductivity–intrinsic property of the electrolyte (in S/cm)

The conductivity ρ of the electrolyte has a contribution from every ion in solution that is proportional to the concentration of the ions (*c*), the charge of the ions (*z*), and a property that determines their migration-velocity—the mobility, μ. In Chapter 6 we defined mobility, μ, as the limiting velocity of the ion in an electric field of unit strength. As an electric field (F = eEz, where *e* is the electronic charge) forces ions to move through the solution, an opposing force resulting from frictional drag is generated. The latter is represented by the Stokes equation:

$F_D = 6\pi\eta Vr$ (see Equation 6.26)

where η = viscosity of the solution
r = Stokes radius of the ion
V = ion velocity

When the opposing frictional force exactly counterbalances the force exerted on the ion by the electrical field, the ion attains a steady-state velocity called the *terminal velocity*. This terminal velocity is termed the mobility (μ) when the electric field strength is unity:

$$\mu = \frac{ze}{6\pi\eta r} \tag{7.70}$$

With this expression for mobility μ, we can write the following expression for conductivity ρ:

$$\rho = F\sum_i z_i \mu_l c_i \tag{7.71}$$

This is often expressed as molar ionic conductivity Λ, which is given as:

$$\Lambda = \frac{\rho}{c} \tag{7.72}$$

where *c* is in moles and Λ is in units of S m^2/mol. Some examples of molar ionic conductivity for ions in water at 25°C and at infinite dilution are given in Table 7.15.

At infinite dilution, no interionic interactions take place; thus, the molar conductivity of a salt C_cA_a can simply be calculated from its constituent ions as:

$$\Lambda_{C_cA_a} = c\Lambda_c + a\Lambda_a \tag{7.73}$$

Example 7.7:

Calculate the molar conductivity of KCl and $BaCl_2$ (two good electrolytes):

- $\Lambda_{KCl} = \Lambda_{K^+} + \Lambda_{Cl^-} = (74 + 77) \times 10^{-4}$ S m^2/mol
  $= 151 \times 10^{-4}$ S m^2/cm
- $\Lambda_{BaCl_2} = \Lambda_{Ba^{+2}} + 2\Lambda_{Cl^-} = \left[127 + (2 \times 77)\right] \times 10^{-4}$
  S m^2/mol $= 281 \times 10^{-4}$ S m^2/mol

A useful measure of how much of the current is carried by the cations versus the anions of a salt

Table 7.15 Molar Ionic Conductivity

Ion	$\Lambda(10^{-4}$ S m²/mol) at Infinite Dilution (25°C)
H^+	350
OH^-	200
Ba^{2+}	127
K^+	74
Cl^-	77
HCO_3^-	45
TBA^+	24

is the transference or transport number. The fractions of current carried by the positive and negative ions are given by their transport numbers t_+ and t_-, respectively:

$$t_+ = c_+\Lambda_+ / \Lambda_{C_cA_a} \tag{7.74}$$

$$t_- = a_-\Lambda_- / \Lambda_{C_cA_a} \tag{7.75}$$

where $c_+\Lambda_+ + a_-\Lambda_- = \Lambda_{C_cA_a}$. Because each mole of current passed through the cell corresponds to 1 mole of electrochemical change at each electrode, the amount of ions transported in the electrolyte also equals 1 mole. Thus:

$$t_+ + t_- = 1 \tag{7.76}$$

Example 7.8:

Calculate the transference numbers for the cations in KCl and $BaCl_2$ (two good electrolytes):

- t_+ (KCl) = 74/151 = 0.49
- t_+ ($BaCl_2$) = 127/281 = 0.45

Solvent and concentration affect ionization and therefore both ionic conductivity and transference numbers.

For multiple species, Equation 7.76 is generalized to:

$$\sum_i t_i = 1 \tag{7.77}$$

This equation is valid when more than one type of ion is in the solution. Now the transport numbers of ions are determined by the conductivity (ρ) of the electrolyte (Equation 7.71). The transport numbers may be represented as the ratio of the contribution to conductivity made by a particular ion to the total conductivity of the solution, or based on Equation 7.71:

$$t_i = \frac{\rho_i}{\rho} = \frac{z_i\mu_i c_i}{\sum_i z_i\mu_i c_i} \tag{7.78}$$

This equation gives us a clue how to eliminate migration for an analyte ion of interest, say, redox species *i*. Current flow resulting from electrostatic attraction (or repulsion) of analyte ion *i* by the electrode is reduced to a negligible level by the presence of a high concentration of supporting or indifferent electrolyte. By increasing the concentration for all the other ions but ion *i*, the transport number for ion *i* is minimized. The only way for an analyte ion, present in much lower concentration than the supporting electrolyte, to reach the electrode is by diffusion. Typically, a supporting electrolyte concentration 50–100 times greater than the analyte concentration will reduce electrostatic transport of the analyte to a negligible level and minimize the iR drop in the solution as well. Under the latter circumstances, qualitative and quantitative analysis of an ion analyte, using Equation 7.124 (see further below), is possible.

Energetics of Metals, Semiconductors, Membranes, and Mixed Conductors in Contact with an Electrolyte

Introduction

In Chapters 3 and 4, we introduced the band theory of solids and learned how to draw energy diagrams for solid-state junctions, such as metal/semiconductor and *p*-type and *n*-type semiconductor combinations. In this section, we derive the energy diagrams for solid/liquid junctions that explain the operation of these materials as sensor electrodes, in fuel cells, in batteries, as liquid junction solar cells, ISFETs, during corrosion processes (including the anisotropic and isotropic etching of semiconductors), and so on.

When electrons or ions pass through a solid/electrolyte interface, a reversible electrode potential E_{rev} is set up. This equilibrium is a dynamic equilibrium, meaning that the rates of charge carriers passing

through the interface in either direction are equal. We denote the forward electron/ion transfer and the backward electron/ion transfer rates as $\vec{i}$ and $\overleftarrow{i}$, respectively. At equilibrium, the exchange current density is the same in both directions, or $\vec{i} = \overleftarrow{i} = i_0$. Thermodynamic equilibrium between two phases is reached when the electrochemical potentials on either side of the interface become equal. To refresh the reader's understanding of this process, we briefly reconsider here the relation between chemical potential μ, electrochemical potential $\bar{\mu}_e$, and Fermi level E_F. Every substance has a unique propensity to contribute to a system's energy. We call this property the chemical potential μ. When the substance is a charged particle (such as an electron or an ion with charge z) we must include the response of the particle to an electrical field in addition to its chemical potential. This sum is called the *electrochemical potential*, which in the case of electrons is given by $\bar{\mu}_e = \mu + zF\phi$ with F the Faraday constant and ϕ the potential drop. It can be demonstrated that the Fermi level, E_F, in a given material is equivalent to the electrochemical potential of the electrons, $\bar{\mu}_e$, in that material expressed per particle, or:

$$E_F = \frac{\bar{\mu}_e}{N_A} \tag{7.79}$$

As explained in Chapters 3 and 4, when bringing a solid in contact with another solid, the Fermi levels line up, and a potential drop ϕ is established across the interface. The potential drop is always the largest in the phase with the highest resistance (Ohm's law). For example, for a metal/semiconductor contact the whole potential drop is located in the semiconductor space charge (there are many more charge carriers in a metal than in a semiconductor), but for a metal/electrolyte contact the potential drop is all in the electrolyte (there are many more charge carriers in the metal than in the electrolyte).

Metal/Electrolyte Interface

Introduction In this section we detail the electron exchange current $i_{0,e}$ at a metal/electrolyte contact, as well as the current i as a function of the applied overvoltage η. We first derive these properties of the metal/liquid junction phenomenologically before we approach the same problem semiquantitatively, introducing the energetics of the solid/liquid interface. For simplicity in equations we will abbreviate $i_{0,e}$ as i_0.

Phenomenological Description of the Exchange Current $i_{0,e}$ and the Relationship between Current and Metal Electrode Overpotential We will first assume that the reactions at the metal electrode involve the two partners of the same redox system (say, Fe^{3+} and Fe^{2+}), so that at equilibrium no macroscopic changes take place at the electrode. The forward current $\vec{i}$ ($Fe^{3+} + e^- \rightarrow Fe^{2+}$) and the backward current $\overleftarrow{i}$ ($Fe^{2+} - e^- \rightarrow Fe^{3+}$) cancel each other out, i.e., the exchange current density is the same in both directions, or $|\vec{i}| = |\overleftarrow{i}| = i_0$ and the total current $i = \vec{i} - \overleftarrow{i} = 0$. This situation is called a *dynamic equilibrium at a potential* E^0. When no thermodynamic equilibrium is established for zero total current ($i = 0$ but $i \neq i_0$), $\vec{i}$ and $\overleftarrow{i}$ belong to different redox couples, and macroscopic changes occur at $i = 0$. In this case the potential at $i = 0$ is called a *mixed potential*, E^{mix} (e.g., in iron corrosion two redox couples, one involving oxygen and one iron, are responsible for this mixed potential).

Overpotentials occur when an external current is superimposed on the electrochemical cell. The electrode then assumes a voltage E_i different than the equilibrium value E^0 to an extent governed by the current i. The difference between E_i and the equilibrium voltage is known as the *overpotential*, generally denoted by η:

$$\eta = E_i - E^0 = \phi - \phi^0_{eq} \tag{7.80}$$

The rate of electron transfer between the metal and the redox couple, v, can be simply described as in homogeneous chemical kinetics:

$$v = k_{ox} c^s_{red} - k_{red} c^s_{ox} \tag{7.81}$$

From the absolute rate theory it follows that:

$$k_{ox} = A \exp\left[-\frac{\Delta G^*_{ox}(\phi)}{kT}\right]$$
$$k_{red} = A \exp\left[-\frac{\Delta G^*_{red}(\phi)}{kT}\right] \tag{7.82}$$

where ΔG^*_{ox} and ΔG^*_{red} are activation energies.

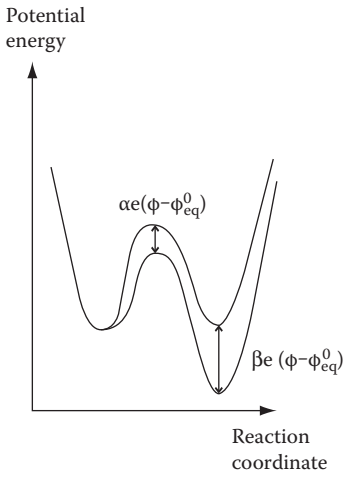

FIGURE 7.51 Reaction coordinate in the metal redox system.

The activation terms are dependent on the electrode potential but not the pre-exponential factor *A*, and with reference to Figure 7.51 we can write:

$$\Delta G^*_{ox}(\phi) = \Delta G^*_{ox}\left(\phi^0_{eq}\right) - \alpha e\left(\phi - \phi^0_{eq}\right)$$

$$\Delta G^*_{red}(\phi) = \Delta G^*_{red}\left(\phi^0_{eq}\right) + \beta e\left(\phi - \phi^0_{eq}\right)$$

$$\text{with } \alpha = -\frac{1}{e}\frac{\partial \Delta G^*_{ox}(\phi)}{\partial \phi}\Big|_{\phi^0_{eq}}$$

$$\text{and } \beta = \frac{1}{e}\frac{\partial \Delta G^*_{red}(\phi)}{\partial \phi}\Big|_{\phi^0_{eq}} \qquad (7.83)$$

The Gibbs energy of activation and reaction are correlated by:

$$\Delta G^*_{ox}(\phi) - \Delta G^*_{red}(\phi) = G_{ox} - G_{red}$$

and

$$\Delta G^*_{ox}\left(\phi^0_{eq}\right) = \Delta G^*_{red}\left(\phi^0_{eq}\right) = \Delta G^*_{eq} \qquad (7.84)$$

Assuming a transfer reaction in which the electrostatic energy of the ionic species is not significantly affected by the electrode potential (referred to as an *outer sphere electrode reaction*), it follows that:

$$\Delta G^*_{ox}(\phi) - \Delta G^*_{red}(\phi) = -e\left(\phi - \phi^0_{eq}\right) \qquad (7.85)$$

Based on Equations 7.83 and 7.85, we obtain:

$$\alpha + \beta = 1 \qquad (7.86)$$

We further develop Equation 7.81 to obtain:

$$i = ek_0 c^s_{red} \exp\left[\frac{\alpha e\left(\phi - \phi^0_{eq}\right)}{kT}\right] - ek_0 c^s_{ox} \exp\left[-\frac{(1-\alpha)e\left(\phi - \phi^0_{eq}\right)}{kT}\right] \qquad (7.87)$$

$$\text{where } k_0 = A\exp\left(-\frac{\Delta G^*_{eq}}{kT}\right)$$

To connect voltages to concentrations we recall the Nernst expression (Equation 7.56), which we rewrite here as:

$$\phi_{eq} = \phi^0_{eq} + \frac{kT}{e}\ln\left(\frac{c^s_{ox}}{c^s_{red}}\right) \qquad (7.88)$$

Using the expression for the overpotential η (Equation 7.80), we can finally derive the so-called *Butler-Volmer equation* for charge transfer reactions at a metal/electrolyte interface as:

$$i = i_0\left[\exp\left(\frac{\alpha e\eta}{kT}\right) - \exp\left(-\frac{(1-\alpha)e\eta}{kT}\right)\right] \qquad (7.89)$$

This relationship is illustrated in Figure 7.52a for three different values of α. The transfer coefficient

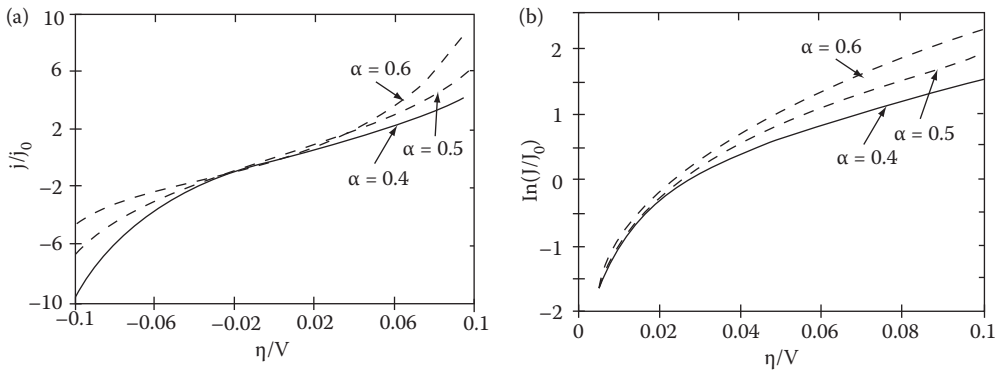

FIGURE 7.52 (a) The Butler-Volmer expression for three different values of α. (b) The Tafel law.

α determines the symmetry (or lack thereof) of the current potential curve. Notice that the Butler-Volmer analysis is based on surface concentrations. The exchange current density i_0 in Equation 7.89 is given by:

$$i_0 = ek_0\left(c^s_{red}\right)^{1-\alpha}\left(c^s_{ox}\right)^{\alpha} \tag{7.90}$$

For low overpotentials (η) the system behaves as an ohmic resistance:

$$i = i_0\frac{e\eta}{kT} \tag{7.91}$$

It follows that the charge transfer resistance, R_{ct}, is given by:

$$R_{ct} = \frac{N_A kF}{N_A ei_0} = \frac{RF}{Fi_0} \tag{7.92}$$

For large overpotentials the Butler-Volmer equation becomes logarithmic (Tafel regime):

$$\eta = a + \log i \tag{7.93}$$

The Tafel regime is illustrated in Figure 7.52b.

Semiquantitative Description of the Exchange Current $i_{0,e}$ and the Relationship between Current and Metal Electrode Overpotential

Equilibrium Current Exchange Density $i_{0,e}$ To derive the electron transfer rate at the metal/redox electrolyte interface semiquantitatively we must establish the energy density of empty and filled states that electrons can tunnel to and from on both sides of the interface. The question, as in the case of electron transfer between two solids, is whether there will be electron transfer from the metal electrode to the redox molecules in solution (or vice versa). This, we find, depends on the alignment of the density of states of the redox molecules relative to the Fermi level of the metal electrode. In Chapter 3, we learned how to calculate the density of states in solids, and here we do the same for redox couples in solution. In molecules, the lowest empty states are the lowest unoccupied molecular orbitals (LUMOs), and the highest filled states are the highest occupied molecular orbitals (HOMOs). The Fermi level in a solid metal is like the HOMO in a molecule (Figure 7.53).

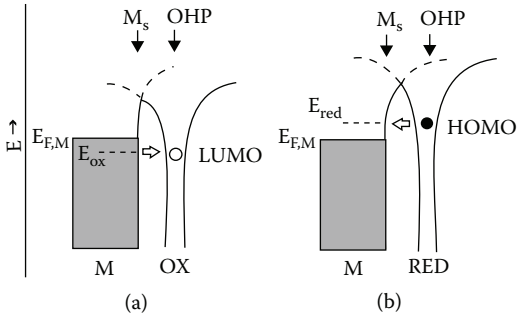

FIGURE 7.53 Solid metal/redox molecule interface energy levels. Fermi level of a solid metal and (a) energy levels of an oxidized (LUMO) and (b) a reduced (HOMO) redox species.

We can understand the concept of density of states of a redox couple in a solution in the following way. When a molecule is in the oxidized state, it has empty levels centered at E_{ox}. Once an electron occupies the oxidized state, the molecule relaxes to a lower energy level, marked as E_{red} in Figure 7.54. The relaxation includes the reorientation of the surrounding solvent molecules and changes in the chemical bonds of the reacting molecule. For example, consider the simple redox couple, Fe^{3+}/Fe^{2+}. The solvent polarization for Fe^{3+} is different from that of Fe^{2+}. Following the electron transfer $Fe^{3+} \rightarrow Fe^{2+}$, the dipoles of the solvent molecules reorient. The extra negative charge on the central ion causes the negative poles of the solvent dipoles to rotate away from the central ion, making the potential at the central ion higher and more attractive to electrons. This explains why E_{red} is always below E_{ox}. The shift in energy level

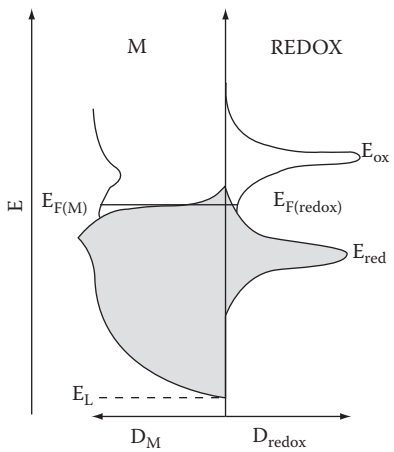

FIGURE 7.54 Time-fluctuating energy levels of the redox system can be regarded as bands of energy levels.

between oxidized (unoccupied) and reduced (occupied) levels is called the *Frank-Condon shift*. The Frank-Condon principle states that during electron transfer from one level to another, atoms and ions are effectively frozen in their positions; thus, they can move or relax only before or after the electron transfer. The amount of Frank-Condon shift, or $E_{ox} - E_{red}$, is given by:

$$E_{ox} - E_{red} = 2\lambda \tag{7.94}$$

where λ is called the *reorganization energy*. The reorganization energy contains contributions from all involved bonds and solvent polarization and is normally on the order of a few tenths of electron volts. In some cases, such as ions or metal ion complexes, the reorganization caused by bond length and angle changes is small, and the main contribution results from solvent polarization.

According to Morrison,[9] the time-fluctuating energy levels of the redox system can be regarded as bands of energy levels and are described by the densities of the oxidized and reduced states. The state density of electrons in the reduced $[D_{red}(E)]$ and oxidized $[D_{ox}(E)]$ states is given by the product of the probability density distribution, $W(E)$, and the concentration, c, or:

$$D_{red}(E) = c_{red}W_{red}(E) \text{ and } D_{ox}(E) = c_{ox}W_{ox}(E) \tag{7.95}$$

The total density of states for a redox couple is defined as:

$$D_{redox}(E) = D_{red}(E) + D_{ox}(E) \tag{7.96}$$

Similarly, for the density of states of electrons in the metal:

$$D_M(E) = D_{M(e)}(E) + D_{M(h)}(E) \tag{7.97}$$

where *e* means a filled state and h an empty one. The probability density distribution curves in solution, $W(E)$, take the form of:

$$W_{red}(E) = W_{red}(E_{red})\sqrt{\frac{c_{ox}}{c_{red}}}\exp\left(-\frac{\lambda_{red}}{4kT}\right)\exp\left\{-\frac{(1-\beta)\left[E - E_{F(redox)}\right]}{kT}\right\} \tag{7.98}$$

and:

$$W_{ox}(E) = W_{ox}(E_{ox})\sqrt{\frac{c_{red}}{c_{ox}}}\exp\left(-\frac{\lambda_{ox}}{4kT}\right)\exp\left\{-\frac{\beta\left[E - E_{F(redox)}\right]}{kT}\right\} \tag{7.99}$$

where β is the same symmetry factor we encountered in the Butler-Volmer expression; if $\lambda_{ox} = \lambda_{red}$, then $\beta = 0.5$. Equations 7.98 and 7.99 describe Gaussian distributions of energy states around E_{red} and E_{ox}, respectively, and these two curves, for $c_{ox} = c_{red}$, intersect at E^0. This intersection corresponds to the Fermi level of the redox species, $E_{F(redox)}$:

$$E_{F(redox)} = E^0 = (1/2)\,(E_{ox} + E_{red}) \tag{7.100}$$

Based on Equation 7.96 it then also holds that:

$$\frac{1}{2}D_{redox}\left[E_{F(redox)}\right] = D_{red}\left[E_{F(redox)}\right] = D_{ox}\left[E_{F(redox)}\right] \tag{7.101}$$

Consequently, we derive from Equations 7.96, 7.98, 7.99, and 7.101:

$$D_{redox}(E) = \frac{1}{2}D_{redox}\left[E_{F(redox)}\right]\left\{\exp\left\{\frac{\beta\left[E - E_{F(redox)}\right]}{kT}\right\} + \exp\left\{-\frac{(1-\beta)\left[E - E_{F(redox)}\right]}{kT}\right\}\right\} \tag{7.102}$$

This expression is sketched in Figure 7.55.

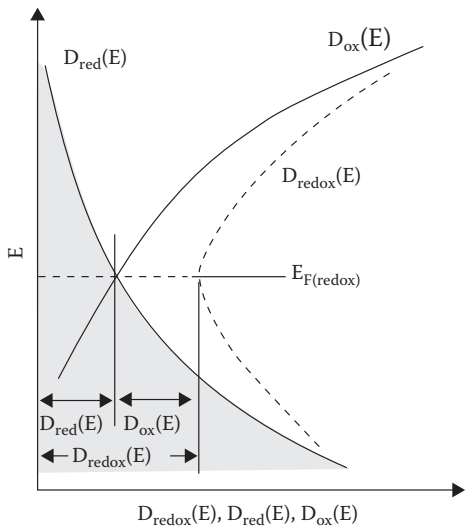

FIGURE 7.55 The state density of electrons in the reduced $D_{red}(E)$ and oxidized $D_{ox}(E)$ and the total density of states for a redox couple $D_{redox}(E) = D_{red}(E) + D_{ox}(E)$.

Because we derived expressions for the density of state functions on both sides of the interface, we are now in a position to calculate the equilibrium current exchange density i_0 across the metal/electrolyte interface. Electron transfer takes place by isoenergetic tunneling across the 0.3–0.5-nm compact layer at the metal electrode interface (OHP, see Figure 7.14). The rate of the reaction will depend on the density of states in the metal and in the redox couple. Using Fermi's golden rule (FGR) approximation (see Chapter 3, Equation 3.285), we calculate the probability of transitions of electrons between the eigenstates associated with the metal and the redox system. In this model one assumes that electron exchange occurs between levels of equal energies in both phases (the metal and the redox species in this case), and an electronic coupling strength, H, between metal electrode and the redox state modulates that transition probability. We can express the forward (cathodic) and backward (anodic) currents as a function of the energy level as:

$$\vec{i}(E) = ek_c D_{M(e)}(E) D_{ox}(E) \tag{7.103}$$

and:

$$\overleftarrow{i}(E) = ek_a D_{M(h)}(E) D_{red}(E) \tag{7.104}$$

where k_c and k_a are electron tunnel constants. Because we are dealing with electrons we also have to introduce the Fermi-Dirac distribution functions:

$$\vec{i}(E) = ek_c(E) D_M(E) f\left[E - E_{F(M)}\right] D_{redox}(E)(1-f)\left[E - E_{F(redox)}\right] \tag{7.105}$$

and:

$$\overleftarrow{i}(E) = ek_a(E) D_M(E)\left\{(1-f)\left[E - E_{F(M)}\right]\right\} D_{redox}(E) f\left[E - E_{F(redox)}\right] \tag{7.106}$$

With the Fermi level of the metal electrode being level with the redox couple's Fermi level [$E_{F(M)} = E^0 = E_{F(redox)}$], the oxidation probability (electron transfer from the molecule to the electrode) equals the reduction probability (electron from the electrode to the molecule), i.e., the exchange current density is the same in both directions, or $|\vec{i}| = |\overleftarrow{i}| = i_0$ and the total current $i = \vec{i} - \overleftarrow{i} = 0$. At equilibrium it also holds that the tunneling constant $k_t = k_a = k_c$, i.e., principle of microreversibility:

$$\begin{aligned} i_0 = \vec{i}_0(E) &= ek_t(E) D_M(E) f\left[E - E_{F(M)}\right] D_{redox}(E)(1-f)\left[E - E_{F(redox)}\right] \\ &= ek_t(E) D_M(E)\left\{(1-f)\left[E - E_{F(M)}\right]\right\} D_{redox}(E) f\left[E - E_{F(redox)}\right] = \overleftarrow{i}_0(E) \end{aligned} \tag{7.107}$$

The overall electron exchange current is obtained by integration of the microscopic current elements over the entire energy range:

$$i_0 = \int_{-\infty}^{\infty} ek_t(E) D_M(E) f\left[E - E_{F(M)}\right] D_{redox}(E)(1-f)\left[E - E_{F(redox)}\right] dE \tag{7.108}$$

Assuming $D_M(E)$ and k_t are energy-independent, Equation 7.108 can be somewhat simplified, and with further development this leads to:

$$i_0 = ek_t D_M\left[E_{F(M)}\right] \frac{1}{2} D_{redox}\left(E_{F(redox)}\right) B(\beta) \tag{7.109}$$

$$B(\beta) = \int_{-\infty}^{\infty} \exp\left\{\frac{\beta\left[E - E_{F(redox)}\right]}{kT}\right\} f\left[E - E_{F(M)}\right] dE \approx \frac{\pi kT}{\sin\left[(1-\beta)\pi\right]} \tag{7.110}$$

Ninety percent of the integrand falls in a zone of 0.25 eV around the Fermi level, and we finally obtain:

$$i_0 \approx \frac{e\pi kT}{2\sin\left[(1-\beta)\pi\right]} k_t\left[E_{F(M)}\right] D_M\left[E_{F(M)}\right] D_{redox}\left[E_{F(redox)}\right] \tag{7.111}$$

This expression is plotted in Figure 7.56. Figure 7.56a repeats the time-fluctuating energy levels of the redox system and the energy bands in the metal. The relation $k_t(E)$ is illustrated in Figure 7.56b, and $i_0(E)$ is shown in Figure 7.56c.

Out of Equilibrium: Current under Polarization

Applying an overvoltage shifts the redox states of the molecule in solution relative to the Fermi level of the metal electrode. This triggers electron transfer between the electrode and the molecule in an energy

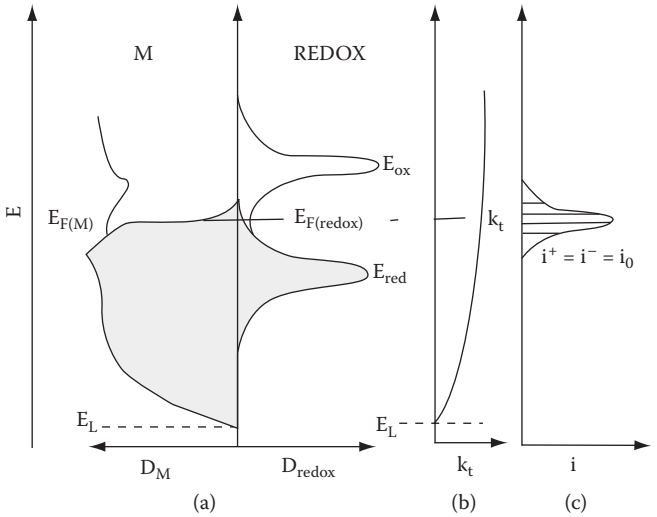

FIGURE 7.56 Using Fermi's golden rule, we can calculate the current exchange density i_0 across the metal/electrolyte interface in the presence of a redox couple. (a) Time-fluctuating energy levels of the redox system can be regarded as bands of energy levels. (b) The relation of tunneling constant k_t and energy E. (c) Electron exchange current density i_0 versus energy. The lowest energy level is E_L.

range close to the Fermi level. Out of equilibrium, the Fermi levels are offset by the overvoltage η or the total current $i(\eta) = \overleftarrow{i}(\eta) - \vec{i}(\eta) \neq 0$. Based on Equation 7.80 we rewrite the overvoltage here as:

$$\eta = E_{F(M)} - E_{F(redox)} \tag{7.112}$$

With this simple expression we can rework Equations 7.105 and 7.106 as:

$$\vec{i}(\eta) = e\int_{-\infty}^{\infty} k_t(E,\eta) D_M(E) f\left[E - E_{F(redox)} + e\eta\right] D_{redox}(E)(1-f)\left[E - E_{F(redox)}\right] dE \tag{7.113}$$

$$\overleftarrow{i}(\eta) = e\int_{-\infty}^{\infty} k_t(E,\eta) D_M(E)\left\{(1-f)\left[E - E_{F(redox)}\right] D_{redox}(E) f\left[E - E_{F(redox)}\right] dE \tag{7.114}$$

Using Equation 7.102, we find another Butler-Volmer-type expression (Equation 7.89: remember $\alpha + \beta = 1$) for the current i versus η:

$$i = i_0 \frac{k_t\left[E_{F(M)}\right]}{k_t\left[E_{F(redox)}\right]}\left[\exp\left(\frac{(1-\beta)e\eta}{kT}\right) - \exp\left(\frac{-\beta e\eta}{kT}\right)\right] \tag{7.115}$$

This expression explicitly contains the electron tunneling rate constant k_t, for which there are semi-quantitative data (see section below). In Figure 7.57, we illustrate forward and backward currents across the metal/electrolyte interface.

Notice that all the potential changes fall within the less conductive medium, i.e., the electrolyte in this case.

Electron Tunneling Transfer Rate k_t According to the Marcus theory (1992 Nobel Prize),[10] the electron transfer rate k_t in Equation 7.115 depends on the activation energy for electron transfer, ΔG^*_{ACT}, and the electronic coupling, H_{DA}, between the two electron-exchanging species (say, a redox enzyme and a metal electrode). The electronic coupling is often very difficult to calculate and is widely treated as a fitting parameter to experimental data. With reference to Figure 7.58, at the interception point of the potential energy curves, the acceptor energy level (A) is equal to the donor level (D). The energy

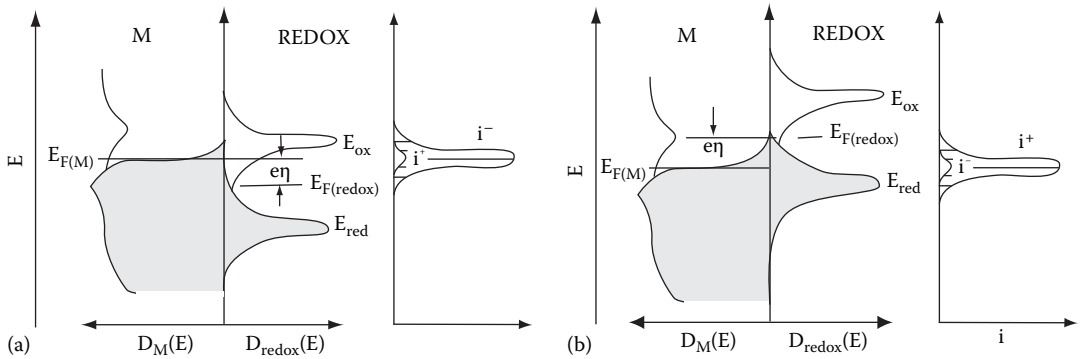

FIGURE 7.57 Applying a voltage across the metal/electrolyte interface that is different from the equilibrium potential leads to cathodic (a) or anodic (b) currents that are different from the equilibrium exchange current i_0.

barrier (activation energy) or charge transfer at this point is given as:

$$\Delta G^{*}_{ACT} = \frac{\lambda}{4}\left(1+\frac{\Delta G^{0}}{\lambda}\right)^{2} \tag{7.116}$$

where ΔG^0 is the free energy difference between initial and final states. In Figure 7.58 we made $\Delta G^0 = 0$ for simplicity so that both curves have a minimum at the same energy level. If thermal fluctuations change the distance between *D* and *A* (see reaction coordinate in Figure 7.58), then the electron transfer between donor and acceptor will be modified with a probability factor of:

$$k_t = \frac{1}{\sqrt{4\pi\lambda k_B T}}\exp\left[-\frac{\left(\Delta G^{0}+\lambda\right)^{2}}{4k_B T\lambda}\right] \tag{7.117}$$

In the case of strong coupling between the donor and acceptor orbitals, i.e., a large H_{DA}, electron transfer takes place as soon as the donor and acceptor levels line up. In this case, the electron transfer rate k_t is simply given as:

$$k_t = \nu\exp\left[-\frac{\left(\Delta G^{0}+\lambda\right)^{2}}{4k_B T\lambda}\right] \tag{7.118}$$

where ν is the frequency of the nuclear coordinate, which is typically between 10^{12} and 10^{14} s^{-1}. This extreme situation represents the so-called *adiabatic electron transfer*. On the other hand, in the weak coupling limit or the nonadiabatic case, the electron transfer rate, obtained by applying Fermi's golden rule (Equation 3.285), is given by:

$$k_t = \frac{2\pi}{\hbar}H^{2}_{DA}\frac{1}{\sqrt{4\pi\lambda k_B T}}\exp\left[-\frac{\Delta G^{*}}{k_B T}\right]$$

$$\text{where } \Delta G^{*} = \frac{\lambda}{4}\left(1+\frac{\Delta G^{0}}{\lambda}\right)^{2} \tag{7.119}$$

The above considerations include only one nuclear coordinate, but the result is essentially the same when multiple nuclear coordinates are considered except that the reorganization energy, λ, contains contributions from all involved bonds and solvent polarization. As mentioned before, the reorganization energy λ is normally on the order of a few tenths of electron volts.

Because H_{DA} in general diminishes exponentially with distance (like any orbital), the distance dependence of the rate of electron transfer thus can be described by:

$$k_t = k_0 e^{-\beta d} e^{-\frac{\left(\Delta G^{0}+\lambda\right)^{2}}{4k_B T\lambda}} \tag{7.120}$$

in which β (the attenuation factor) is a constant scaling the distance dependence and k_0 is the rate at close contact (~10^{13} s^{-1}). The medium between donor and acceptor strongly influences the rate of the electron transfer process through solvation and the value of β. Many researchers have focused on determining the electron transfer rate k_t as a function of the donor-acceptor separation that they systematically controlled experimentally. If donor and acceptor are separated by a vacuum, the interaction (through space interaction) is much less (β ≈ 2.8–3.8 $Å^{-1}$) than when a protein, DNA (β ≈ 1.4 $Å^{-1}$), or a solvent (through solvent coupling), like benzene, is the medium (β ≈ 1 $Å^{-1}$). In contrast, for highly conjugated organic bridges, β is much smaller, lying in the range of 0.2–0.6 $Å^{-1}$. With DNA, proteins immobilized on electrodes, and saturated organic molecules, β is found between these two limits. But if the energy level of the bridge becomes too low, it can work as a trap for electrons, and the transfer stops (now the electrons localize on the bridge).

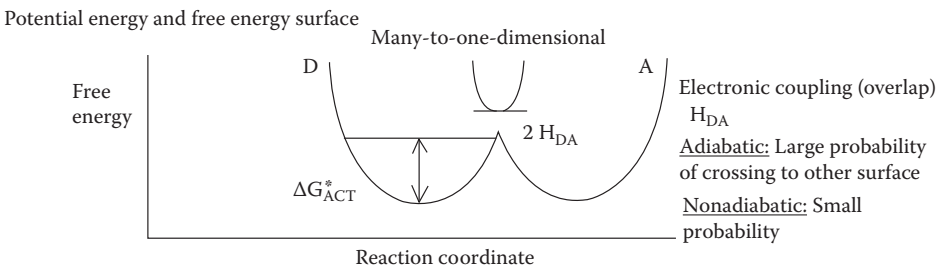

FIGURE 7.58 Potential energy and free energy surface, where H_{DA} is the electronic coupling and the electron transfer (ET) is thermal instead of optical.

Equation 7.120 is of utmost importance when attaching large molecules with reaction sites or redox centers to electrode surfaces. If the redox center is too far removed from the metal surface, no electron transfer can occur. Direct electron transfer between enzymes and metal electrodes, for example, is normally very slow as a consequence of steric insulation of the redox center in the protein. To illustrate this point, the "depth" of the redox center in glucose oxidase enzyme (GOx) is 8.7 Å, whereas for horseradish peroxidase (HRP) it is 4.1 Å. This is too deep below the protein surface for efficient electron transport to the underlying metal electrode. One solution to electronically connect to such a deep-lying redox center [flavin adenine dinucleotide ($FAD/FADH_2$) in the case of GOx (Figure 7.59)] is to rely on an electron acceptor molecule (mediator) to establish electrical communication with the electrode. Enzyme mediators are used in current (second-generation) commercial glucose sensors. Before introducing a second and even a third generation of these sensors, we consider how a first generation of glucose sensors operated.

When an enzyme reacts with its substrate *S*, product *P* is generated. In the case of GOx, this reaction is given as:

$$\text{Glucose (S)} + O_2 \xrightarrow{\underline{\text{GOx}}} \text{glucono-}\delta\text{-lactone} + H_2O_2\ \text{(P)} \qquad \text{Reaction 7.5}$$

As illustrated in Figure 7.60a, in this process the redox center in the enzyme is reduced from FAD to $FADH_2$, and it is the oxygen present in the sample that regenerates the enzyme by acting as an electron acceptor. Oxygen is called a *cosubstrate of the enzyme* in this case. To make a sensor based on this reaction, one might follow the anodic oxidation of H_2O_2 or the cathodic reduction of O_2. A first generation of glucose sensor was made this way.

In a second generation of sensors, the rationale was to monitor the redox center of the enzyme more efficiently. In the case of GOx, that means monitoring the $FAD/FADH_2$ redox couple directly. But, as we just saw, that redox center is located too far from the surface of the enzyme to be electrically accessible. The solution is to rely on a fast mediator redox system (MED_{red}/MED_{ox}) to establish electrical communication with the electrode (see Figure 7.60b). These mediators are chosen to regenerate FAD from $FADH_2$ much faster than oxygen does; in other words, a mediator redox couple where MED_{ox} is a much better electron acceptor than oxygen. The ferrocene/ferrocinium redox couple self-exchanges electrons very rapidly and is used as a diffusing mediator to shuttle electrons between the protein redox center and the electrode. Mediators can also be provided at much larger concentrations than

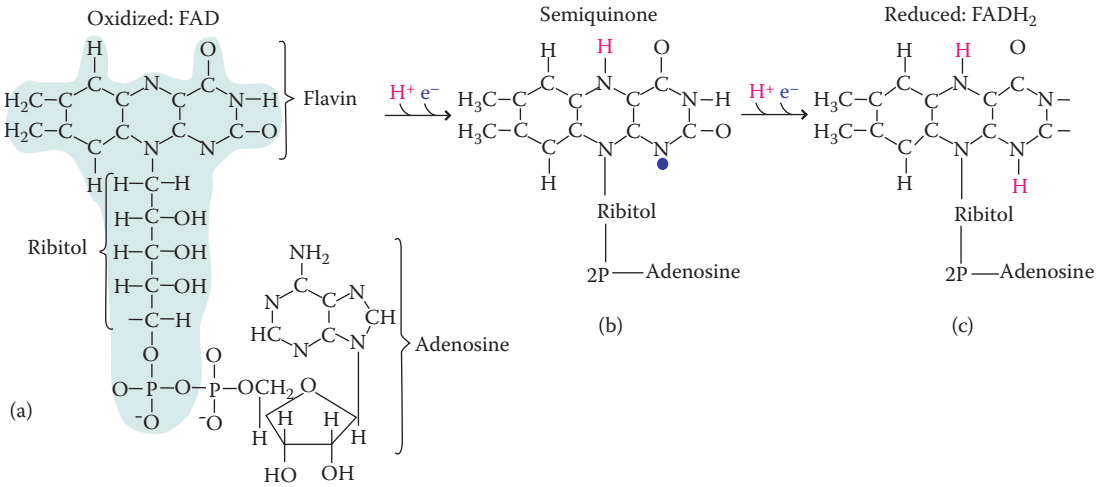

FIGURE 7.59 The redox center, flavin adenine dinucleotide ($FAD/FADH_2$). In the case of glucose oxidase (GOx) this center is buried 8.7 Å deep within the enzyme. The reduced form of the redox center or hydroquinone form is $FADH_2$ (a), and the oxidized form or the quinone form is FAD (c). Flavin adenine dinucleotide (FAD) can accept one or two hydrogen atoms. The addition of one electron together with a proton (i.e., a hydrogen atom) generates a semiquinone intermediate (b). The semiquinone is a free radical because it contains an unpaired electron (denoted by a blue dot), which is delocalized by resonance to all the flavin ring atoms. The addition of a second electron and proton (i.e., a second hydrogen atom) generates the reduced form, $FADH_2$.

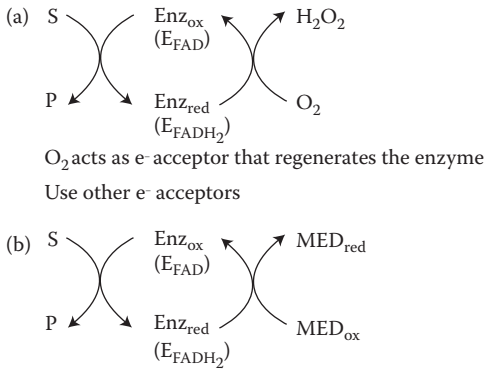

FIGURE 7.60 Glucose oxidase (GOx) reaction with its substrate (*S*) glucose in the presence of oxygen (a) and a mediator (b).

oxygen, which also makes electron transfer faster. Besides a higher current, another added benefit of these mediated enzyme-based sensors is that they are independent of the oxygen content in the sample, a factor that sometimes limits Reaction 7.5. During the regeneration of FAD, ferrocene (MED_{red}) is produced and can be measured by anodic oxidation. Alternatively, the decrease in ferrocinium (MED_{ox}) can be monitored by cathodic reduction. Medisense/Abbott uses a ferrocene derivative (carboxy ferrocene) in their commercial glucose sensor for diabetes management. This sensor is also used as an example of an amperometric device at the end of this section.

Third-generation glucose sensors were pioneered by Adam Heller and involve wiring the enzyme redox center directly to the electrode.[11,12] The $FADH_2$ redox centers of GOx can be electrically "wired" to an electrode by precipitation on the surface of thin films of the electrostatic adduct of GOx, which is a polyanion at neutral pH, and polycationic copolymers of vinyl ferrocene. This approach has the benefit of immobilizing the mediator molecules. The best approach, also invented by Heller, is currently the use of an electroactive enzyme-containing hydrogel. This is made by cross-linking nonprecipitating electrostatic adducts of polyanionic GOx and an excess of a polycationic osmium complex redox center containing polyvinyl pyridine-based redox polymer.[13,14] This cocktail creates a 3D matrix that is reversibly electroreduced and electrooxidized, extending electrochemistry from the 2D surface of the metal electrode to the 3D volume of the electron-conducting hydrogel. These wiring gels are highly permeable to facilitate the transport of reactants and products. In the volume of the hydrogel, electrons and holes are transported through collisions between Os^{2+} and Os^{3+} redox centers, which are tethered to the polyvinyl pyridine backbone, but with polymer segments that remain mobile within the polymer. A more recent optimized version of such a polymer, designed by Fei Mao,[15] is shown in Figure 7.61. In this example, the enzyme is wired using a polymer chain that folds along the enzyme structure.

The state-of-the-art glucose sensors are reviewed as the biggest bio-MEMS commercial success in Volume III, Chapter 10.

Semiconductor/Electrolyte and Insulator/Electrolyte Interface The semiconductor/electrolyte interface behaves significantly different than the metal/electrolyte interface. First, because there are many more free charge carriers in the solution than in the semiconductor, all potential changes in the electrical double layer occur on the semiconductor side, not in the electrolyte. Second, because of the

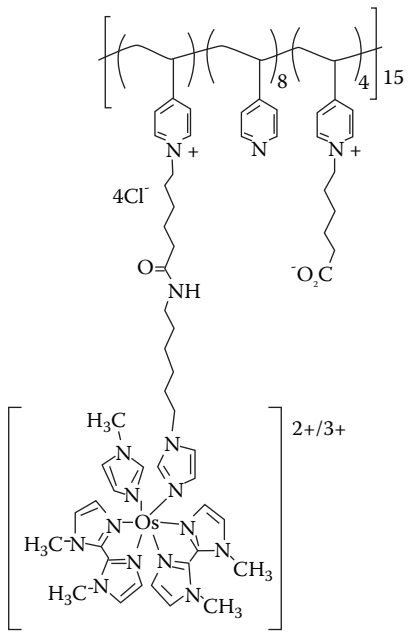

FIGURE 7.61 Os^{2+} and Os^{3+} redox centers are tethered to the polyvinyl pyridine backbone, but polymer segments remain mobile within the polymer. A more recently optimized version of such a polymer, designed by Fei Mao. (Mao, F., N. Mano, and A. Heller. 2003. *J Am Chem Soc* 125:4951.[15])

bandgap in the semiconductor, many electron transitions between redox levels and semiconductor are forbidden. In the case of an insulator/electrolyte interface, all electron transitions are forbidden. In Figure 7.62, we show what happens when we bring the same redox couple in contact with an n- and p-type semiconductor of the same material (e.g., *n*- and *p*-type Si). As in the case of the metal/electrolyte interface, equilibrium is reached when Fermi levels have lined up across the interface, which leads to a space-charge layer in the semiconductor. The reductant of a redox couple (filled electron levels) may inject electrons in the empty conduction band of the semiconductor if those energy levels overlap. Similarly, the oxidant may inject holes in the valence band if there is energy overlap in those bands.

A redox couple with energy levels that overlap only with the semiconductor bandgap does not lead to any current. Mathematically, this is expressed in the overlap integrals of Equations 7.113 and 7.114. In the case of semiconductors, there is a small range, known as the *forbidden bandgap*, where the overlap integral vanishes. In the case of an insulator that gap is large, and the overlap integral is always zero. To illustrate the previous points, consider Figure 7.63, where we show an n-type semiconductor/electrolyte contact for three different redox systems. For redox system 1, with its standard redox potential (E^0_{redox}) close to the conduction band edge, a high rate of electron exchange can be expected, and an accumulation layer forms in the semiconductor. For redox system 2, a depletion layer is formed in the semiconductor, and the electron exchange is expected to be low as the redox system significantly overlaps with the forbidden bandgap. In the case of redox system 3, the barrier height in the semiconductor is even higher (close to E_g, the bandgap), but (E^0_{redox}) is now close to the valence band edge and electron exchange is possible again. In the latter case, empty levels (holes) must be available in the valence band for electrons of reductant molecules to jump into. These holes can be generated, for example, by shining light on the semiconductor or by a strong oxidant. These holes react with the semiconductor itself and, in the presence of the appropriate electrolyte solution, may etch/corrode the semiconductor material. In Volume II, Chapter 4, in the section on wet bulk micromachining, we will expand on the concepts developed here to explain the difference between isotropic and anisotropic etching of silicon. We will also learn that current/overvoltage curves (i-η) on semiconductor/electrolyte contacts take on distinct diode characteristics. In liquid-junction solar cells, appropriate reductants compete effectively with the oxidation/corrosion of the semiconductor because they react more avidly with the holes in the valence band than the semiconductor material itself.[16]

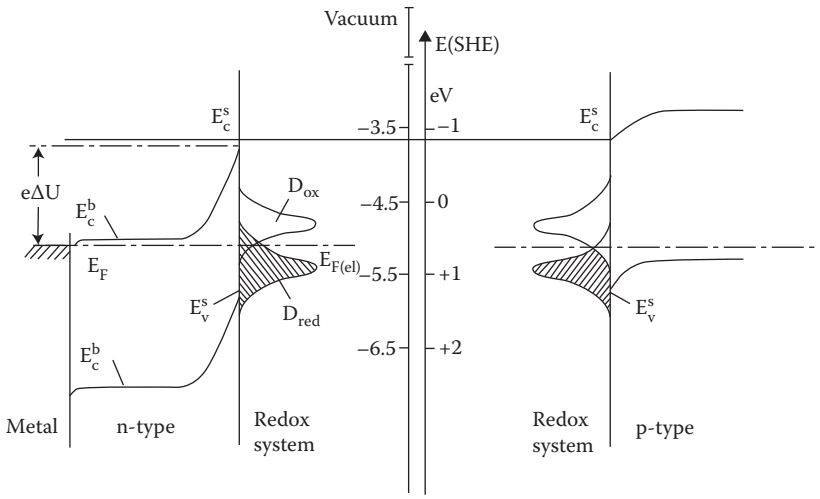

FIGURE 7.62 Energy diagram of the same redox couple in contact with *n*- and *p*-type Si (two energy scales are shown: electron in vacuum at infinity and SHE).

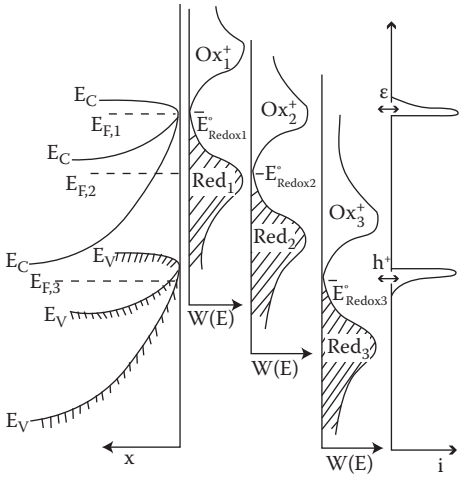

FIGURE 7.63 Energy diagram of three different redox couples in contact with n-type silicon.

For a certain value of the applied potential, there is equality between the number of electrons removed from and supplied to the semiconductor electrode. In this situation there will be no space-charge region in the semiconductor, and the potential is called the *flat band potential* E_{fb} (= E_F in the semiconductor). This potential can be established from impedance measurements on the semiconductor/electrolyte interface. From the flat band potential, the band edges of the semiconductor can be calculated if the dopant concentration is known (see Equations 4.38 and 4.39) (for details, see Madou and Morisson[15]). In Figure 7.64, we show a number of common semiconductor band edges and redox couples all referenced to the same reference electrode (REF E) on the right and with respect to an electron at infinity in vacuum on the left. Using this figure one can, in principle, predict the expected electron exchange for any semiconductor redox couple system by evaluating the overlap integral of energy levels on both sides of the interface (again using Equations 7.113 and 7.114). For example, in liquid-junction solar cells, for the reductant to compete effectively for holes in the valence band and avoid corrosion of the solar cell, one chooses a redox system where the maximum density of states of the reductant (the peak of the Gaussian) is at the same level as the valence band edge of the semiconductor.[15]

In a flat band situation, a potential drop remains on the solution side, and this remaining potential drop can be changed by ion adsorption on the semiconductor surface. Semiconductors in general develop a thin oxide coat on their surface. The hydroxyl groups at the surface of these oxide films will be more or less ionized, depending on the pH of the solution. This makes for a flat band potential,

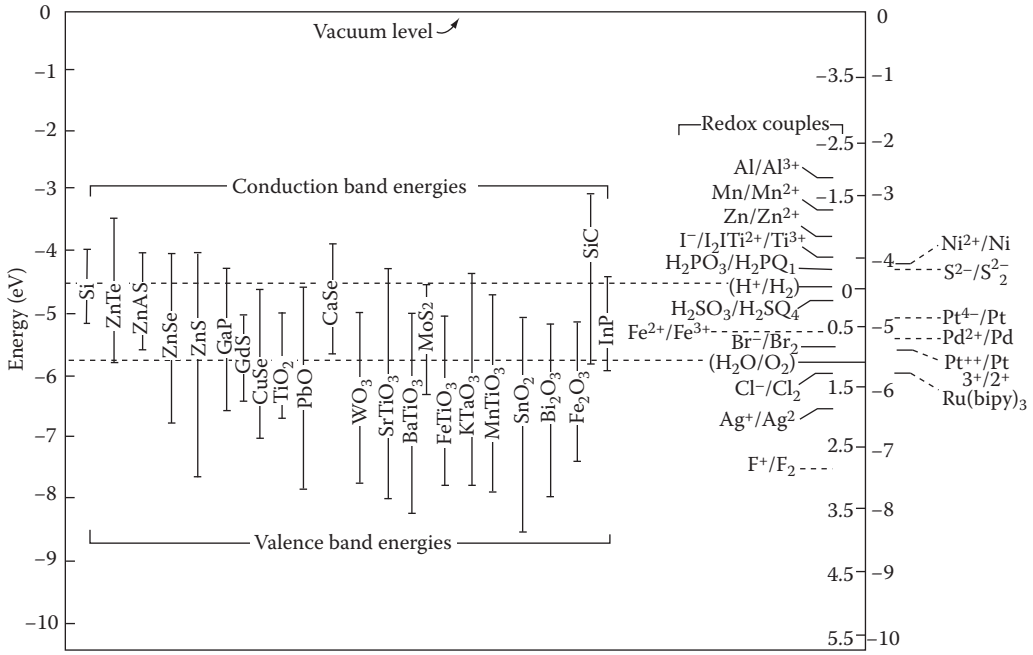

FIGURE 7.64 Relative energy levels of some common semiconductor and redox systems. The scale on the left is the energy with respect to an electron at infinity in vacuum. The scale on the right is the standard hydrogen electrode (SHE).

E_{fb}, that is a function of the pH of the solution (typically about 59 mV/pH unit change). If the redox system is not pH-dependent, this means that we can shift the semiconductor band edges with respect to the redox levels in solution. This is exploited in semiconductor electrochemistry to probe the density of energy levels of redox couples by changing the pH in small steps and observing the measured currents across the interface.[9]

With semiconductors, considerable electron transfer can only occur if the redox potential is located close to the band edges. In such a case, the electron equilibrium exchange current, $i_{0,e}$ is high but lower than for a metal. Any ion exchange processes, e.g., proton exchange, at the semiconductor surface would have difficulties competing with the electron exchange for establishing the open circuit voltage ($i_{0,e} >> i_{0,i}$). In principle, the pH dependence of the flat band potential of a semiconductor could be used as a good pH sensor, but only if the electron exchange current does not overwhelm the ion exchange current. In other words, in the presence of redox couples, a wide bandgap semiconductor or, better yet, an insulator, would make the better solid-state pH sensor. However, the pH sensitivity of an insulator normally cannot be measured because a thick insulator has too high of an impedance. Further below, we will see that the solution is to use an ion-sensitive field-effect transistor (ISFET), where the dielectric is so thin that a substantial electric field across it can influence the drain-source current of the transistor. These devices enable one to measure potentials on insulator/electrolyte contacts, ensuring that no electron exchange current ($i_{0,e}$) will interfere with the ion exchange current ($i_{0,i}$).

Membrane/Electrolyte and Mixed Conductor/Electrolyte Interfaces At an ionically conductive membrane/electrolyte interface, ideally only the fast exchange of one type of ion with the solution determines the open circuit potential. Because ions do not follow Fermi-Dirac statistics, the theory of ion transfer at the solid/liquid differs from that of electron exchange. Despite this obvious difference and the fact that ions must leave behind their hydration shell if they want to cross the phase boundary, the calculations for the equilibrium ion exchange current, $i_{0,i}$, and the polarization curves (i-η) lead to results very similar to those obtained for electron transfer at the metal/electrolyte interface. The ionic species that carries the greatest number of electric charges across the phase boundary is potential determining (largest $i_{0,i}$). For a "good" ion-selective membrane, the ion exchange current $i_{0,i}$ should be 10^{-5} A cm^{-2}. For membranes with an ion exchange current $i_{0,i} < 10^{-7}$ A cm^{-2}, mixed potentials are common. A Butler-Volmer-type expression for reactions under kinetic control and a diffusional expression similar to the ones derived for metals can be also derived for the membrane electrolyte interface but will not be developed here. For a more detailed treatise on ion exchange at solid/electrolyte interfaces consult Madou and Morrison[16] and Camman.[17]

We touched on mixed conductors, with ions and electrons as the charge transport species, when introducing IrO_x as a pH probe on page 557 "Electrodes of the Second Kind." Depending on the relative magnitude of $i_{0,e}$ versus $i_{0,i}$, a mixed conductor acts as a redox probe, a pH sensor, or both. For most mixed conductors $i_{0,e} >>> i_{0,i}$, one expects severe redox interference when used as pH sensors. As mentioned before, for reasons not well understood, from the noble metal mixed conductor oxide electrodes, IrO_x holds the most promise as a very fast, stable, low impedance pH sensor with surprisingly small redox interference.[8]

Cyclic Voltammetry and Ultramicroelectrodes

Cyclic Voltammetry

Earlier, we mentioned that the most important example of voltammetry is cyclic voltammetry, an electrochemical method in which information about an analyte is obtained by measuring current (i) as a function of an applied potential using a triangular waveform for excitation (Figure 7.40). We also explained the need of adding a high concentration of an inert supporting electrolyte to the solution (the large excess of inert ions ensures that few reactant and product ions will move as a result of migration). A typical, potentiostat-controlled, three-electrode system to carry out these experiments was shown in Figure 7.38.

Species in the electrolyte must be transported to and from the electrode before electrode reactions can occur. As species are being consumed or generated at the electrode surface via electrochemical reactions, the concentration of these species at the electrode surface will become smaller or larger, respectively, than in the bulk of the electrolyte. Suppose we are dealing with a redox species of concentration c_{bulk} in the bulk of the electrolyte ($x = \infty$) being consumed at the electrode. The concentration gradient at the electrode is then given as:

$$\frac{dc}{dx} = \frac{c_{bulk}(x=\infty) - c_{surface}(x=0)}{\delta} \qquad (7.121)$$

where $c_{surface}$ ($x = 0$) is the concentration of the redox species at the electrode surface, and δ represents the boundary layer thickness. From the thermodynamic relationship between the potential imposed on the metal electrode by the potentiostat and the concentration of the reacting redox species at its surface (i.e., the Nernst equation, Equation 7.56), we conclude that the concentration difference between surface and bulk leads to an overpotential:

$$\eta_c = E - E^0 = \frac{RT}{nF} \ln \frac{c_{surface}(x=0)}{c_{bulk}(x=\infty)} \qquad (7.122)$$

i.e., the expression for the concentration polarization, η_c, where n is the number of electrons involved in the reaction. For a planar electrode, which is much larger than the diffusion layer thickness, the measured current is given by Faraday's law (Equation 7.44):

$$i = nFAD_0 \left[\frac{c_{bulk}(x=\infty) - c_{surface}(x=0)}{\delta} \right] \qquad (7.123)$$

with D_0 ($cm^2\ s^{-1}$) representing the diffusion coefficient of the electroactive species and n the number of electrons transferred. At a certain overpotential, η_c, all of the reacting redox species arriving at the electrode are immediately consumed, and from that overpotential onward, the concentration of the electroactive ion at the surface decreases to 0, that is, $c_{surface}(x = 0) = 0$, and we reach the limiting current density i_l:

$$i_l = nFAD_0 \left[\frac{c_{bulk}(x=\infty)}{\delta} \right] \qquad (7.124)$$

The largest current (the diffusion-limited current) is established when every arriving species at the electrode is consumed immediately so that the surface concentration of it is zero, as illustrated in Figure 7.65. In the case shown we consider a cathodic reduction reaction (say, of $Fe^{3+} + e^- \rightarrow Fe^{2+}$, at a potential $E \ll E^0$).

Equation 7.124 shows that the limiting current is proportional to the bulk concentration of the ionic species. On this basis, classical amperometric (current-based) sensors are used as analytical devices (such as the amperometric glucose sensors we introduced earlier). We can rewrite $c_{surface}(x = 0)/c_{bulk}(x = \infty)$ in Equation 7.122 in terms of i and i_l to obtain:

$$i = i_l \left(1 - e^{\frac{nF\eta_c}{RT}} \right) \qquad (7.125)$$

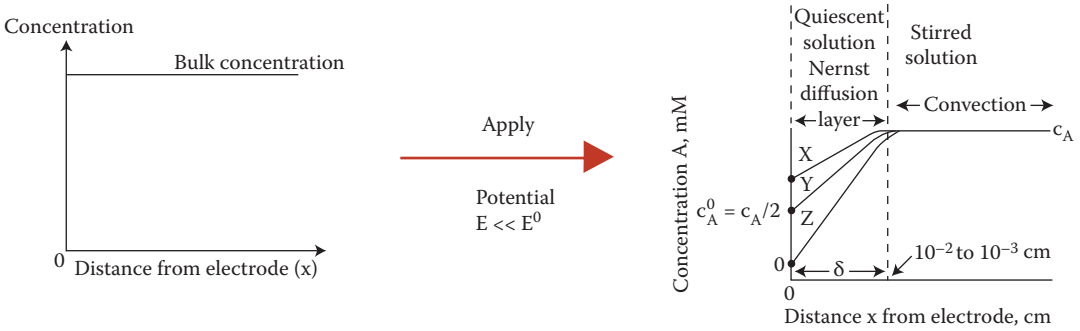

FIGURE 7.65 Applying a potential at a metal electrode that is sufficient to reduce a species in solution ($E \ll E^0$) sets up a concentration gradient that evolves over time (*X*, *Y*, *Z*). The concentration of c_A at various times after application of a voltage sufficient to consume c_A. At *Y*, the concentration of c_A has fallen to half of that in the bulk.

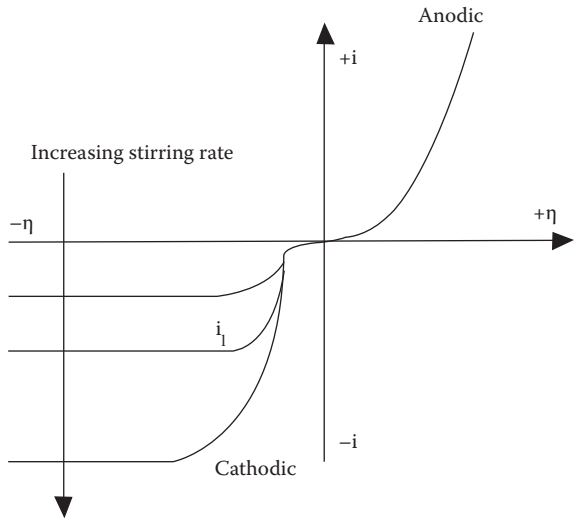

FIGURE 7.66 A diffusion-limited current is indicated for different stirring rates. The limiting current appears as a horizontal straight line limiting the current that can be achieved at a large value of the overpotential, whereas activation-controlled currents keep on increasing. This situation could come about when the concentration of oxidant is much lower than that of reductant.

This expression is illustrated for a cathodic diffusion-limited reaction in Figure 7.66. The cathodic current quickly becomes diffusion-limited, whereas the activation-controlled anodic current keeps on increasing. This situation could come about when there is very little oxidant (say, 10^{-4} M) but an abundance of reductant (say, 1 M), so that a diffusion plateau is not obtained in the anodic branch of the i-η curve.

The concentration overpotential and the activation overpotential have different origins. In the case of activation overpotential, the slope of i versus η increases with η, whereas in the transport-limiting case, the slope of i versus η decreases with increasing η and effectively becomes zero for sufficiently large values of the overpotential.

As shown in Figure 7.66, stirring of the electrolyte strongly affects the limiting current. Higher stirring rates promote convective transport of the ions toward the electrode and result in a smaller boundary layer δ.

For reversible systems, the i-E response shows an anodic and a cathodic plateau as illustrated in Figure 7.67a (assume that O and R are at the same concentrations). This can be ascertained by writing the surface concentration values for oxidant and reductant $c_{o,surface}(x = 0)$ and $c_{r,surface}(x = 0)$ in the Nernst equation in terms of i and i_l to obtain:

$$E = E^0 + \frac{RT}{nF}\ln\frac{c_{o,surface}\left(x=0\right)}{c_{r,surface}\left(x=0\right)}$$
$$= E^0 - \frac{RT}{nF}\ln\frac{D_0/\delta_0}{D_R/\delta_R} + \frac{RT}{nF}\ln\frac{i_l - i}{i}$$

or:

$$E = E_{\frac{1}{2}} + \frac{RT}{nF}\ln\frac{i_l - i}{i} \qquad (7.126)$$

The value of $E_{1/2}$ is the half-wave potential or the potential where the current is one-half the limiting current ($i_l/2$), and it is characteristic for the specific redox couple O/R only (qualitative analysis), whereas the height of the current plateau is proportional to the analyte concentration (quantitative analysis). In most cases, $E_{1/2}$ is the same as the reaction's standard state potential. A voltammetric wave and the half-wave potential $E_{1/2}$ are illustrated in Figure 7.67a. From Equation 7.126, a plot of E

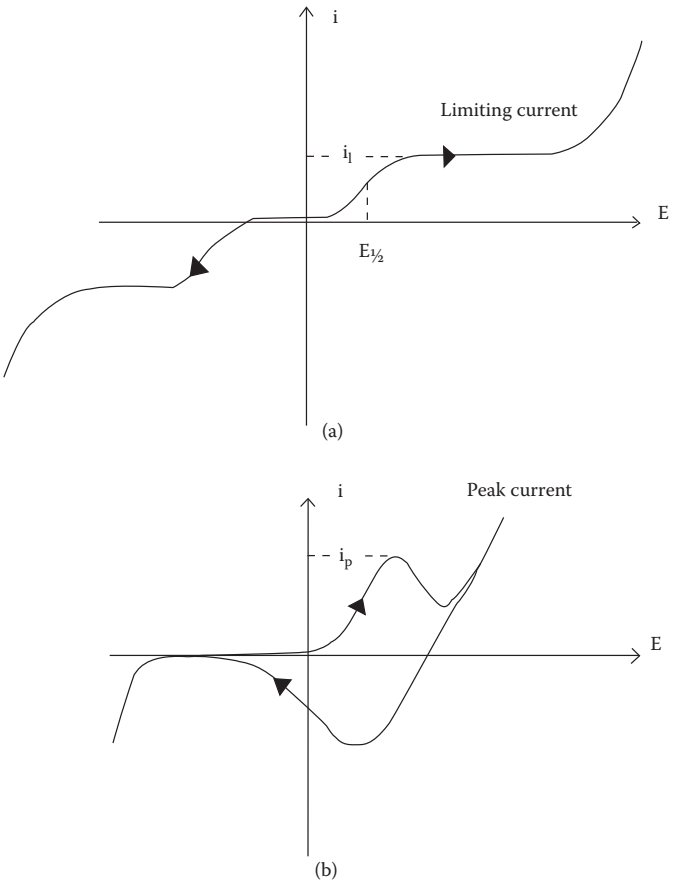

FIGURE 7.67 Cyclic voltammograms with slow (a) and fast (b) sweep rates.

versus ln $(i_l - i)/i$ yields a straight line with a slope of RT/nF (or $0.059/nV$ in a log plot) at room temperature and is used to determine the reversibility of a reaction.

The voltammetric wave in Figure 7.67a applies only when sweeping the voltage ($v = dE/dt$, where v is the voltage sweep rate) relatively slow. At higher sweep rates, cyclic voltammograms are obtained, as illustrated in Figures 7.67b and 7.68. When changes in the potential are made slowly, at such a rate that the rates of diffusion of oxidized and reduced species to and from the electrode can always keep the system in equilibrium with the bulk of the solution at all times (the steady-state value for δ is achieved in a short period compared with the measurement), the cyclic voltammogram exhibits a plateau corresponding to i_l as shown in Figure 7.67a. Most amperometric sensors work within this diffusion plateau, where operation is more forgiving for small potential drifts because the current is independent of the applied potential in that plateau. This also explains why commercial amperometric sensors mostly come without real reference electrodes (less expensive two-electrode system rather than the more complicated and more expensive three-electrode system): the correct knowledge of the voltage is not that important in a current plateau. The time necessary for diffusion to and from the electrode is crudely given by $t \approx \delta^2/2D$ (for a more correct expression, see Equation 7.128), where δ is the thickness of the diffusion layer. The diffusion layer δ will grow with $t^{1/2}$ so that a diffusion layer thickness of 10^{-4} cm is built up in 1 ms and of 10^{-2} cm in 10 s (using a typical value for the diffusion coefficent D of 5×10^{-6} cm^2s^{-1}). In the absence of convection δ keeps on increasing, but with convection present it finally approaches a steady-state value.

At fast sweep rates, the potential rapidly moves into the diffusion-limited regime. As a consequence, the concentration gradient is very large, and the initial current is very high. The rate of potential change is too rapid for diffusional processes to maintain equilibrium with the bulk of the solution. As a result, when sweeping the potential the current will not be maintained. Instead, it will peak and then decay as illustrated in Figure 7.67b. The peak value of the current, i_p, for a reversible reaction is given by the Randles-Sevcik equation:

$$i_p = 2.69\ 10^5 n^{\frac{3}{2}} A (Dv)^{\frac{1}{2}} c(x = \infty) \qquad (7.127)$$

where $c(x = \infty)$ is the bulk concentration, A is the electrode area, and v is the sweep rate (dE/dt). Comparing this expression for the peak current with the expression for the limiting current i_l in Equation 7.123, we see that the main difference is the appearance of the square-root sweep rate dependency.

A more detailed fast-sweep cyclic voltammogram is shown in Figure 7.68. In the forward direction, voltage window A to B, no electron transfer occurs. Between B and C, the voltage is sufficient for a reduction reaction to take place, and concentrations of reactants and products are given by the Nernst equation at the surface. At potential D, a maximum current is reached as diffusion limitation sets in. Because the solution

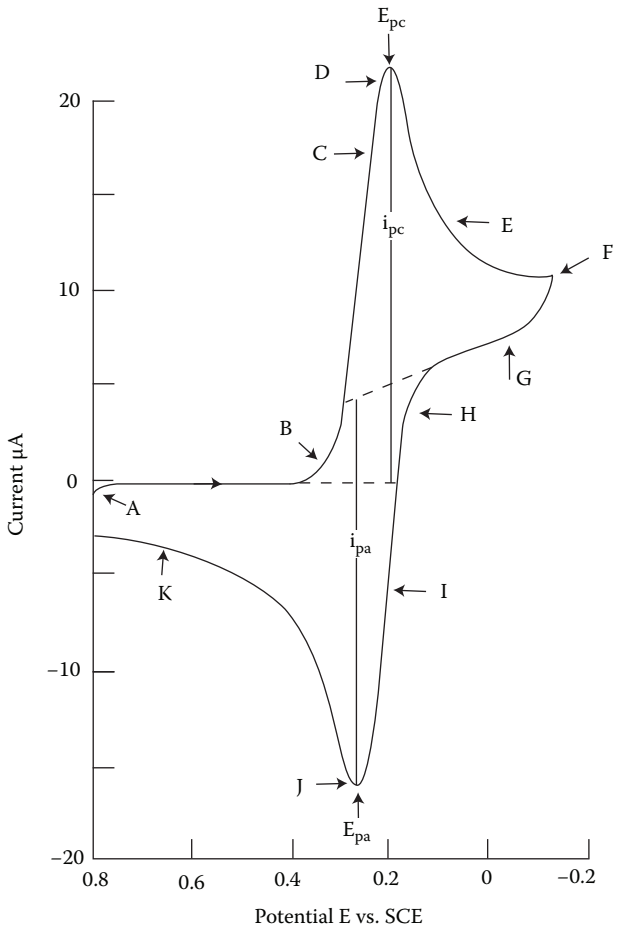

FIGURE 7.68 Fast-sweep cyclic voltammogram (*i-E*); see text.

is not stirred, δ increases with time, resulting in a decrease in current (D to E). At potential F we start the reverse scan, and we observe less current as the potential increases (F to G) until reduction no longer occurs. The reverse reaction (oxidation) then takes off at H to I (if we are dealing with a reversible reaction) and reaches a peak at J. The current decreases again because of the widening of the diffusion layer over time (J to K). A cyclic voltammogram provides a wealth of information. The cathodic (i_{pc}) and anodic peak (i_{pa}) currents at the cathodic (E_{pc}) and anodic peak (E_{pa}) potentials are all important parameters. For a reversible process, $E_{1/2} = E^0$ is the midpoint between E_{pc} and E_{pa}; also, $\Delta(E_{pa} - E_{pc}) = 0.0592/n$, independently of the sweep rate v (where n = number of electrons in reaction). For such a Nernstian process, the peak currents are proportional to the square root of the sweep rate (diffusional control) (see Equation 7.127) and $i_{pc}/i_{pa} = 1$. For a quasireversible reaction, $\Delta(E_{pa} - E_{pc}) > 0.0592/n$, which increases with increasing v. For an irreversible reaction, there is no return wave or the two waves do not overlap.

Higher sensitivities can be reached by increasing the sweep rate v (i.e., 10^{-7}–10^{-8} M; i.e., 10–100 times higher than with the slow sweep technique). This gain in sensitivity is limited by the capacitive, non-Faradaic current, because the capacitive current is linearly proportional to v [$i_C = C_H v$; see Equation 7.43, where v = dV/dt (V was used instead of E in this equation)] and increases faster than the Faradaic peak current. In the next section, we will see that the use of ultrasmall electrodes enables one to measure at higher sweep rates (as high as 20,000 Vs^{-1}) because the Faradaic current on those types of electrodes is relatively larger, allowing for more sensitive measurements.

Nonlinear Diffusion Effects on Ultramicroelectrodes

Electrochemical reactions are influenced by the electrode size relative to the thickness of the diffusion layer, δ. With microstructures of the dimensions of the diffusion layer, macroscale electrochemistry theory breaks down, and we can exploit some unexpected beneficial effects afforded through miniaturization. An ultramicroelectrode (UME) is an electrode having one of its dimensions (called the *critical dimension*) equal to or smaller than 20 μm.

For a small, spatially isolated electrode, with its size reduced to a range comparable with the thickness of the diffusion layer, nonlinear diffusion caused by curvature effects must be taken into account. In Figure 7.69a we illustrate various types of UMEs, including disc shaped (most common are planar or recessed), spherical (drop), band, ring, array, and so on. The diffusional fields for various types of microelectrode shapes and a semi-infinite planar electrode are shown in Figure 7.69b. The analysis shows that as the curvature effects become more pronounced, more diffusion of ions from all

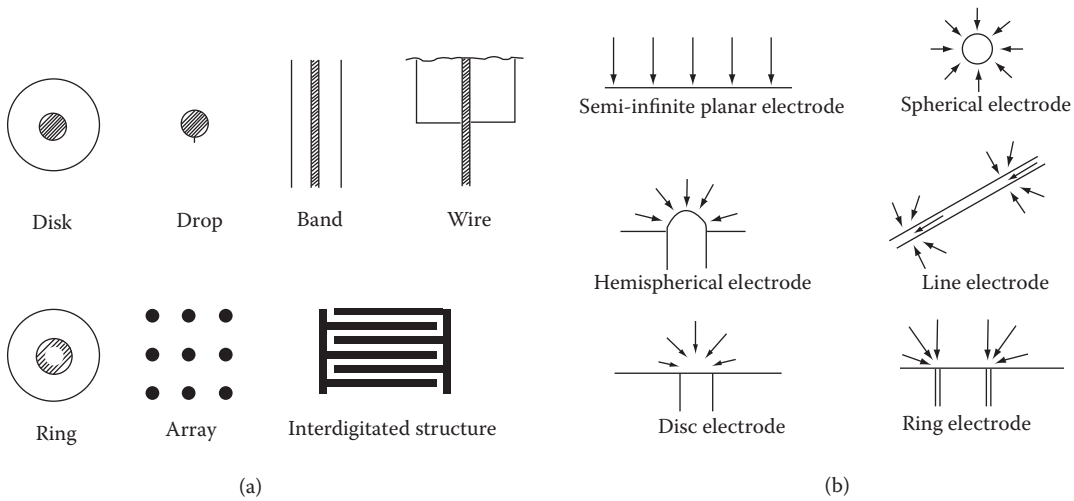

FIGURE 7.69 (a) Examples of types of ultramicroelectrodes (UMEs). (b) Diffusional fields around a semi-infinite planar electrode and various UMEs.

directions takes place, thus increasing the supply of reactants to the electrode.

The diffusion layer thickness arising from linear diffusion is time-dependent and given by [16,18]:

$$\delta = \left(\pi D_0 t\right)^{\frac{1}{2}} \tag{7.128}$$

δ is essentially the distance moved by a molecule during the experiment. Substituting Equation 7.128 into Equation 7.124, we obtain the *Cottrell equation for planar diffusion*:

$$i_1 = nFAc\left(x=\infty\right)\left(\frac{D_0}{\pi t}\right)^{\frac{1}{2}} \tag{7.129}$$

This equation represents the current-versus-time response on an electrode after application of a potential step sufficiently large to cause the surface concentration of electroactive species to reach zero. This equation, at short times after the potential step application, is appropriate regardless of electrode geometry and rate of solution stirring as long as the diffusion layer thickness is much less than the hydrodynamic boundary layer thickness.* Nonlinear diffusion at the edges of microelectrodes results in deviation from the simple Cottrell equation at longer times. The total current time relation with the correction term is given as:

$$i_1 = \frac{nFAD_0^{\frac{1}{2}}c\left(x=\infty\right)}{\pi^{\frac{1}{2}}t^{\frac{1}{2}}} + \frac{nFAD_0c\left(x=\infty\right)}{r} \tag{7.130}$$

At short times, when the diffusion layer is thin compared with radius *r*, Equation 7.129 holds. At longer times and for small electrodes, Equation 7.130 predicts that the correction term can become significant. In practice, a study on ultrasmall electrodes often starts with a linear regression of the measured current versus $t^{-1/2}$ after application of a potential step. The intercept gives the steady-state term. This term, the diffusion-limited current, $i_{l,m}$, at sufficiently long times on UMEs for some important electrode shapes, is given by[18]:

$$\begin{aligned} i_{l,m} &= \pi rnFD_0c_{bulk}\left(x=\infty\right) && \text{DISC} \\ i_{l,m} &= 2\pi rnFD_0c_{bulk}\left(x=\infty\right) && \text{HEMISPERE} \\ i_{l,m} &= 4\pi rnFD_0c_{bulk}\left(x=\infty\right) && \text{SPHERE} \end{aligned} \tag{7.131}$$

In the correction term of Equation 7.130, the electrode surface area *A* is divided by the radius *r*. Hence the principal location of charge transfer appears to be on the outer edge of the electrode. This constitutes a very favorable scaling. Phenomena scaling with the linear dimension to the power of one becomes important in the microdomain. Surface tension exemplifies another scaling law with the power of one as a very dominant force in the microdomain. In the current case, $i_{l,m}$ is proportional to the electrode radius ($\sim r^1$), whereas the background current i_c (associated with the charging current of the Helmholtz capacitance) is proportional to the area ($\sim r^2$); the ratio of the Faradaic current (the charging current) to background currents should increase with decreasing electrode radius (l/*r*). For electrodeposition, this means that smaller features will be plated faster; for sensor applications, this translates into a higher S/N ratio or improved sensitivity. In the previous section, we saw that scanning the potential faster (v = dE/dt) leads to higher sensitivities (see Equation 7.127), limited by the even faster increase in capacitive current. We recognize here that the capacitive contribution of a microelectrode is relatively small, so faster scan rates are possible. The latter makes amperometric sensing with microelectrodes possible at unprecedented sensitivities.

With a single microelectrode, the analytical current remains small, and the analytical gain is relative. However, using an array of microelectrodes (see example in Figure 7.69) with all electrodes connected in parallel and separated by an insulating layer provides an elegant solution to this problem.

* In diffusion the parameter *D* is analogous to the kinematic viscosity ν_k in convection. These parameters are important in determining the thickness of the diffusion layer and the hydrodynamic boundary layer, respectively. For aqueous solutions, the diffusion coefficient is typically 1000 times smaller than the kinematic viscosity ($D = 10^{-5}$ $cm^2\,s^{-1}$ and $\nu_k = 10^{-2}$ $cm^2\,s^{-1}$). It can be shown that the relation between δ, the thickness of a steady-state diffusion layer, and δ_h, the thickness of the stagnant layer on an electrode in a stirred solution, is $\delta = (D/\nu_k)^{1/2}\delta_h$. For $D = 10^{-5}$ $cm^2\,s^{-1}$ and $\nu_k = 10^{-2}$ $cm^2\,s^{-1}$, $\delta = 0.1\,\delta_h$. Thus, the thickness of the diffusion boundary layer, δ, is considerably smaller than that of the hydrodynamic boundary layer. In an unstirred solution, δ is not well defined, and all types of disturbances can affect the transport. To prevent random convective motion from affecting transport to and from the sensing electrode, we want the diffusion layer thickness to be smaller than the hydrodynamic boundary layer and δ_h to be regular.

In arrays of ultrasmall electrodes, the electrodes behave as an equivalent number of individual microelectrodes when the spacing between them is sufficiently large. This configuration enables analytical currents in a higher range compared with the single-electrode case. This gain is temporary because the diffusion layers around the individual microelectrodes expand across the insulating surface at a rate given by Equation 7.128. The time at which the overlap occurs is both a function of electrode size and spacing in the array, resulting in a decrease in the steady-state current. In an analytical experiment, short compared with the time frame of overlap, more sensitive measurements at reasonably high currents become possible. Another gain, besides higher currents and improved S/N ratio through higher mass transport, results from using an array because the signal can be averaged over many electrodes in parallel (an $\sqrt{n}$ improvement in S/N, with n the number of electrodes). An example of an array of UMEs based on carbon nanotubes is shown in Figure 7.70.[19]

Advantages of using UMEs include:

- High mass transfer rates at ultrasmall electrodes make it possible to experiment with shorter time scales (faster kinetics).
- An array of closely spaced ultrasmall electrodes can collect electrogenerated species from adjacent electrodes with very high efficiency.
- At high scan rates, greater than 500 V/s, the data obtained from conventional electrodes are useless because they are impossible to interpret as a result of growing *iR* drop and increasing influence of charging current. With UMEs, because of reduction in size and hence the current, the *RC* and *iR* effect are greatly reduced so that UMEs can be used for fast-scan voltammetry up to 10^5–10^6 V/s.
- Electrochemical measurements in high-resistivity media, including possibly in air, become feasible.[20]
- Microelectrodes can be used as probes for local environment and processes, in which the small physical size of the electrode is important.
- The steady-state diffusion layer thickness is equal to the electrode dimension. Hence, any process with a larger characteristic dimension, such as convection, will not influence the steady-state current. This means that these electrodes can be used independent of the flow characteristics of the medium in which they are used.
- Another important analytical advantage is that greatly reduced background signals afford a greater S/N.

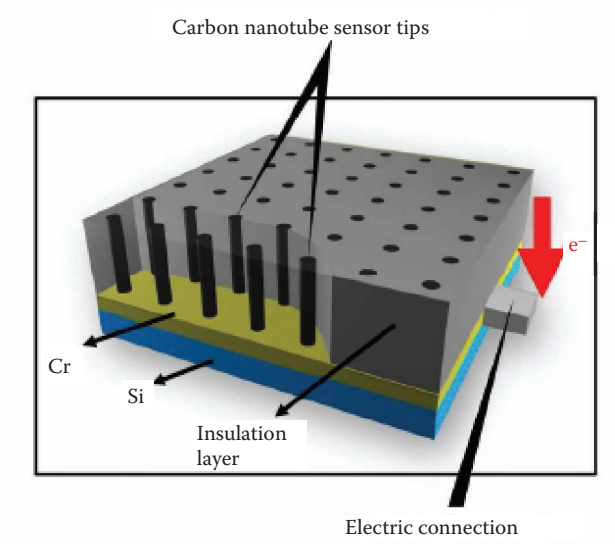

FIGURE 7.70 Arrays of CNT ultramicroelectrodes. (Lin, Y.H, W. Yantasee, F. Lu, J. Wang, M. Musameh, Y. Tu, and Z.F. Ren. 2004. *Dekker encyclopedia of nanoscience and nanotechnology.* Eds. J.A. Schwartz, C. Contescu, and K. Putyera. New York: Taylor & Francis.[19])

For example, microarray electrochemical detectors were applied in liquid chromatography for the detection of carbamate pesticides in river water.[21] The detection limits, in the subnanogram range (50–430 pg), represent a 60-fold improvement over other reported liquid chromatography detectors such as fluorescence detection and electrochemical detection with a single macroelectrode. In this early work, the electrochemical detector array consisted of a mixture of graphite and Kel-F, the so-called *Kelgraf electrode* with a microarray-like structure. Platinum microelectrodes have been microfabricated as detector electrodes for capillary electrophoresis.[22]

Micromachining small reaction chambers in which L, the outer boundary of the electrochemical cell, is made smaller than the diffusion layer thickness, δ, also increases the sensitivity of an

electrochemical sensor. In Equation 7.124, δ is now replaced by a smaller L, resulting in a higher diffusion-limited current i_l. The latter finds its application in the design of thin-layer, channel-type flow cells.

When considering a small metal disc embedded in a photoresist, nonlinear diffusion can be neglected for large electrodes (r large or $i_{l,m}$ small). If r becomes small (i.e., of the dimension of and smaller than δ), the contribution of $i_{l,m}$ to the total current becomes larger than i_l; that is, an enhanced mass transport to small electrodes occurs compared with large area electrodes. As pointed out above, we can expect that nonlinear behavior increases the plating rate of small features over large features.

But another factor influences the deposition rate on a small electrode, i.e., the level or position of the conductor surface with respect to surrounding insulating surfaces. The correction term in Equation 7.130 was derived for an inlaid microdisc electrode for which the electrochemically active substrate coincides with the dielectric insulation level (Figure 7.71a). If the conductor disc is recessed within an insulating medium (Figure 7.71b), the diffusion inside the hole must be considered as well, leading to a slight modification of the correction term $i_{l,m}$:

$$i_{l,m} = \frac{nFAD_0 c(x=\infty)}{r+L} \qquad (7.132)$$

in which L stands for the depth of the recession. Mass transport is only enhanced compared with

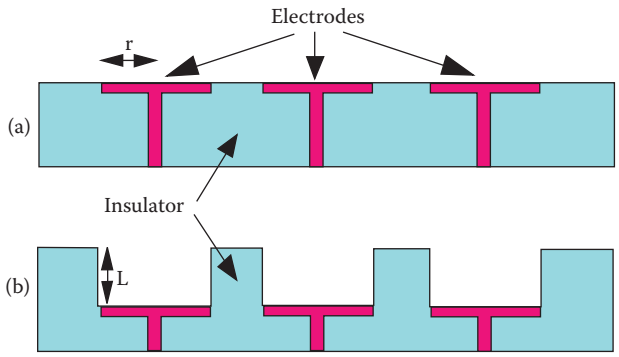

FIGURE 7.71 Nonlinear diffusion on inlaid and recessed electrodes. (a) Inlaid microelectrodes. (b) Recessed microelectrodes.

large area electrodes for small values of L. Van der Putten et al.[23] found that the metal deposition rate at smaller recessed areas (with $r \le L$) was greater than on larger areas because overfilling was obtained faster for smaller recessed features. When plating features in the LIGA process (see Volume II, Chapter 10), we may deal with situations where a metal layer is deeply recessed ($r \ll L$) in a layer of insulating photoresist. As very high-aspect-ratio features (L/r large) can be made with LIGA, the thickness of the diffusion layers is increased artificially by the microstructured photoresist layer because it is more difficult for convective flow to reach the bottom of the deep gaps.

A microelectrode of the same size or smaller than the diffusion layer thickness could be expected to plate faster than a larger electrode because of the extra increment of current resulting from the nonlinear diffusion contribution (Equation 7.130). On the other hand, as derived from Equation 7.132, describing the current to a metal electrode recessed in a resist layer, the nonlinear diffusion contribution increases with decreasing radius r but decreases with increasing resist thickness, L. High-aspect-ratio features consequently will plate slower than low-aspect-ratio features. Moreover, the consumption of hydrogen ions in the high-aspect-ratio features during electroplating causes the pH to increase locally. Because no intense agitation is possible in these crevices, an isolating layer of metal hydroxide might form, preventing further metal deposition. This all contributes to make the deposition rate, important for economical production, much slower than the rates expected from the linear diffusion model for the current density in large, low-aspect-ratio structures.

The treatise of electroplating in micropatterned resists is important for both micromachining and the IC industry. We cover the topic of electroplating in microstructures in Volume II, Chapter 8 on electrochemical-based forming. Additional reading on this topic is suggested (e.g., Masuko et al.,[24] Dukovic,[25] and Leyendecker et al.[26]).

Scaling in Electrochemistry/Summary

Potentiometric devices such as ISEs or ISFETs (see examples in the following section) measure a

voltage and are scaling invariant (voltage is an intrinsic parameter). Amperometric devices, on the other hand, measure a current and are scaling-sensitive (current is an extrinsic parameter). Miniaturization efforts have gone predominantly into the miniaturization of potentiometric devices, although more benefits can be derived from miniaturizing amperometric ones.[16] Scaling of amperometric detector electrodes was addressed in the preceding section. Here we summarize several benefits that derive from miniaturization of amperometric detectors, including higher sensitivity and the possibility of measuring in solutions with higher resistivity. Closely spaced ultramicroelectrodes (UMEs) are highly efficient in collecting electrogenerated species, and the high mass transfer rate makes it possible to experiment with shorter time scales. Nonlinear diffusion effects in amperometric microelectrodes lead to improved sensitivities for sensors with electrode dimensions of a size comparable to the diffusion layer thickness. To compensate for the decrease of the overall absolute current level, an array of microelectrodes is used. Using an array of microelectrodes in a thin, chamber-like configuration could further enhance sensitivity.

Other electrochemical devices such as batteries, as we discuss in Volume III, Chapter 9 on power in miniature devices, scale disadvantageously as the battery capacity is based on its volume.

Example Electroanalytical Devices

Potentiometric Sensors

Ion-Sensitive Field-Effect Transistors, Extended Gate Field-Effect Transistors, and Isn't FET The cable (signal line) connecting an ion-sensitive electrode (ISE) to a high-impedance voltmeter is typically about 1 m long. Because the electrical impedance of a sensor goes up as its size goes down, noise for MEMS- and NEMS-based ISEs with long signal lines is often intolerably high (this is a special problem in hospital settings that constitute an electronically very noisy environment). Integrating the ISE membrane directly onto the gate of a metal oxide semiconductor field-effect transistor (MOSFET) reduces the signal line to practically zero. This arrangement is known as an *ion-sensitive field-effect transistor* (ISFET). Pieter Bergveld invented the ISFET in 1970 at the University of Twente, Enschede, the Netherlands.[27] The operation of ISFETs, also called *CHEMFETS* (chemically sensitive FETs), and the technical and fundamental problems associated with their construction and use, were treated in detail by Madou et al.[16] and will only be summarized here. The structure of the ISFET is essentially a MOS transistor rendered ion-sensitive by eliminating its metal gate electrode to expose the gate insulator either directly to a solution or by putting an ISE membrane on top of the dielectric to interface with the solution (Figure 7.72). In the MOSFET, the metallic gate electrode controls the drain-source current, I_{ds}, through the external voltage, V_{gs}. The metallic gate electrode is insulated from both drain and source by a thin silicon dioxide layer and controls the magnitude of drain-source current electrostatically (see Chapter 4). The only difference between the electrical circuits of a MOSFET and an ISFET is the replacement of the metal gate electrode of the MOS transistor by a series combination of a reference electrode, electrolyte, and a chemically sensitive gate insulator or gate with an ion-selective membrane on top (Figure 7.73). As we saw earlier, insulators do not support any electron exchange at the interface with the solution, but hydroxyl groups at the surface ionize and are charged differently depending on the value of the pH of the surrounding solution. This electrostatic charge influences the drain-source current of the transistor.

The pH sensitivity of an insulator normally cannot be measured because a thick insulator has too high an impedance. A voltmeter, measuring the voltage between an insulator and a reference electrode, would go in overload. Typical dielectric gate materials used as pH sensors are very thin films of Al_2O_3, Ta_2O_5, and Si_3N_4 (even this dielectric has plenty of –OH surface groups in an aqueous medium). With these pH-sensitive thin-film dielectric gate materials immersed in a solution, the hydrogen ion concentration in solution influences the drain-source current, I_{ds}. The reason is that the dielectric is so thin that a substantial electric field across it can influence the magnitude of the drain-source current just as a gate voltage on the metal electrode in a MOSFET would. In an actual ISFET, the drain current value is kept

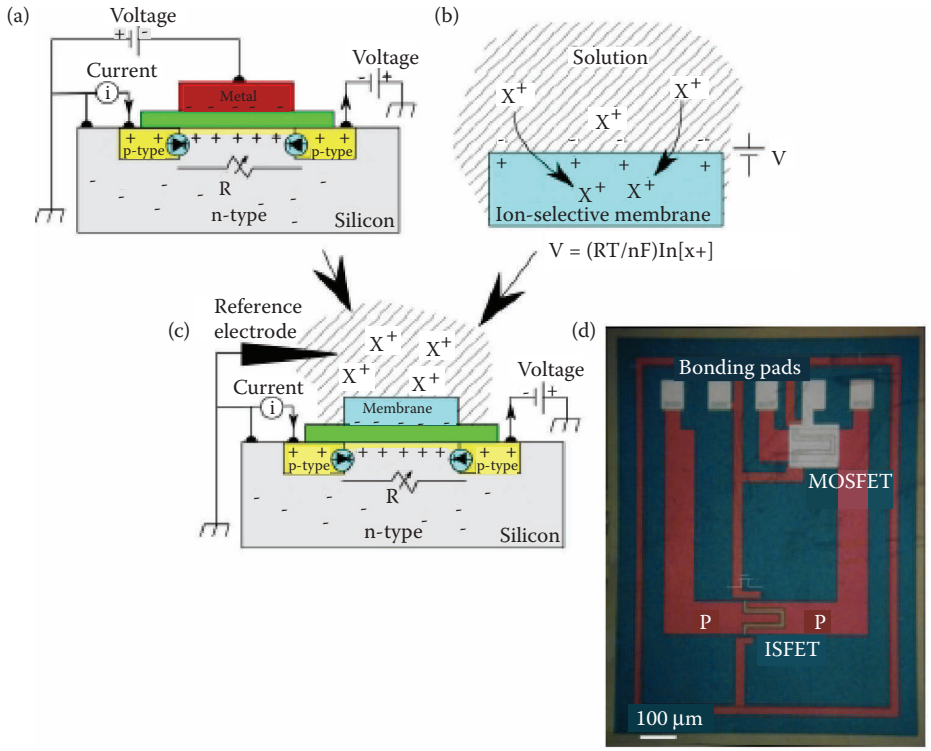

FIGURE 7.72 (a) Classical MOSFET. (b) Ion-selective membrane (ISE) for cation X^+ produces a Nernstian response. (c) Metal gate is replaced by the ion-selective membrane. (d) ISFET device (reference electrode not shown). A differential measurement between the ISFET and an on-board MOSFET helps reduce drift.

constant by means of electronic feedback, and if the pH value of the solution changes, the potential of the gate changes, and, therefore, also the drain current.

Besides using gate dielectrics directly, any of the membranes discussed above may be deposited on top of the gate dielectric.

Three important lessons were learned from working with ISFETs.

1. NEED FOR A REFERENCE ELECTRODE. In the early ISFET days, it was erroneously believed that an ISFET could work without the reference electrode (REF E). Early devices had been found to operate without them. However, it was later discovered that this was an effect caused by leaky SiO_2 gate oxides, and that provided a current return path, which, for reliable operation, should be provided via the REF E.[16] Although a FET device relates a signal through a dielectric via an electrical field, the countercharge of the charge built up in front of the dielectric needs to arrive somehow to the other plate of the capacitor, and this is only possible if a current return path is provided.
2. DEBYE SHIELDING. If a charged group is attached to a long chain (spacer arm) extending from the gate insulator, say, at a distance d into the solution, that charge may be neutralized by counterions in solution, diminishing the surface potential. The higher the ionic strength of the solution, the more the charge will be shielded. This is illustrated in Figure 7.74, where we consider a film with 4′-nitrobenzo-18-crown-6 ether groups on spacer arms. Calculated curves

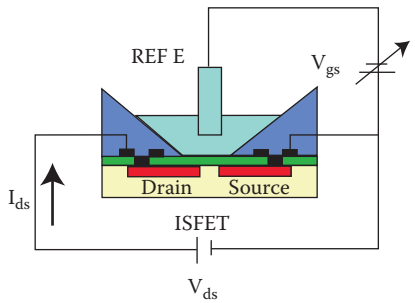

FIGURE 7.73 ISFET operation. Ions do not have to pass through the ion-sensitive membrane. The membrane's control of the drain-source current is solely based on electrostatic effects.

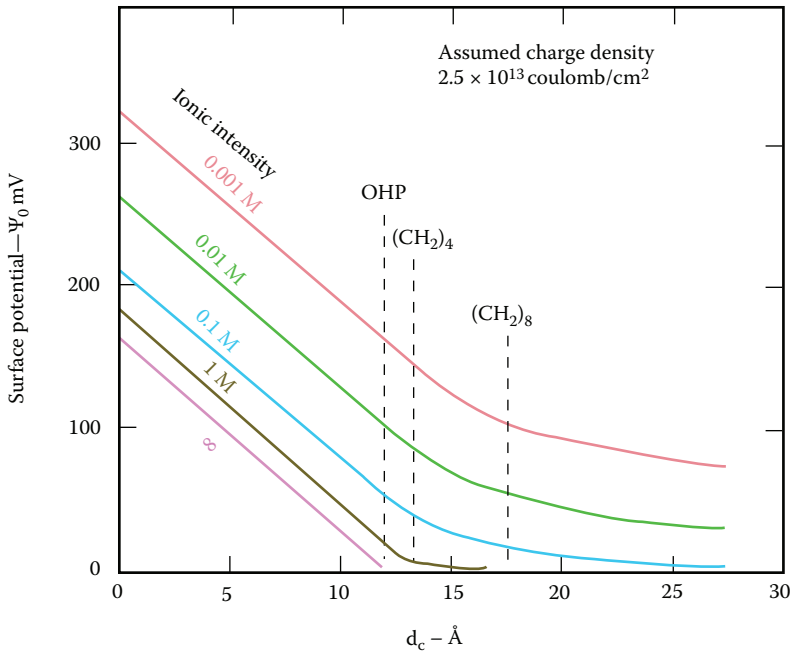

FIGURE 7.74 Calculated surface potential versus chain length d_c. Charges on spacer arms are shielded by ions from solution. This might make the signal of a large charged molecule ionic strength-dependent. (Matsuo, T., and H. Nakajima. 1984. Characteristics of reference electrodes using a polymer gate, ISFET. *Sensors Actuators* 5:293.[28])

of surface potential versus spacer chain length (d_c) by Matsuo and Nakajima[28] are shown. It can be seen that at the highest concentration of the indifferent electrolyte in the solution (∞), the surface potential becomes zero when charged centers extend all the way to the OHP or beyond. This observation is extremely important for the construction of derivatized FET devices. Obviously, sensitivity will be lost if the charge groups are big; sensitivity will depend on the ionic strength of the analyte solution. Attempts to build immunologically sensitive FET devices are hampered by this effect. Moreover, smaller charged molecules can go between the large forest of proteins on the surface and set up a mixed potential at the FET surface. Furthermore, the nonavailability of perfectly polarizable electrodes, nonselective protein interactions with the electrode, and the influence of pH and ionic strength (through Debye shielding) all make the prospect of developing selective and sensitive direct potentiometric or capacitive immunosensors rather dim.

3. IC COMPATIBILITY AND DRIFT. After more than 37 years, ISFETs are still plagued with at least four critical problems. 1) Putting a very high-impedance FET in a conductive solution requires tremendous care in packaging the device; 2) implementing a true reference electrode with a Luggin capillary and a sufficient amount of REF E to survive for an extended period, is very difficult to implement in a CMOS-compatible technology; 3) even a modest-size REF E renders the ISFET large, and the hope for IC miniaturization benefits are lost; and 4) the membranes in an ISFET have no internal electrolyte to fix the Donnan potential on the inside of the membrane. As a consequence, the drift of an ISFET is typically large compared with that of an ISE. A differential measurement between the ISFET and an on-board MOSFET as illustrated in Figure 7.72d does not help reduce this drift source. The on-board reference MOSFET only reduces solid-state-based drift sources.

Most sensor experts have come to appreciate that for chemical sensors, one should only implement on-board electronics if it is absolutely essential for the integrity of the signal. The extended

gate field effect transistor (EGFET) device was conceived to avoid some of the problems associated with the leakage problems of an ISFET.[29] By depositing the ISE membranes a short distance away on conducting lines extending from the FET gates, encapsulation is made easier, and the sensors are light-insensitive. The EGFET seemed like an elegant solution at the time (Figure 7.75), but i-STAT (now Abbott), a commercial entity selling blood electrolyte analysis equipment, eliminated all on-board electronics and abandoned the EGFET approach after extensive research.

For multiuse electrochemical reference electrodes, thick hydrogel films with a large capacity to store reference solution are preferred for long-term stability, and for electrochemical sensor electrodes, thick ion-selective membranes are better at preventing pinholes. Consequently, optimized chemical sensor materials end up much thicker than the common IC electronics layers and are more easily prepared with thick-film technology. An additional reason for the slow commercialization of silicon-based electrochemical sensors is that the currently available electrochemical and chemical sensing technologies are multiuse, proven, and cost-effective. Usually, it is simpler and less expensive to build electrochemistry on a nonsilicon substrate (see Volume III, Figure 1.19).

NOTE: During a 37-year period, we went from a long-signal line (e.g., 1 m long) of a large-sized ISE to a zero signal line in an ISFET. In an EGFET, the signal line was extended back to about 100 μm, but with the latest hybrid ISEs, built on plastic substrates, the signal lengths are again from a couple of millimeters to 1 cm long. In other words, we went from ISEs to ISFETs to something that is not even a FET anymore (Isn't FET!). Hopefully, this lesson will be taken at heart in the development of nano-FETs and nanowires.

Potentiometric Immunosensors

From Immunoassays to Immunosensors Immunoassays, introduced in the late 1950s, constitute a major class of medical diagnostic tests that, along with DNA probes, have become an established tool

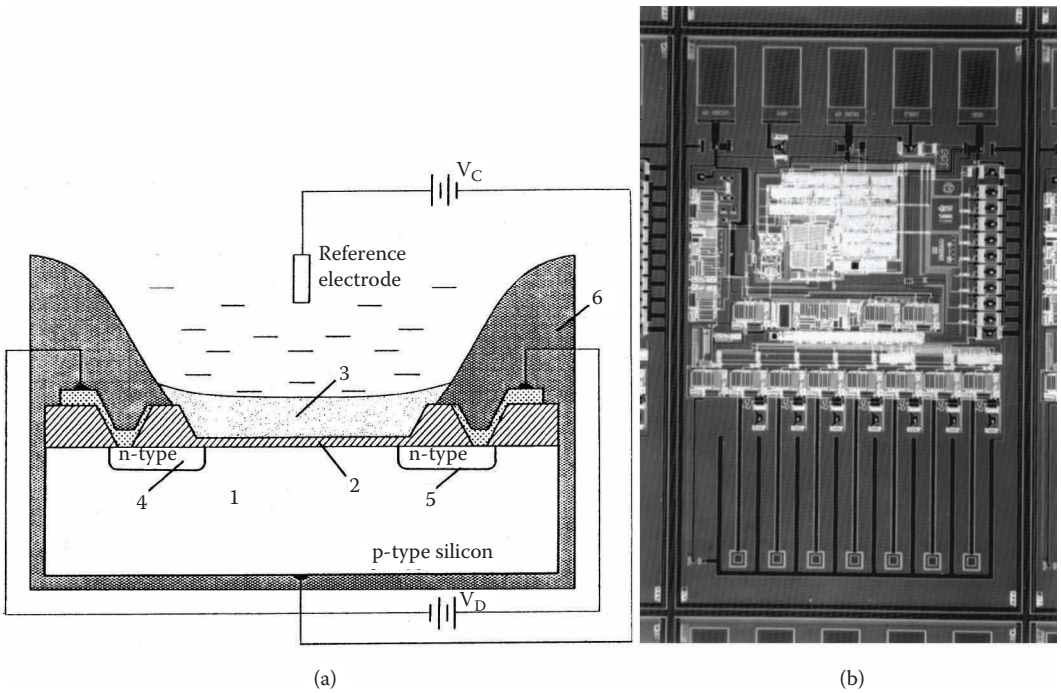

FIGURE 7.75 Integration of chemical-sensitive material and FETs. (a) Chemistry layers on the gate of the FET: ion-sensitive field effect transistor (ISFET). Si substrate (1), insulator (2), chemically sensitive membrane (3), source (4), drain (5), and insulating encapsulant (6). The rectangular pads on top are the contact pads.

in analyzing clinically important analytes. Immunoassays are used to detect hormones, vitamins, metabolites, diagnostic markers for therapeutic drug monitoring, and diagnostic procedures for detecting infections. Clinical analytes, as we can learn from Volume III, Figure 10.49, are often present in extremely low concentrations (e.g., 0.1 ng/mL).

The immunoassay principle is based on the use of antibodies (Ab) and a signal-generating irreversible chemical reaction of an antibody with an antigen (Ag, the analyte). The irreversibility of the reaction stems from the large association constants (*Ka*) involved in the antigen-antibody binding; typical values range between 10^5 and 10^9 M^{-1}. The antigen-antibody association constants are composed of large forward (k_1) and small reverse (k_{-1}) rates. These kinetic parameters make antibodies very selective for the analyte of interest but also make the binding irreversible. In fact, "reversible" immunosensors have been developed with lower *Ka*'s to allow for repeated measurements. The ability of natural cells to monitor biochemical events is mimicked in immunoassays. Therefore, these assays constitute the ultimate in selectivity and sensitivity. The utility of antibodies for detecting and isolating antigens can hardly be overstated, given the wide spectrum of extremely powerful antibody applications developed over the years. The use of antibodies is further enhanced by their relative stability in various chemical modification reactions that alter the antibody structure without destroying their capacity to bind to antigens. The two major configurations for immunoassays are 1) solid-phase/heterogeneous assays (often in microtiter plate wells) that require immobilization and separation steps, and 2) solution-phase/homogeneous assays that only involve mixing and measuring.

The binding event for an immunoassay may be sensed directly or via a label; the latter is the more common approach. For example, in an enzyme-linked immunosorbent assay (ELISA), developed in 1971, immunochemical affinity is relied on for selectivity and chemical amplification of an enzyme label for sensitivity. In an ELISA, the enzyme label on the bound Ab-Ag, in the presence of its substrate, generates a reaction product that is measurable (e.g., with GOx as the enzyme and glucose as its substrate, hydrogen peroxide is produced, which may be detected electrochemically). In a typical procedure, titer wells are coated with antibody and known quantities of antigen-containing patient sample, and labeled antigens (e.g., with GOx enzyme) are incubated in the titer wells until the antigen-antibody reaction is complete. Washing removes the unbound antigens, and adding substrate (glucose in the example case) to the bound antigen leads to an electrochemical active reaction product (H_2O_2 in this case). A crucial step is the removal of unbound and nonselectively bound antigens. This is achieved by binding the antibodies to a solid surface, such as a microtiter well surface. Antigens bound to the fixed antibodies remain stuck to the solid surface, whereas washing and decanting removes unbound and nonselective bound antigens. One appreciates that one can either detect the antigen or the antibody in an immunoassay.

The assay illustrated in Figure 7.76 is a competitive electrochemical assay, with native antigen

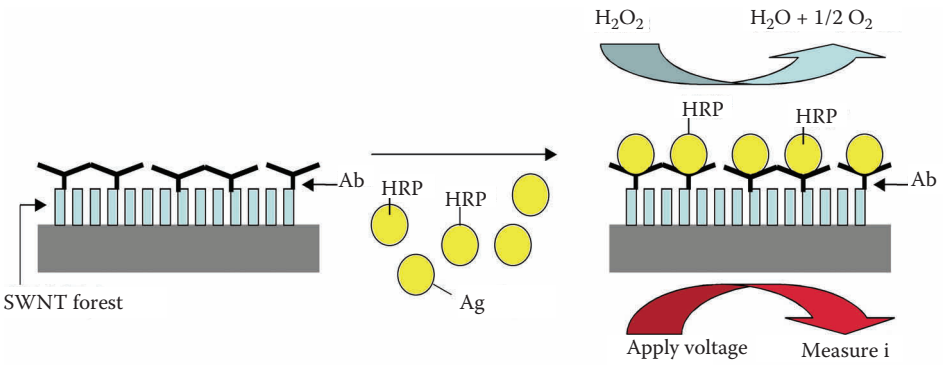

FIGURE 7.76 Enzyme-linked immunosorbent assay (ELISA). Antibody is bound to a forest of single-wall nanotubes. The current is inversely proportional to the amount of nonlabeled antigen (Ag; i.e., native antigen); antigen was prebound on antibody (Ab). Applying a voltage enables one to measure a current proportional to the amount of oxygen.

competing with labeled antigen for reaction sites on a solid surface. The solid surface in the example consists of a forest of single-wall carbon nanotubes (SWNTs) with antibody bound to it. An electrode of SWNTs has the potential of leading to higher sensitivity. The label on the antigen we use in this example of an ELISA is the enzyme horseradish peroxidase (HRP), which converts peroxide to oxygen and water. After competitive binding of the native and labeled antigen on the solid surface and washing off of unbound antigen, the substrate of the HRP enzyme, hydrogen peroxide, is added. The HRP converts hydrogen peroxide to oxygen, which diffuses to the SWNT electrode surface. Current *i* measures the amount of oxygen at the electrode with an applied potential E. The more native species (analyte in the patient's blood), the more effective the competition with labeled species and the lower the resulting signal (less oxygen means less native antigen). Frustratingly, this means that the less native species (analyte), the higher the signal, and vice versa.

In Figure 7.77, an alternative noncompetitive or sandwich assay is illustrated we again use an electrochemical antigen-measuring system, for example). The SWNT forest is coated first with a suitable antibody (Ab1), and a patient sample containing the antigen (Ag; analyte) is then added and incubated until the antigen-antibody reaction is complete. A washing step removes unbound antigen, and a second antibody (Ab2) labeled with enzyme is added and incubated until the antigen binds with this second antibody. A new wash removes the unbound labeled antibody, whereas adding substrate for the enzyme (hydrogen peroxide) leads again to a measurable reaction product.

Antibodies/antigens have also been chemically tagged with fluorescent, magnetic, radioactive (e.g., ^{125}I,^{14}C,^{3}H), and other assorted compounds, called *reporters* or *labels*, as a way of facilitating antigen or antibody detection or isolation under a variety of experimental conditions. Different types of immunoassays include Western blotting, agglutination, precipitation, radioimmunoassay (RIA), enzyme-linked immunosorbent assay (ELISA), bioluminescent immunoassay, homogeneous immunoassay, magnetic particle immunoassay, immunofluorescence, and flow cytometry assay. Typical sensitivities in microgram per milliliter for various immunoassays are listed in Table 7.16.

A major problem introduced through the use of most labeling techniques is that a separation step is the only possible way to differentiate between free and bound labeled species because both contribute to the signal. An assay involving such a separation step is called a *heterogeneous assay*. These assays are simpler to develop but somewhat more complicated to perform. A homogeneous assay, in contrast, requires no separation because the signal-producing reaction is affected in some way by the binding of the antigen to the antibody without interference from the unbound species.

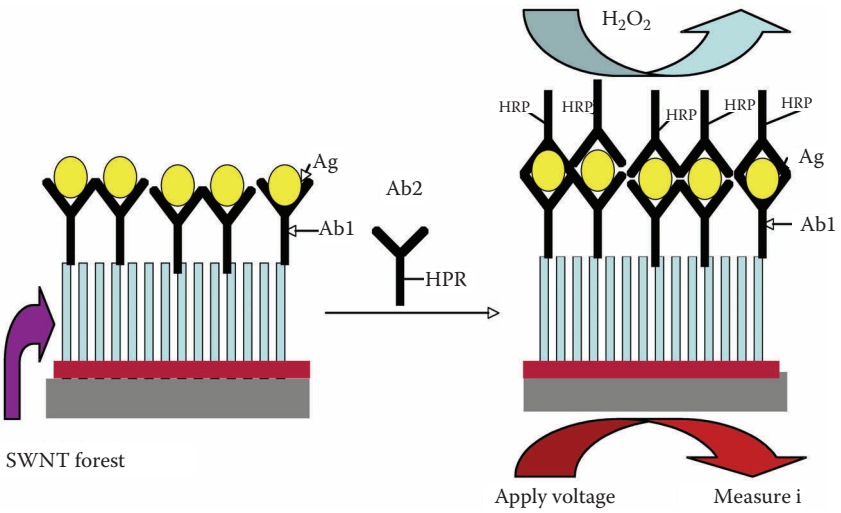

FIGURE 7.77 Noncompetitive assay or sandwich assay.

Table 7.16 Sensitivity of Various Immunoassays

Assay	Sensitivity* (μg antibody/mL)
Precipitation reaction in fluids	20–200
Precipitation reaction in gels	
Mancini radial immunodiffusion	10–50
Ouchterlony double immunodiffusion	20–200
Immunoelectrophoresis	20–200
Rocket electrophoresis	2
Agglutination reactions	
Direct	0.3
Passive agglutination	0.006–0.06
Agglutination inhibition	0.006–0.06
Radioimmunoassay	0.0006–0.006
Enzyme-linked immunosorbent assay (ELISA)	<0.0001–0.01
ELISA using chemiluminescence	<0.0001–0.01†
Immunofluorescence	1.0
Flow cytometry	0.06–0.006

*The sensitivity depends on the affinity of the antibody and the epitope density and distribution.
†Note that the sensitivity of the chemiluminescence-based ELISA assays can be made to match that of a radioimmunoassay.

Ideally, the assay and its accompanying instrumentation should not require a label, and detection thereof, to ascertain the binding of any type of biological affinity pair. It should also be inexpensive, easy to use, and compact. The latter assays are called *direct binding* or *label-less assays*. They continue to be a topic of intense research.

An immunosensor is a sensor monitoring either an antigen or an antibody based on the selective binding of antigen-antibody pairs. The interest in immunosensing is to adapt the above-described assays (Figures 7.76 and 7.77) into a sensor format and to make measurements by simply bringing the sample in contact with the sensor. Our interest here is to explore how micromachining could help this cause. It is especially challenging to develop a homogeneous immunosensor where a washing step is not required. Micromachining might result in a microinstrument, perhaps with some microfluidics flushing the unbound species from the sensor surface. Better yet, micromachining might open the road to label-less detection, as demonstrated with the static cantilever approach for DNA SNP detection in Example 4.1.

Several difficulties still must be overcome in immunosensors, such as assays involving too many steps to qualify as sensors, the deposition of uniform protein coatings, unselective protein adsorption, distinguishing between bound and unbound antigen, and the inherent irreversibility of immunosensors.

Micromachined Potentiometric Immunosensors

We highlight a few developments here to illustrate how new detection schemes and micromachining techniques affect the commercialization of immunosensing. For a more detailed review on immunosensors with commercial potential, we refer to Buerk,[30] Madou et al.,[31] and the March/April 2000 issue of *Fresenius' Journal of Analytical Chemistry*.[32]

Early on, immunosensor work was geared toward direct detection of antigens or antibodies with potentiometric techniques, that is, by simply measuring a voltage. Antigen-antibody binding on the surface of a potentiometric-sensing electrode leads to a new charge distribution. In principle, this redistribution of charges should be measurable. The effect of direct binding on the potential of a sensing electrode was observed on polymeric membrane-coated electrodes, as well as on metal electrodes. However, the signal was found to be small (1–5 mV), making the precision of the measurement poor.[33] Also, ISFETs (see above) have been attempted as one special embodiment of potentiometric devices, and several "immunoFETs" were made in laboratories around the world.[34] Unfortunately, as Janata et al.[35,36] concluded, the potential changes on potentiometric devices are caused by a mixed potential generated from the antigen-antibody binding, as well as other charge transfer reactions occurring at the electrode surface/electrolyte interface. To make a potentiometric sensor work, Janata et al. pointed out that a substrate surface with an infinitely high-charge transfer resistance is needed, as only then will protein charges exclusively account for the potential generated. Such a perfect polarizable surface has yet to be identified (see Figure 7.43). Not even densely packed Langmuir-Blodgett films qualify because they do not block all current across the interface.[37] In Figure 7.78A, an "immunoFET" is schematically shown with a membrane (perhaps

a Langmuir-Blodgett film) and attached antibody molecules.

An alternative, direct-measuring immunosensor is the capacitive affinity sensor (Figure 7.78B). This immunosensor is based on the capacitance change associated with the antigen-antibody binding between an insulated pair of interdigitated electrodes on a dielectric surface. The capacitance change arises because the antibody, a large molecule with a small dielectric constant, displaces water with a high dielectric constant. Again, as with the potentiometric sensor, unless a perfect polarizable interface (i.e., a perfect stacking of only the antigen-antibody complexes at the capacitor surface) is realized, capacitive changes cannot unequivocally be associated with the reaction of interest. Along this line, Interuniversity Microelectronics Centre (IMEC, in Leuven, Belgium) is developing capacitive biosensors that allow for the detection of affinity binding of biomolecules (e.g., antigens,

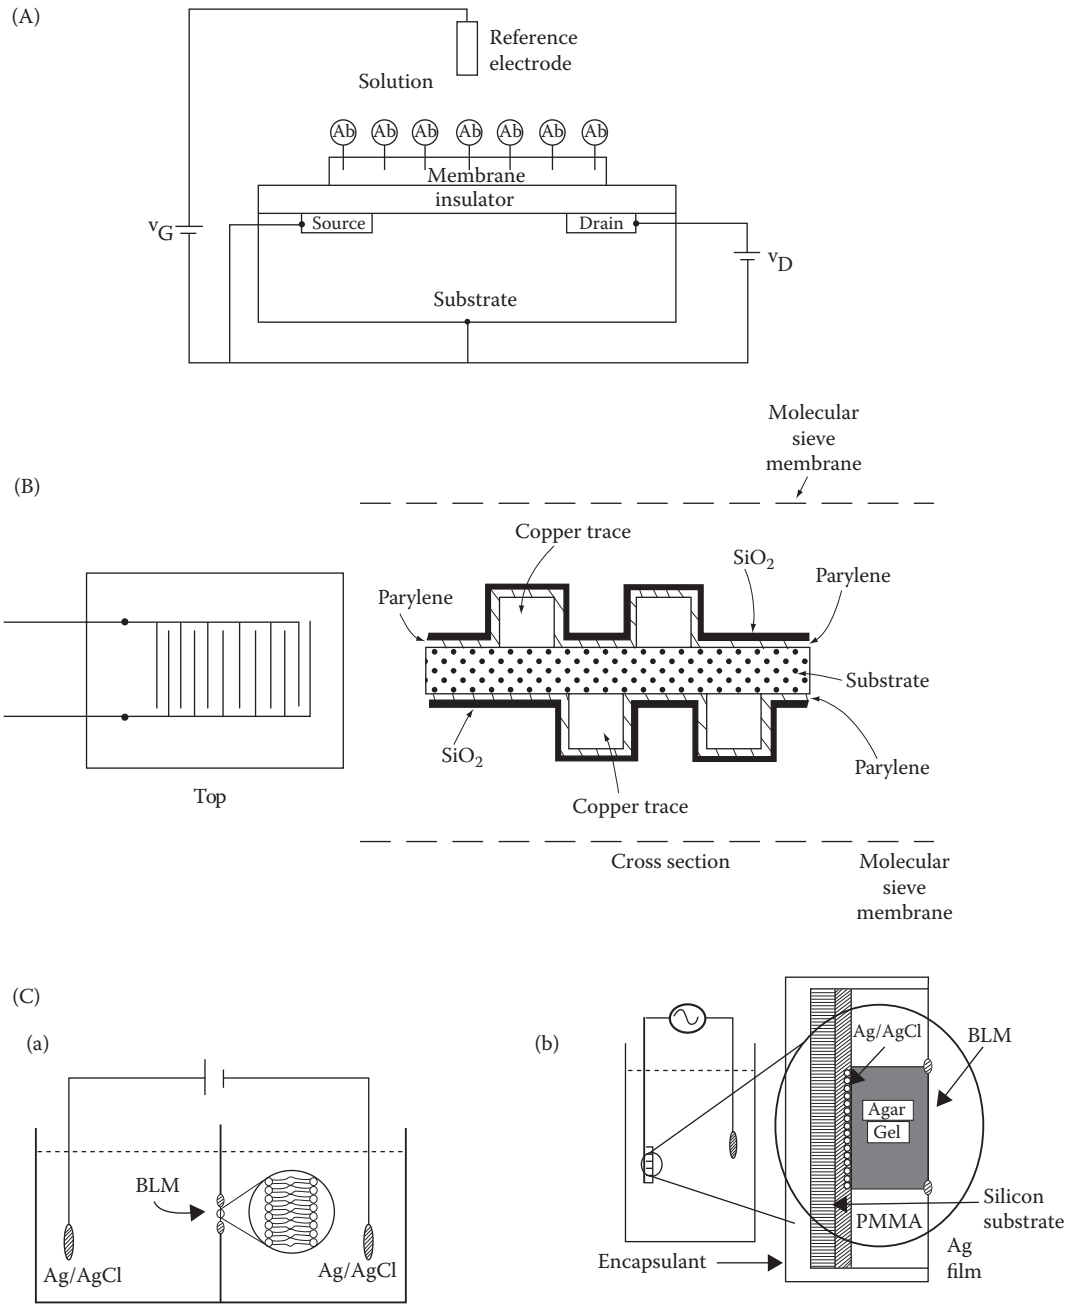

FIGURE 7.78 Schematic diagram of an immunoFET (A). Examples of micromachined, direct immunosensors (B). (C) Lipid membrane suspended in a pinhole (a) and more robust Langmuir-Blodgett lipid layer deposited on a hydrogel (b). See text.

DNA). The presence of DNA sequences or antigen-antibody binding can be detected by looking for impedance changes between closely spaced pairs of electrodes, as sketched in Figure 7.79 (http://www.wtec.org/loyola/mcc/mems_eu/Pages/Chapter-5.html). Nanoscaled interdigitated electrode arrays, as shown here, are made with deep UV lithography. Electrode widths and spacings from 500 nm to 250 nm are produced on a dielectric substrate (0.5 mm × 1 mm). In Figure 7.78Ca, a lipid membrane is suspended in a pinhole between two water reservoirs. Upon exposure to certain analytes, a current across the membrane is observed. This very brittle configuration is rendered a little bit more robust by depositing a thin Langmuir-Blodgett lipid film on a hydrogel as shown in Figure 7.78Cb.

The nonexistence of perfectly polarizable electrodes, nonselective protein interactions with the electrode, and the influence of pH and ionic strength (through Debye shielding) make the prospect of developing selective and sensitive direct potentiometric or capacitive immunosensors rather dim.

Amperometric Sensors

Glucose Sensor The amperometric glucose sensor we are using as a commercial example is a second-generation (see page 571 "Electron Tunneling Transfer Rate k_t," for a discussion of three generations of glucose sensors), disposable glucose sensor strip for diabetes management that relies on an electron acceptor (mediator) to establish electrical communication between the redox center in the glucose oxidase (GOx) enzyme and the electrode. This MediSense/Abbott sensor, the Precision QID, is shown in Figure 7.80. The sensor consists basically of a two-electrode system with counter and reference electrodes combined in a Ag/AgCl electrode. Blood is sufficiently conductive, and the sensor works in the diffusion-limited regime; thus, there is no need for a real reference electrode that is expensive to implement. The working electrode is made of carbon. A second, dummy working electrode has a mediator, but no enzyme for background correction; the mediator used is carboxy-ferrocene. A differential current measurement between the two working electrodes makes for more precise measurement of the additional ferrocene generated in regeneration of the FAD (see Figure 7.60, bottom). All films are silk-screened onto a PVC substrate. Single sensors are less than $0.50 each.

Amperometric Immunosensor A one-step amperometric immunosensor developed by this author and his coworkers is shown in Figure 7.81. The approach combines the fundamentals of enzyme immunoassay, electrochemistry, and gel filtration.[38] All the components necessary for the assay are incorporated into the sensor; only the sample has to be added for analysis. The base of the sensor consists of working and reference electrodes deposited onto an appropriate substrate. To make the components as cheaply as possible, one may use thick-film technology on a

plastic substrate. Layered onto the electrode surface is a mixture of an inactive apoenzyme (apo-GOx), an enzyme substrate (glucose in case the enzyme is GOx), and a mediator—reagents necessary to generate an electrical signal. Above the apoenzyme matrix, there is a wettable gel containing the antibody specific for the analyte of interest, topped with a layer of analyte labeled with a prosthetic group or cofactor capable of activating the apoenzyme. A drop of sample placed on the surface of the sensor immediately hydrates the sensor with a fixed volume dictated by the total volume of hydrogel in the device. Sample analyte and cofactor-labeled analyte compete for a limiting amount of immobilized antibody in layer 1. The amount of cofactor-labeled analyte that diffuses to the apoenzyme layer is directly proportional to the concentration of sample analyte. If the sample does not contain antigen, the labeled antigen remains firmly bound to the antibody layer and will not be able to activate the apoenzyme. Activation of apoenzyme by cofactor-labeled analyte results in catalytic breakdown of the enzyme substrate. Reduction or oxidation of one of the reaction products results in a current proportional to the amount of apoenzyme activated, and thus to the concentration of analyte in the sample. The working electrode detects a product of the enzyme reaction with the substrate in an amperometric mode. Using theophylline for analyte and apo-GOx as an inactive enzyme that FAD renders active demonstrates this simple, easy to use, and quantitative immunodiagnostic system. The principle of the new assay is generic and may be applicable to the development of sensors for a variety of analytes with biomedical interest. The detection limit of the FAD/apo-GOx system is well below 10^{-10} M, adequate for the analysis of a majority of analytes. This detection limit can be reduced further by optimization of the system. A further challenge is to find ways of reproducibly layering the different organic materials shown in Figure 7.81. This challenge does not concern Si micromachining but rather involves learning how to manufacture and manipulate hydrogel materials.

Optical Spectroscopy

Quantum Mechanics in Spectroscopy

Optical spectroscopy is the study of the interaction between matter and light. By measuring and

TABLE 7.17 The Energy of the Electromagnetic Radiation Determines the Type of Interaction with Matter

EM Radiation	Interaction Type	Energy/ Mole	Energy/ Photon
γ-rays	Nuclear transitions	10^{7} kJ/mole	10^{-14} J/photon
x-rays	Core e^-	10^{6} kJ/mole	10^{-16} J/photon
Ultraviolet	Valence e^-	10^{3} kJ/mole	10^{-18} J/photon
Visible	Valence e^-	10^{2} kJ/mole	10^{-19} J/photon
Infrared	Molecular vibrations	10^{1} kJ/mole	10^{-20} J/photon
Microwave	Molecular rotations	10^{-2} kJ/mole	10^{-22} J/photon
Radio	Nuclear spin	10^{-4} kJ/mole	10^{-24} J/photon

quantifying that interaction, it becomes an analytical technique that can be used to identify (wavelength) and quantify (intensity) the constituents in a sample. When electromagnetic energy is applied to matter, it can be absorbed, emitted, transmitted, or induce chemical changes (reactions). The precise mode of interaction depends on the energy of the electromagnetic radiation involved, as illustrated in Figure 5.2 and Table 7.17. From quantum mechanics (Chapter 3), we know that particles are restricted to fixed energy levels: molecules can only rotate and vibrate at certain frequencies, and electrons in atoms can only move at certain velocities. Quantum numbers define the electronic, vibrational, and rotational states of a species. These quantum numbers are obtained from the Schrödinger equation, the solution to which is a wavefunction (ψ) describing these states. As a consequence, molecules absorb energy as quanta (photons with energy E = hν) based on criteria specific to each molecular structure. This is what makes the absorption process selective to specific wavelengths of the electromagnetic spectrum ($E = hc/\lambda$, with c the velocity of light at 2.9972×10^{10} cm/s). Molecular rotation involves an entire molecule moving, and the energy change, ΔE, involved is very small (~0.1 kcal/mol). Bond vibrations involve a few nuclei moving, and ΔE is therefore larger (~1–10 kcal/mol), whereas electronic states involve an electron moving out of its bonding orbital, with ΔE the largest among the three (~100 kcal/mol). It is normally the electron spin angular momentum, the orbital angular momentum, and the symmetry properties of the two wavefunctions (initial and final state) that determine whether an energy transition is allowed or forbidden. The feasibility of a transition is given by selection rules in terms of the quantum numbers of the states involved.

UV/VIS Absorption Spectroscopy

Absorption is the most widely used spectroscopic technique because most materials absorb electromagnetic radiation. Absorption of a photon increases the energy of a molecule from a ground state to an excited state (Figure 7.82a). When a molecule emits light, the energy level of the molecule is decreased (Figure 7.82b). The total energy of a molecule is the sum of electronic, vibrational, rotational, translational, and spin orientation energies, some of which are sketched in Figure 7.83. The mechanism of absorption of radiation energy is different in each case; however, the fundamental process is the absorption of a certain amount of energy. Valence electrons are excited in UV/VIS (PHz) spectroscopy, whereas more energetic x-rays excite core electrons in x-ray spectroscopy, and gamma rays (EHz) induce nuclear transitions in Mössbauer spectroscopy. At lower energies, radiofrequencies (MHz) involve the nuclear spin in nuclear magnetic resonance (NMR); microwaves (GHz) involve electron spin and are used in electron spin resonance; and in microwave spectroscopy, molecular rotations are probed. Infrared (THz) excites molecular vibrations and is relied on in IR and Raman spectroscopy.

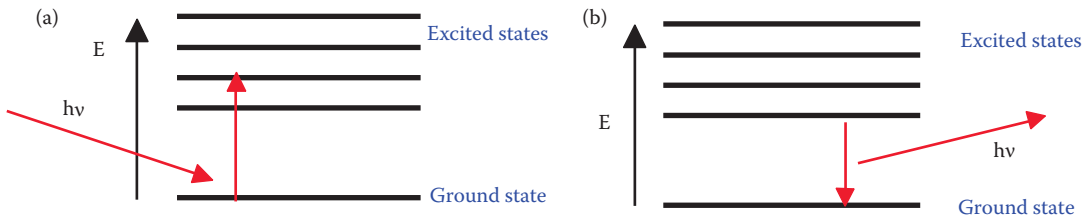

FIGURE 7.82 Absorption of a photon (a) and emission of a photon (b).

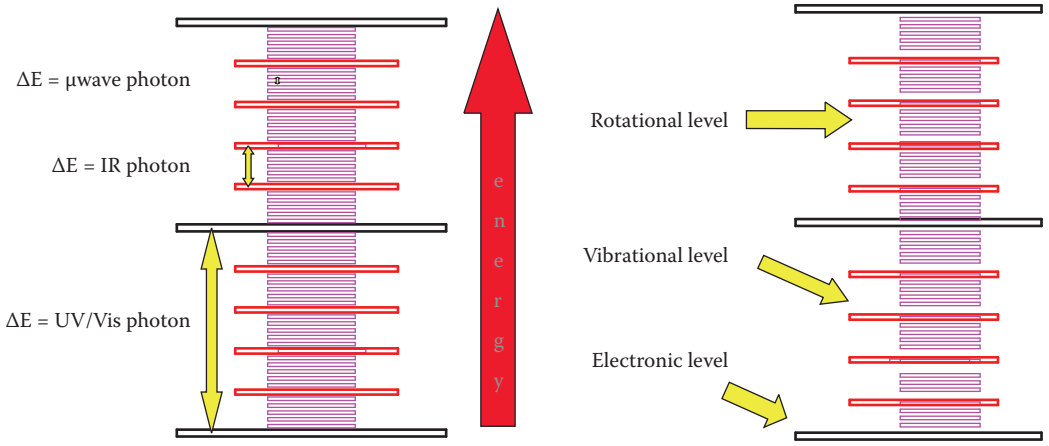

FIGURE 7.83 The total energy of a molecule is the sum of electronic, vibrational, rotational, translational, and spin orientation energies, some of which are sketched here.

Let us focus for a moment on the absorbance, *A*, of visible or UV light (from 160–780 nm) by a solution containing absorbing molecules. Groups of atoms that are responsible for color or pigmentation are called *chromophores*. They come with characteristic optical absorptions and usually contain alternating single and double bonds (such as in aromatic rings). The transmittance of light, *T*, through the solution is given as $T = P/P_0$, with P_0 the incoming light intensity (i.e., *P* at x = 0) and *P* the light leaving the absorbing medium (e.g., at x = b) (see Figure 7.84). Transmittance *T* has values between 0 and 1 and is independent of P_0. The absorbance may also be expressed as $A = \log(P_0/P) = -\log T$. Absorbance or optical density is given by Beer's law (also Beer-Lambert law):

$$A = \varepsilon bc \tag{7.133}$$

where ε is the molar absorptivity or absorption coefficient (wavelength-dependent but also a function of solvent, ionic strength, temperature, and pressure): absorbance of a solution when b = 1 cm and c = 1 M. The molar absorptivity or molar extinction coefficient has units of $M^{-1}\,cm^{-1}$ if *b* is in centimeters and *c* is M. The extinction coefficient of a chemical species at a given wavelength is a measure of how strongly the species absorbs and refers to a single wavelength, usually the absorption maximum. Additionally, *c* is the molar concentration, and *b* is the distance into the absorbing medium (optical path length typically 1 cm).

Equation 7.133 can be derived as follows. In a solution element *dx*, the intensity of the incoming light, *P*, is decreased by *dP* because of absorption. With *dP* given by:

$$dP = -Pc\beta dx \tag{7.134}$$

where c = molar concentration
P = light intensity
β = probability of a photon being absorbed

We can rewrite Equation 7.134 as $dP/P = -c\beta dx$ or:

$$\int_{P_0}^{P} \frac{dP}{P} = -c\beta \int_0^b dx \quad \text{or} \quad \ln P - \ln P_0 = -c\beta x \tag{7.135}$$

where P_0 is the value of *P* at x = 0. In other words:

$$\ln \frac{P_0}{P} = c\beta b = 2.303 \log \frac{P_0}{P} \tag{7.136}$$

The latter expression can be rewritten in the familiar format:

$$A = \log \frac{P_0}{P} = \frac{\beta}{2.303} cb = \varepsilon cb \tag{7.137}$$

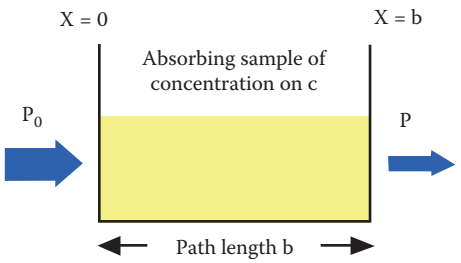

FIGURE 7.84 Absorbance of visible light in a solution of concentration c.

The lowest energy transition (and the most often observed in UV/VIS spectroscopy) is typically that of an electron going from the highest occupied molecular orbit (HOMO) to the lowest occupied molecular orbit (LUMO). For any bond (pair of electrons) in a molecule, the molecular orbitals are a mixture of the two contributing atomic orbitals; for every bonding orbital "created" from this mixing (σ, π), there is a corresponding antibonding orbital of symmetrically higher energy (σ*, π*) (see Chapter 3 and Figure 7.85). The lowest energy-occupying orbitals are typically the σ orbitals; likewise, the corresponding antibonding σ* orbitals are of the highest energy. The π orbitals are of somewhat higher energy than σ orbitals, and their complementary antibonding orbitals are somewhat lower in energy than σ*. Unshared electron pairs lie at the energy of the original atomic orbital, shown as n in Figure 7.85. Most often this energy is higher than π or σ (because no bond is formed, there is no lowering of the energy for *n*).

Electronic absorption spectroscopy of molecules usually measures $\pi \rightarrow \pi^*$ and $n \rightarrow \pi^*$ transitions. Even if the incoming light has the correct energy (i.e., the frequency is exactly right) for an optical transition, not much may happen if a selection rule is broken, i.e., the specific transition is forbidden. However, selection rules are rarely absolute, and in practice even forbidden transitions can still occur (especially in solution), but such transitions will usually have low intensities. For example, $n \rightarrow \pi^*$ electronic transitions are "forbidden" (so they are inefficient), whereas $\pi \rightarrow \pi^*$ electronic transitions are "allowed" (so they are very efficient). The *n* orbitals do not overlap well with the π* orbital, so the probability of this excitation is small.

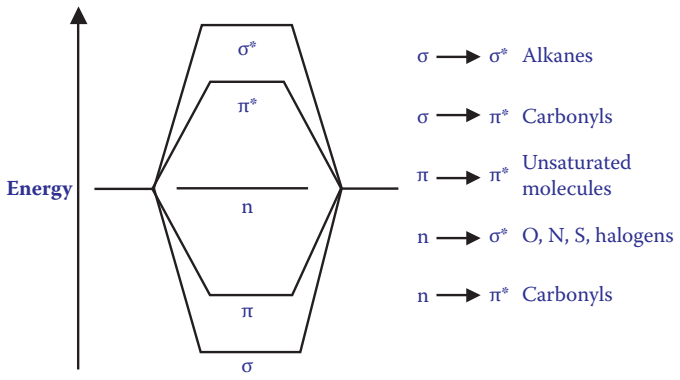

FIGURE 7.85 Electronic transitions in UV spectroscopy with example molecules.

Molar absorptivities, ε, are very large for strongly absorbing chromophores, with ε > 10,000 M^{-1} cm^{-1}; a weak chromophore is one with ε = 10–100 M^{-1} cm^{-1}. The magnitude of ε reflects both the size of the chromophore and the probability that light of a given wavelength will be absorbed when it strikes the chromophore. A general equation stating this relationship may be written as follows: $\varepsilon = 0.87 \times 10^{20}$ *Ta*, where *T* is the transition probability (0–1) and *a* is the chromophore area in square centimeters. Chromophores are typically about 10 Å long; therefore, a transition of T = 1 will have an ε of 10^5.

Absorption measurements are widely applicable but offer only medium sensitivity in the 10^{-4}–10^{-5} M range. Optimization of the measurement procedure can extend the range to 10^{-6} M or even 10^{-7} M. Selectivity is only moderate, and separation before measurement is often required.

Standard absorption spectrometers are shown schematically in Figure 7.86. Light sources are tungsten-halogen (visible) and hydrogen or deuterium discharge (UV) lamps; a typical monochromator is a Czerny-Turner, and detectors are photomultiplier tubes (PMT) or diode arrays (which are less sensitive than PMTs but allow for faster spectral scanning).

Light intensity passing through the sample is measured directly in the path of the incoming light. In the system depicted in Figure 7.86a (a so-called

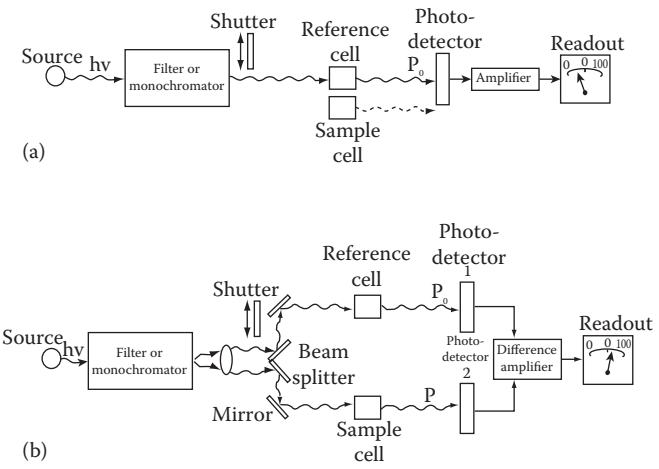

FIGURE 7.86 Two types of optical absorption spectrometers. In the system depicted in (a), the user has to switch sample and reference cell. The system in (b), using a beam splitter, accomplishes the referencing automatically.

single-beam instrument), the user has to switch between sample and reference cell manually. Spectra of absorbing species and solvent are additive. Therefore, one takes the spectrum of a blank solution and subtracts this spectrum from that of the sample solution. The measurement setup in Figure 7.86b is a double-beam system, where a beam splitter accomplishes this referencing automatically. After passing through a monochromator, a light beam splits into two beams; one goes to the sample and the other one to the reference. The beams pass to each photodetector at alternate times by virtue of a chopper. Double-beam instruments compensate for all but very short-term electrical fluctuations because measuring P_0 and P is made almost simultaneously. When many wavelengths must be measured, double beam is a time saver. A single beam is simpler and easier to maintain and is used for quantitative analysis at a single wavelength because it is cheaper.

A fiberoptic-based absorption measurement instrument is very useful when the sample cannot be placed in a cuvette, for example, in a flowing solution or in a 96-well plate reader.

IR and Raman Spectroscopy

The above analysis focused on UV and visible light absorption spectroscopy. A few words about IR absorption and Raman spectroscopy follow. As discussed in Chapter 5, IR absorption and Raman are complementary techniques based on vibrational transitions. They are not used much for quantitative work (their detection limits are not very good) and are most useful for the identification of molecules. As such, they are more often used in studies of structure and conformation of complex molecules. In Raman spectroscopy one measures the frequency (wavelength) change of the incident radiation through inelastic scattering with molecules in a wide range of wavelengths (not only those corresponding to vibrational levels). Scattered light under these circumstances reveals satellite lines below and above the Rayleigh scattering peak at the incident frequency. Raman scattering depends on the polarizability of the scattering molecules (see Chapter 5).

In IR absorption spectroscopy one measures the absorption of the IR radiation at any specific wavelength that matches (in energy) a vibrational transition of the molecule. If the selection rules for optical transitions were all the same for IR and Raman, the peak intensity may be different, but the energy shifts observed in Raman spectra should be identical to the energies of its IR absorption. However, IR absorption selection rules require that a vibrational mode of the molecule have a change in dipole moment or charge distribution associated with it. For example, homonuclear molecules, N_2, Cl_2, and H_2, are not IR active, but they are Raman active because the polarizability of the bond varies periodically in phase with the stretching vibrations. Thus, IR and Raman differ with regard to which vibrational energy transitions are active as a result of selection rules. Some important advantages of Raman over IR are as follows. First, sample preparation for Raman is easy: water is an excellent solvent for Raman, but it is a serious interference for IR absorption. Also, Raman spectra can be measured with normal transparent sample holders like glass or quartz, whereas IR measurement requires KBr or other atmospherically unstable window materials. Moreover, because Raman can also involve rotational or electronic transitions of the molecules from which the scattering occurs, a much wider range of energy sources can be used (to interact with the electronic, vibrational, and rotational energies of molecules as calculated in Chapter 3). Raman intensity increases with the fourth power of the frequency of the source (see Chapter 5, Equation 5.261), and a high Raman peak intensity can be obtained by using a short wavelength laser source.

Photodecomposition of samples may be avoided by using red or near-infrared irradiation sources, such as a diode laser (782 or 830 nm) or a neodymium-doped/yttrium aluminium garnet (Nd-YAG) laser (1064 nm). Higher-temperature studies are possible in Raman spectrometry because IR radiation at higher temperature does not affect the measurement; this would interfere with IR spectroscopy, but Raman spectrometry measures the shift (energy difference). On the other hand, IR is better than Raman for measuring molecules with a highly asymmetrical charge distribution and has a lower detection limit than Raman [except when comparing with surface-enhanced Raman spectroscopy (SERS); see Chapter 5]. Also, Raman must use much more

intense sources than IR to get a measurable signal, and IR instruments are also much cheaper.

Many variations of powerful Raman spectroscopy have been developed, such as surface-enhanced Raman spectroscopy (SERS), where surface plasmons of Ag or Au surfaces or nanoparticles are excited by a laser. The resulting electric fields cause nearby molecules to become Raman active, resulting in an amplification of their detection by a factor up to 10^{11}! This effect was originally observed by Fleischmann[39] and was explained by Van Dyune in 1977.[40] Surface plasmon resonance (SPR) and SERS were discussed in Chapter 5.

Scaling in Absorption Spectroscopy and Cavity Ring-Down Spectroscopy

From Beer's law, optical absorption of any type of wavelength through a material scales poorly in the microdomain because it depends on the path length b (see Equation 7.133). Therefore, miniaturization of the absorption path length always decreases the sensitivity! This is unfortunate because besides being the most generic optical spectroscopic method (all molecules absorb electromagnetic radiation at some frequency), the intrinsic molecular cross-sections are typically largest for absorption (compared with any other optical technique, such as fluorescence).

To miniaturize an absorption spectrometer without losing sensitivity, the optical absorption path can be folded and put on a small footprint by bouncing the light from a set of mirrors. Although an improvement, the reflectivity of the mirrors limits the maximum number of bounces typically to about 100, thereby limiting the ultimate total optical path length, and thus the sensitivity of the miniaturized instrument. The best alternative absorption method, originally devised for use in the visible, UV, and infrared spectra, was developed during the 1980s by O'Keefe[41] at Stanford University and later by Saykally[42] at the University of California, Berkeley and Meijer[43] at the University of Nijmegen. This new method is the so-called *cavity ring-down spectroscopy* (CRDS), a highly sensitive method for absorption spectroscopy using pulsed lasers. It can be viewed as a multipass technique affording 10–1000 times longer path lengths than traditional multipass reflection cells. The problem in conventional multipass approaches lies in the requirement for the light beam to traverse distinct paths for each pass. In CRDS one does not take measure of the absorbed signal strength for a given distinct sample path, but instead measures the time rate of absorption of a sample located within a closed optical cavity.

In CRDS, the time required for a laser pulse to decay inside an optical cavity, also termed an *optical resonator*, formed from two highly reflective dielectric plano-concave mirrors, is measured.

A schematic is shown in Figure 7.87. In this setup, pulsed laser radiation enters the cavity through the first mirror, M1, and makes a number of round trips (n) between the mirrors.

The mirrors are ultrasmooth surfaces with ~0.05 nm rms surface roughness and may feature a reflectivity R = 0.99999 in the visible part of the spectrum. The intensity of the laser pulse trapped between the two mirrors decays exponentially with time at a rate determined by the round-trip loss experienced by the laser pulse (Figure 7.88).

The round-trip time is controlled by the cavity length L, and at each bounce on the second mirror M2, some light leaks from the cavity and is detected at a photomultiplier (PMT). For a 1-m cavity, the round-trip time is 6.7 ns. The intensity of the light pulse in the cavity decays exponentially

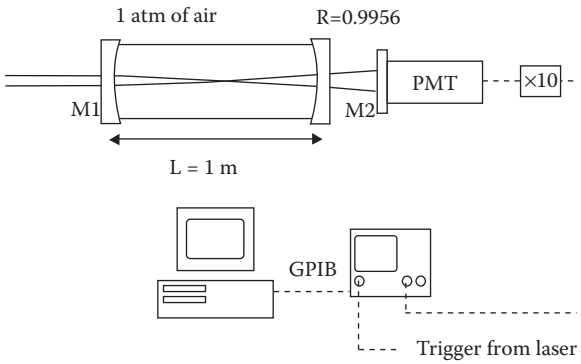

FIGURE 7.87 CRDS, a typical experimental setup. Pulsed narrow band radiation from a tunable (dye) laser system is introduced in the ring-down cavity formed by two plano-concave mirrors (M1 and M2). The mirrors are coated for optimum reflectivity in the desired wavelength range. To ensure that all transverse modes are detected with equal probability, the photomultiplier tube (PMT) that is used to measure the ring-down transients is placed directly behind the output mirror (M2).

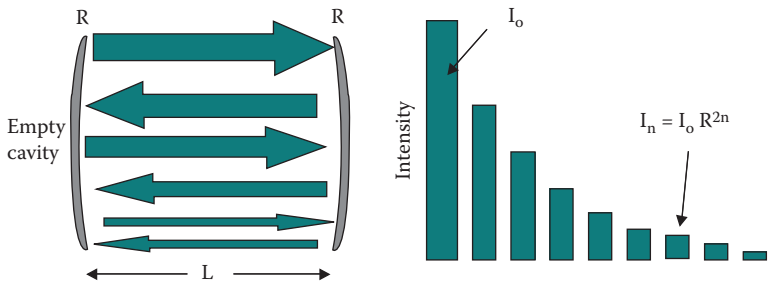

FIGURE 7.88 Decay of light intensity of the laser pulse as a function of the number of round-trips (*n*).

and is characterized by a ring-down lifetime, τ, or the time it takes the intensity to decrease to 1/*e* of its initial value. For mirror reflectivities of 99.99%, the ring-down time is on the order of 30 μs, during which time the pulse has made 5000 round trips for a total path length of 10 km. The decay curve is fit to a single exponential function to determine the ring-down time constant. In the case of an empty absorption cell (i.e., ε = 0), the decay time or ring-down time is approximately given by:

$$\tau_0 = \frac{L}{c\,|\ln(R)|} \cong \frac{L}{c(1-R)} \qquad (7.138)$$

where L = absorption cell length (longest distance between the mirrors)
R = reflectivity of the optical cavity mirrors
c = speed of light

With the absorption cell filled, one obtains:

$$\tau = \frac{L}{c(1-R+\varepsilon L)} \qquad (7.139)$$

with ε equal to the Beer's law absorption coefficient of a sample in the cavity.

Two intensity decay curves for an empty and filled optical resonance cavity are compared in Figure 7.89.

From Equations 7.138 and 7.139 we can derive the absorption coefficient as:

$$\varepsilon = \frac{1}{c}\left(\frac{1}{\tau} - \frac{1}{\tau_0}\right) \qquad (7.140)$$

Typically the ring-down time can be determined with a relative accuracy of 10^{-3}. With a mirror reflectivity loss of $(1 - R) = 10^{-4}$, this implies that line-integrated absorption coefficients of better than 10^{-7} (absorption coefficients less than 10^{-9} cm^{-1} in a 1-m cavity) can be measured. In comparison, conventional absorption experiments can only measure absorption coefficients of 10^{-6} cm^{-1}. The effective sample path lengths in CRDS may be in the tens of kilometers, and the method is in principle intensity-independent. Clever setups that exploit variations in CRDS (e.g., measuring monolayers instead of bulk gas adsorption) are being investigated; see, for example, Pipino et al.[44,45] CRDS has been performed in a large spectral region, from the UV (200 nm) to the infrared (10 mm), almost without gaps. A large variety of molecules have been studied, including radicals, ions, clusters, and even molecules in the solid phase. It is a type of spectroscopy that can be applied in many environments, e.g., open air, cells, jets, supersonic expansions, discharges, and flames. Thus far, no MEMS research group has tackled a micromachined CRDS. This is not too surprising given the difficulty of microfabricating highly reflective dielectric plano-concave mirrors. Lithography-based MEMS are typically very good at making projected shapes, but they are not so good at making truly 3D surfaces as required here.

Luminescence

Introduction

Luminescence is the emission of light by an atom or molecule. In the case of photoluminescence, the first step in the process is the absorption of a photon, but in chemiluminescence, the light emission is caused by a chemical reaction in which chemical energy is converted into light energy. Bioluminescence is a type of chemiluminescence where the production and emission of light in a living organism are the results of a chemical reaction. We also make a distinction between stimulated emission and spontaneous emission. In stimulated emission, an excited species interacts with the incoming oscillating electric field and gives up its energy to the incident radiation. Stimulated emission, as we saw in Chapter 5, is an essential part of laser action. In spontaneous emission, the excited species gives up its energy of its own accord. Fluorescence, phosphorescence, and chemiluminescence are all spontaneous emission processes.

Photoluminescence

Fluorescence and Jablonski Diagrams Photoluminescent processes are divided into fluorescence and phosphorescence. The difference between fluorescence and phosphorescence is best illustrated in an electronic state diagram or Jablonski diagram as shown in Figure 7.90. Electronic transitions responsible for absorption spectra give rise to singlet and triplet states, and hence create fluorescence and phosphorescence, respectively. In the singlet state, electrons spin in the ground and excited states are paired, creating a net spin of zero. In the triplet state, the electron spins in the ground and excited states are not paired, so there is a net spin (Figure 7.91). Fluorescence does not involve change in spin (the transition is spin allowed) and is short lived (10^{-9}–10^{-6} s).

On the other hand, phosphorescence involves a change in electron spin and is long lived (10^{-3}–100 s) (Figure 7.92). Although it is forbidden, it still happens but with a low probability. The lifetime of an excited molecule depends on how the molecule disposes of the extra energy. Because of the uncertainty principle, the more rapidly the energy is changing, the less precisely we can define the energy (see Chapter 3). Therefore, long-lived excited states have narrower absorption peaks, and short-lived excited states have broader absorption peaks.

The blue lines in Figure 7.90 are radiative processes: absorption (1), fluorescence (2), and phosphorescence (3). The red lines are nonradiative processes: vibrational relaxation or deactivation (4), intersystem crossing to triplet state from a singlet state (5), and internal conversion (6). When a fluorophore, a small molecule, or a part of a larger molecule that can be excited by light to emit fluorescence absorbs a photon from an incandescent lamp or a laser, an excited electronic singlet state might result. This excited state exists for a finite time (typically 10^{-10}–10^{-9} s), during which the fluorophore undergoes conformational changes and is subject to interactions with its molecular environment. These processes have two important consequences. First,

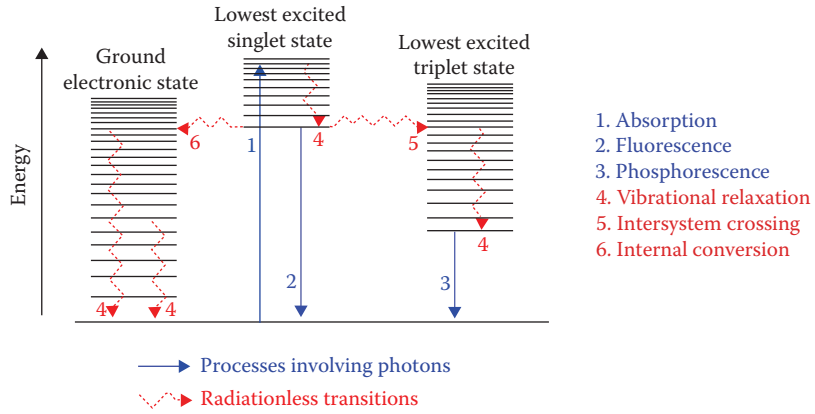

FIGURE 7.90 Electronic state diagram or Jablonski diagram.

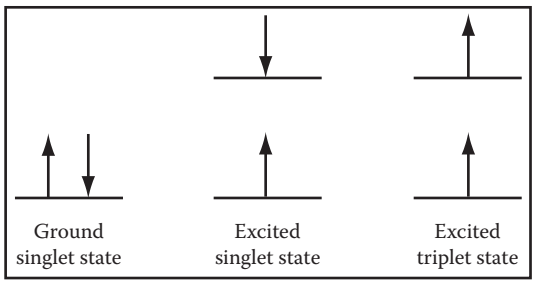

FIGURE 7.91 Singlet ground state and excited singlet and triplet states.

the energy of the excited singlet state is partially dissipated, yielding a more relaxed singlet state from which fluorescence originates. Second, not all the molecules initially excited by absorption return to the ground state by fluorescence emission (i.e., there is a certain limited yield to the process). Other processes such as collisional quenching, Förster resonance energy transfer (FRET) (see 7.147), and intersystem crossing (Figure 7.90, red line 5) may also depopulate the excited singlet state.

George Stokes, professor of mathematics and physics at Cambridge University, interpreted the light-emitting phenomena described here. He formulated the law that fluorescent light is of longer wavelength than the exciting light in 1852 (Stokes law or the Stokes shift), coining the term "fluorescence" instead of the earlier-used term "internal dispersion" in 1853. Stokes law is illustrated in Figure 7.93.

A photon that is absorbed by a molecule does not merely kick that molecule into a higher energetic state, but the molecule also acquires some vibrational energy. It was Franck-Condon who recognized that the photon absorption process is instantaneous, with the rearrangement of almost inertia-free electrons (10^{-16} s) being extremely fast (10^{-16} s) and nuclear motions much slower (10^{-13} s). Nuclear motions are negligible during the time required for an electronic excitation. Because the nucleus does not move during the excitation, the most probable electronic transitions are vertical transitions. In Figure 7.93, the energy diagrams show the potential energy of a molecule as a function of the distance between the nuclei, and according to the Franck-Condon principle, excitation is represented by a vertical arrow. This vertical arrow hits the upper curve not at its lowest point (corresponding to a nonvibrating state), but somewhere higher. After absorbing a photon, the molecule finds itself in a nonequilibrium state and begins to vibrate, lowering the potential energy of the molecule in a radiation-free manner. When the molecule fluoresces, the light originates from near the bottom of the upper potential curve and follows a vertical arrow down until it strikes the lower potential curve. The emission arrow does not

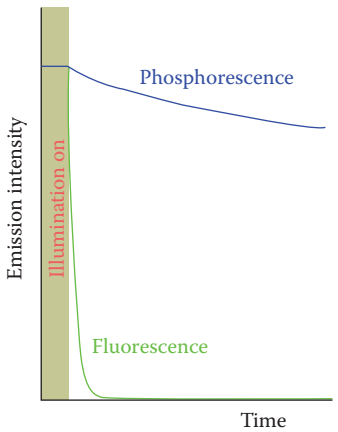

FIGURE 7.92 Decay of phosphorescence and fluorescence.

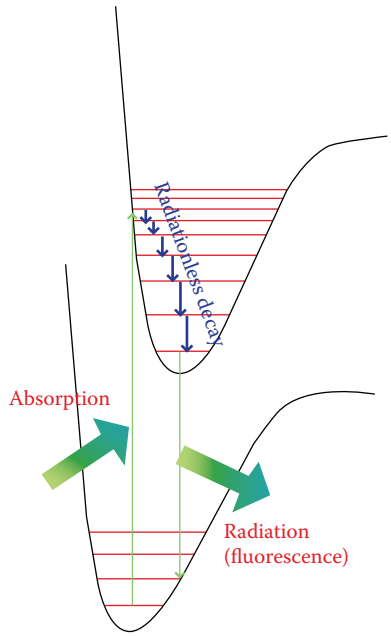

FIGURE 7.93 Stokes law illustrated: fluorescence is at a longer wavelength than absorption. These energy diagrams show the potential energy of a molecule as a function of the distance between the nuclei and, according to the Franck-Condon principle, excitation is represented by a vertical arrow.

strike the lower curve at its deepest point, so again, some excitation energy gets converted into vibrational energy. Because of energy dissipation during the excited state lifetime, the energy of the emitted photon is lower and therefore is of longer wavelength than the excitation photon. This difference in energy or wavelength is called the *Stokes shift*. The Stokes shift is fundamental to the sensitivity of fluorescence techniques because it allows emission photons to be detected against a low background, isolated from excitation photons. There is approximate mirror symmetry between the fluorescence and absorption bands when the shapes of the potential curves in the ground state and the excited state are similar.

The fluorescence quantum yield, which is the ratio of the number of fluorescence photons emitted to the number of photons absorbed, is a measure of the relative extent to which these processes occur. Mathematically, the fluorescence quantum yield is expressed as:

$$\Phi = \frac{\text{Number of emitted photons}}{\text{Number of absorbed photons}} \qquad (7.141)$$

For a highly fluorescent molecule, such as fluorescein, $\phi = 1$, and for a nonfluorescent molecule, $\phi = 0$. The quantum yield can also be defined in terms of various rate constants in the Jablonski diagram. This is shown for a simple system in Figure 7.94, where k_r is the radiative pathway and k_{nr} is the nonradiative pathway:

$$\phi = \frac{k_r}{k_r + k_{nr}} \leq 1 \qquad (7.142)$$

The fluorescence lifetime, τ, is the time delay between the absorbance and the emission and is given by:

$$\tau = \frac{1}{k_r + k_{nr}} \qquad (7.143)$$

Whereas emission of fluorescence occurs in all directions, only the photons emitted at a 90° angle to the incident radiation are monitored to avoid interference from transmitted photons. This is shown schematically in Figure 7.95. An excitation monochromator selects λ_{ex}, the λ of light that the molecule absorbs, and the emission monochromator selects λ_{em}, one of the λ of light emitted by the molecule. Fluorescence detection sensitivity may be severely compromised by background signals, which may originate from endogenous components used in the sample or sample holder (referred to as *autofluorescence*, perhaps of the plastic substrate) or from unbound or nonspecifically fluorescent bound probes (referred to as *reagent background*).

There are many types of fluorescent measuring techniques used in biotechnology. Fluorescence microscopes resolve fluorescence as a function of spatial coordinates in two or three dimensions for microscopic objects (<0.1-mm diameter). Flow cytometers measure fluorescence per cell in a flowing stream, allowing subpopulations within a large sample to be identified, quantitated, and sorted. Flow cytometry involves the use of a beam of laser light projected

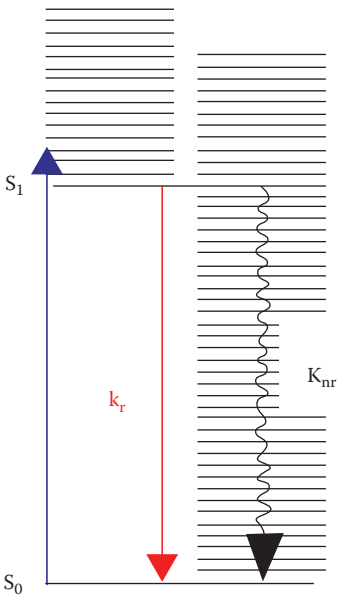

FIGURE 7.94 Simplified Jablonski diagram with rate constants for radiative (k_r) and nonradiative processes (k_{nr}).

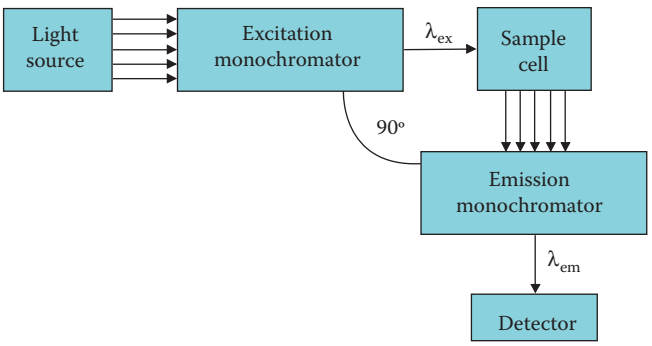

FIGURE 7.95 Simplified fluorescence measurement setup.

through a liquid stream that contains cells or other particles, which, when struck by the focused light, give off signals that are picked up by detectors. These signals are then converted for computer storage and data analysis, and can provide information about various cellular properties. Spectrofluorometers and microplate readers (Figure 7.96) measure the average properties of bulk samples (microliter to milliliter).

Fluorescence scanners resolve fluorescence as a function of spatial coordinates in two dimensions for macroscopic objects such as electrophoresis gels, blots, and chromatograms. In contemporary instruments, the excitation source is usually the 488-nm spectral line of the argon-ion laser. All these mentioned fluorescence instruments are attractive candidates for miniaturization.

Photoluminescence in Analytical Chemistry and Its Scaling Luminescence intensity F of an analytical sample is given by:

$$F = kP_0\varepsilon bc \tag{7.144}$$

where k = constant
P_0 = incident radiant power (W/m^2, also called *intensity*)
c = concentration of the analyte
ε = absorptivity of the sample
b = path length of the sample holder

Fluorescence intensity is quantitatively dependent on the same parameters as absorbance, but a major difference is that luminescence is also dependent on the number of incident photons (P_0). The expression in Equation 7.144 can be derived as follows.

FIGURE 7.96 A typical microplate (96 wells) and microplate reader: the MRX II microplate reader from Dynex.

The fluorescence emission intensity F is given by $F = K'(P_0 - P)$, with P_0 the power of the incident radiation and P the power of the radiation after traversing through a path length b of the medium. The constant K' depends on the quantum efficiency of the fluorescence and the light collection efficiency. In the case of absorption, one measures transmission (T) and determines A as a ratio of P_0 and P, whereas in the case of F, the absolute number of photons is counted. This situation provides fluorescence spectroscopy with a much lower detection limit, and is pictured in Figure 7.97.

We can write $F = K'(P_0 - P)$ as:

$$F = K'\left(P_0 - P_0 10^{-\varepsilon bc}\right) \text{ or } F = K'P_0\left(1 - 10^{-\varepsilon bc}\right) \tag{7.145}$$

Expanding the above equation as a Taylor's series, one obtains:

$$F = K'P_0\left(2.303\varepsilon bc - \frac{(2.303\varepsilon bc)^2}{2!} + \frac{(2.303\varepsilon bc)^3}{3!} + \right) \tag{7.146}$$

If $\varepsilon bc \le 0.05$, then $10^{-\varepsilon bc} \sim 1\text{–}2.3\varepsilon bc$, in which case Equation 7.145 reduces to Equation 7.144 because $F = K'\ P_0\ 2.3\varepsilon bc$ or $F = kP_0\varepsilon bc$.

According to Equation 7.144, fluorescence scales with path length in the same way absorption does. Thus, in theory, both scale poorly into the microdomain, but in the case of fluorescence, we can turn up the number of incoming photons to increase the signal. Therefore, lasers are typically used for excitation because of their higher photon flux, but one needs to be careful about sample decomposition (photobleaching). The lower limit of detection with fluorescence is frequently 10 times better than with absorption measurements, and it is also more specific and less susceptible to interferences because fewer materials absorb and also emit light. Furthermore, fluorescent molecules have different lifetimes, so that the emission from a shorter-lifetime fluorescent interferent might be left to decay before the species of interest is measured (letting the background die out). The concentration detection range is very wide with a reach of three to six decades. With fluorescence, 2–10% accuracy is common because many issues affect the quantum efficiency, ϕ.

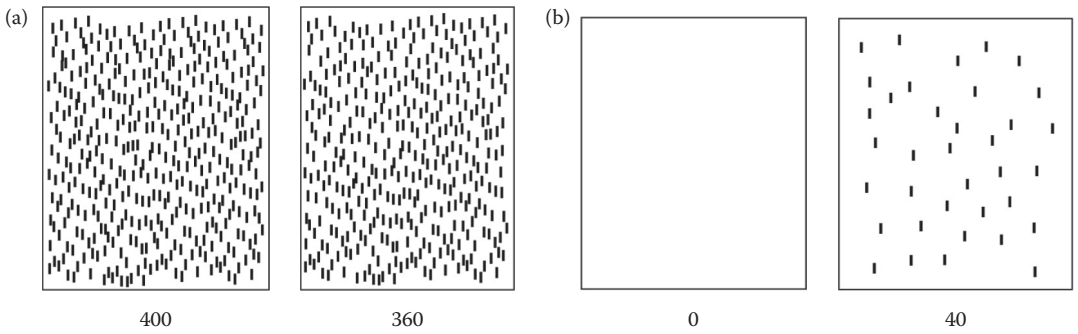

FIGURE 7.97 In absorbance spectroscopy the number of incoming and outgoing photons at the same wavelength are compared (a); in fluorescence the number of emitted photons are counted (b).

Fluorophores, Quantum Dots, and Fluorescent Proteins

Fluorophores A fluorophore is a small molecule, or a part of a larger molecule, that can be excited by light to emit fluorescence by absorbing a photon from an incandescent lamp or a laser. William Perkin, an English chemist, synthesized a coal-tar dye, aniline purple (the first synthetic dye, also known as *mauve* and *mauveine*), in 1856. His breakthrough attracted the attention of numerous synthetic chemists, and a variety of dyes were synthesized soon afterward. Perkin is acknowledged as the founder of the synthetic dye industry. Adolph von Baeyer, a German chemist, synthesized the well-known fluorescent dye fluorescein in 1871 (see Figure 7.98), and Paul Ehrlich, a German bacteriologist, used the fluorescent dye uranin (sodium salt fluorescein) to track the pathway of secretion of aqueous humor in the eye in 1882. The latter represents the first case of the use of in vivo fluorescence in animal physiology. A fluorescent probe is a fluorophore designed to bind to a specific region of a biological structure. Fluorescent probes can be used to tag proteins, nucleotides, lipids, oligosaccharides, and other biological molecules. These fluorescence-tagged molecules may then be used, for example, to localize and monitor interesting biological processes in living cells.

The molar extinction coefficient ε (see Equation 7.133) is a direct measure of a dye's ability to absorb light. This capability is clearly important in determining the amount of light a molecule can generate via fluorescence emission. Most fluorophores in common use have molar extinction coefficients at their wavelength of maximal absorption, ranging between 5,000 and 200,000 $cm^{-1}\ M^{-1}$. The Stokes shift is the difference in wavelength between the fluorescence excitation maximum and the fluorescence emission maximum. Interestingly, dyes with large Stokes shifts tend to have relatively small extinction coefficients, whereas dyes with small Stokes shifts tend to have relatively large extinction coefficients. The fluorescence quantum yield is a measure of the efficiency with which the excited molecule is able to convert absorbed light into emitted light. It is defined as the fraction of absorbed photons that are converted into fluorescence emission (see Equation 7.141). Typical quantum yields for commonly used fluorophores range from 0.05–1.0. The wavelength of absorption of a fluorophore is related to the size of the chromophores, with smaller chromophores leading to higher energy (shorter wavelength). As we just learned, the intensity of a fluorescence measurement is related to the probability of the event and the wavelength of the absorbed light.

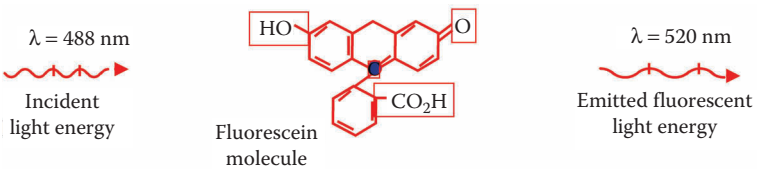

FIGURE 7.98 Fluorescein molecule.

Fluorescence is favored in molecules with structural rigidity. The quantum yields for fluorene and biphenyl, for example (see Figure 7.99), are 1 and 0.2, respectively. The increased rigidity of fluorene stabilizes the π-π* singlet state, leading to higher quantum yield. Chelation also can lead to increased fluorescence. For polyatomic molecules in solution, the discrete electronic transitions are replaced by rather broad energy spectra called the *fluorescence excitation spectrum* and *fluorescence emission spectrum*, respectively. Quantum yield of fluorescence of most molecules decreases with increasing temperature as a result of collisional deactivation of the singlet state. Solvents containing heavy atoms, such as those containing halogens, also decrease fluorescence. Heavy atoms promote intersystem crossing to the triplet state. This decreases fluorescence quantum yield but increases phosphorescence quantum yield (see below). Unless the fluorophore is irreversibly destroyed in the excited state (an important phenomenon known as *photobleaching*), the same fluorophore can be repeatedly excited and detected. Photobleaching is an irreversible photochemical process that causes a molecule to lose its fluorescent property. Countermeasures for photobleaching include the use of shorter illumination, reducing the excitation intensity, and the use of "antifade" reagents. The latter sometimes act by reducing oxygen concentration to prevent formation of singlet oxygen (see below, Reaction 7.6). However, photobleaching has also led to the development of a useful analytical method called *Fluorescence Recovery After Photobleaching* (FRAP). The FRAP method is used to measure the ability of a molecule to move around in a cell over time. A fluorophore is covalently attached to the migrant molecule, and using an epifluorescence microscope, light is focused onto a small subset of the fluorescent molecules. After initial imaging of the amount of fluorescence, a very intense light pulse is flashed onto these same molecules, causing photobleaching. When these molecules are monitored again, the bleached area will now appear dark. If the surrounding fluorescent molecules that were not photobleached are able to diffuse, they will mix with the photobleached molecules, and the dark area will slowly become bright as fluorescent molecules move into it.

Early investigations showed that many substances autofluoresce when irradiated with UV light. In the 1930s, Haitinger and others developed the technique of secondary fluorescence using fluorochrome stains to stain specific tissue components, bacteria, or other pathogens that do not autofluoresce (using acridine orange). In the early 1950s, Coons and Kaplan developed immunofluorescence using fluorescein-tagged antibodies to localize antigens in tissues. They labeled antipneumococcal antibodies with anthracine, allowing them to detect both the organism and the antibody in tissue using UV-excited, blue fluorescence. Two commonly used fluorescent dyes that are covalently bound to antibodies are fluorescein, which emits an intense green fluorescence when excited with blue light (Figure 7.98), and rhodamine, which emits a deep red fluorescence when excited with green-yellow light. Some typical fluorescent dyes are shown in Figure 7.100.

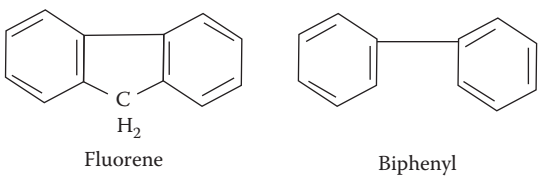

FIGURE 7.99 Fluorene and biphenyl. The fluorescence quantum yields for fluorine and biphenyl are 1 and 0.2, respectively. Fluorene has the higher rigidity and thus the higher quantum yield.

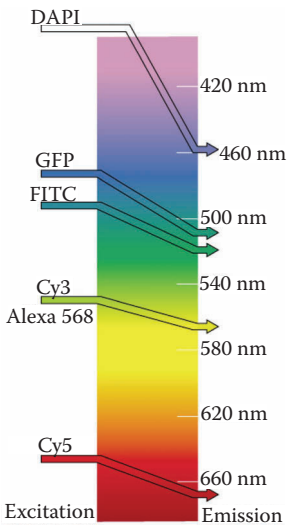

FIGURE 7.100 Typical fluorescent dyes. CY3, indotrimethinecyanines; CY5, indopentamethinecyanines; DAPI, 4′,6-diamidino-2-phenylindole; FITC, fluorescein isothiocyanate; GFP, green fluorescent protein.

Because of their particular structural nature, some fluorescent probes can bind noncovalently to special biomolecules in cells in either a specific or a nonspecific fashion. The binding can dramatically affect the fluorescence quantum yield and wavelength, which is the basis of DNA and RNA probes, protein probes, lipid probes, etc. In Table 7.18, we show some of the fluorophores that are commonly used for lighting up specific cell organelles.

Today there are fluorescent probes for almost any analyte. The binding of hydrogen or metal ions changes the electronic structure of a number of fluorophores, thus affecting the absorption properties and/or the fluorescence properties of the probes. For example, various fluorescein-labeled proteins have quantum yields in the range of 0.2–0.7 at pH 8, but drop off rapidly with decreasing pH, making a fluorescent pH probe. Certain lipophilic ester derivatives of fluorescent probes are cell membrane permeable. Cellular esterases convert these compounds into the free-acid forms of the probes, which are trapped inside the cell and are able to chelate calcium, making for good intercellular calcium probes. Fluorogenic enzyme substrates are fluorescent probes that are converted by specific enzymes into products that have either increased fluorescence or shifted spectra. These are useful probes for monitoring enzyme activities.

In fluorescence quenching, excited molecules relax to ground states via nonradiative pathways instead of fluorescence emission. Nonradiative processes include vibrational relaxation, collision with quenching molecules, and intersystem crossing. Molecular oxygen quenches by increasing the probability of intersystem crossing:

$$M^*(\text{singlet}) + O_2(\text{triplet}) \rightarrow M^*(\text{triplet}) + O_2(\text{singlet})$$

Reaction 7.6

Other typical quenchers are aliphatic and aromatic amines. Polar solvents, such as water, quench fluorescence by orienting around the excited state dipoles. Emission transfer to nonfluorescent molecules, formation of a nonfluorescent complex, aggregation forming a nonfluorescent aggregate, and emission transfer to a fluorescent molecule with an excitation wavelength equal to the emission wavelength of the first fluorescent molecule are all mechanisms that lead to quenching of the fluorescent light signal.

Förster resonance energy transfer (FRET), named after the German scientist Theodor Förster, is a radiationless energy transfer mechanism, where dipole-dipole resonance energy transfers between two chromophores. A donor chromophore in its excited state can transfer energy by a nonradiative long-range dipole-dipole coupling mechanism to an acceptor chromophore in close proximity (typically <100 Å). When both molecules are fluorescent, the term *fluorescence resonance energy transfer* is often used, although the energy is not transferred by fluorescence (there is no emission of a photon during this transfer). The phenomenon is easily detected because instead of the donor fluorescence, the emission of the acceptor is observed. The absorption spectrum of the acceptor must overlap with the fluorescence emission spectrum of the donor as shown in Figure 7.101. Donor and acceptor

Table 7.18 Specific Organelle Probes

Probe	Site	Excitation	Emission
BODIPY	Golgi	505	511
NBD	Golgi	488	525
DPH	Lipid	350	420
TMA-DPH	Lipid	350	420
Rhodamine 123	Mitochondria	488	525
DiO	Lipid	488	500
dil-Cn-(5)	Lipid	550	565
diO-Cn-(3)	Lipid	488	500

BODIPY, borate-dipyrromethene complexes; NBD, nitrobenzoxadiazole; DPH, diphenylhexatriene; TMA, trimethylammonium.

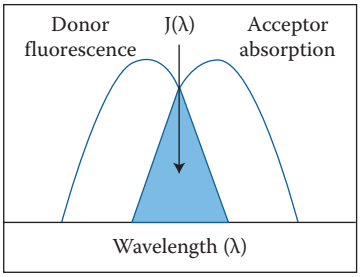

FIGURE 7.101 For fluorescence resonance energy transfer, the absorption spectrum of the acceptor must overlap the fluorescence emission spectrum of the donor. The larger the overlap J(λ), the stronger the FRET.

transition dipole orientations must be approximately parallel. As the intensity of the fluorescence of the acceptor fluorophore increases, the intensity of the fluorescence of the donor fluorophore decreases. Because the interaction between the two fluorophores is a typical dipole-dipole interaction, FRET is dependent on the inverse sixth power of the intermolecular separation (see Equations 7.13 and 7.147), making it useful over distances comparable with the dimensions of biological molecules. Summarizing, the FRET efficiency is determined by three parameters:

1. The distance between the donor and the acceptor
2. The spectral overlap of the donor emission spectrum and the acceptor absorption spectrum
3. The relative orientation of the donor emission dipole moment and the acceptor absorption dipole moment

The FRET efficiency E is defined by the Förster equation:

$$E = \frac{1}{1 + \left(\frac{r}{R_0}\right)^6} \qquad (7.147)$$

From this expression, the efficiency E depends on the donor-to-acceptor separation distance, r, with an inverse sixth order law as a result of the dipole-dipole coupling mechanism, with R_0 being the Förster distance of this pair of donor and acceptor at which the FRET efficiency is 50%. The donor-to-acceptor separation distance r can be from 0–100 Å.

FRET is an important technique for investigating a wide variety of biological phenomena that produce changes in molecular proximity.

A nice illustration of the FRET principle is found in the use of molecular beacons shown in Figure 7.102. The molecular beacon is a single-stranded nucleic acid molecule with a stem-and-loop structure. The loop portion of the molecular beacon "hairpin" is complementary to a target DNA sequence. The hairpin stem is formed by two sequences that are complementary to each other. In hairpin formation, the quencher, attached to one end of the probe, quenches the fluorophore attached to the other end of the probe, and no fluorescence is emitted. On hybridization of the molecular beacon to its target, the stem dissociates, causing the quencher and the fluorophore to move away from each other, resulting in the restoration of fluorescence.

The rate of fluorescence emission depends on the amount of time that the molecule remains within the excited state (say, excited state with lifetime τ_f). Optical saturation occurs when the rate of excitation exceeds the reciprocal of τ_f. Molecules that remain in the excited beam for extended periods have higher probability of interstate crossings and thus phosphorescence (see below). Usually, increasing dye concentration can be the most effective means of increasing signal when energy is not the limiting factor (i.e., using laser-based confocal systems) and until the dye concentration reaches the limit of the inner filter effect.

Quantum Dots Quantum dots, also known as *nanocrystal semiconductors*, are crystals composed of materials from periodic groups II–VI, III–V, or IV–VI

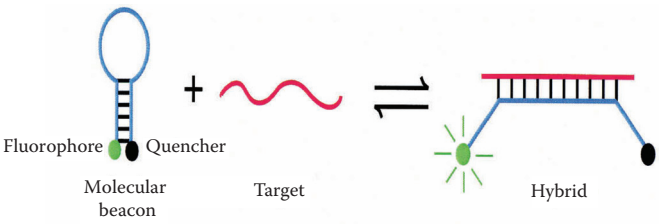

FIGURE 7.102 Schematic presentation of a molecular beacon. In the hairpin loop structure, the quencher (black circle) forms a nonfluorescent complex with the fluorophore (green circle). On hybridization of the molecular beacon to a complementary sequence, the fluorophore and quencher are separated, restoring the fluorescence.

(e.g., CdS, CdSe, PbS, PbSe, PbTd, CuCl). These nanocrystals are used as crystalline fluorophores and can be conjugated to biomolecules as an alternative to the above-reviewed organic dyes. As we saw in Chapter 3, quantum dots (QDs) form a unique class of semiconductors because of their small size, ranging from 2–10 nm (10–50 atoms) in diameter. At these sizes, material properties become size-dependent. In Figure 7.103, we illustrate how smaller dot size leads to emitted light at shorter wavelengths.

With QDs, by adjusting the size of the dot or its composition, the emission wavelength is tunable from blue to the near infrared. CdS and ZnSe dots of decreasing size emit from the blue light region to the near-UV light, different-sized CdSe dots emit light across the visible spectrum; and InP, and InAs QDs emit in the far-red and near-infrared. Elongated QDs (quantum rods) show linearly polarized emission, whereas the fluorescence emission from spherical CdSe dots is circularly polarized or nonpolarized.[46] QDs have a broad absorption spectrum (any light source "bluer" than the dot of interest works) and yield narrow emission. For example, the emission spectra of single ZnS-capped CdSe QDs are as narrow as 13 nm (full-width at half-maximum; FWHM) at room temperature.[47] Symmetric, narrow emission spectra minimize overlap of adjacent colors. Some of the manufacturing techniques of QDs, such as wet chemistry and template chemistry (zeolite, alumina templates), are detailed in Volume III, Chapter 3. See also earlier in this chapter where the Derjaguin, Landau, Verwey, and Overbeek theory (DLVO) was introduced to explain colloid stability. We will learn how crystal size can be controlled by the growth conditions. Before 1993, QDs were often prepared in aqueous solution with added stabilizing agents (e.g., thioglycerol or polyphosphate) to avoid colloid precipitation (see colloid stability, page 519). This procedure yielded low-quality QDs with poor fluorescence efficiencies and large size variations [relative standard deviation (RSD) > 15%]. In 1993, Bawendi and coworkers[48] synthesized better luminescent CdSe QDs using a high-temperature organometallic procedure instead. The resulting nanocrystals had nearly perfect crystal structures and exhibited much narrower size variations RSD < 5%), but the fluorescence quantum yields were still relatively low (~10%). At that time, even if one could make QDs in a narrow size range, they still came with two major problems: poor fluorescence and hydrophobicity, with the latter preventing their use in biological experiments. Today, these problems have been overcome. The addition of semiconductor caps such as ZnS or CdS were found to dramatically increase the fluorescence quantum yield to 45% or higher. A quantum dot often used in this regard is shown in Figure 7.104, a configuration with a CdSe core and a ZnSe shell. The core determines the nanocrystal color, and the shell, of a higher bandgap material (ZnS), dramatically enhances not only the brightness but also the chemical stability. The ZnS protects

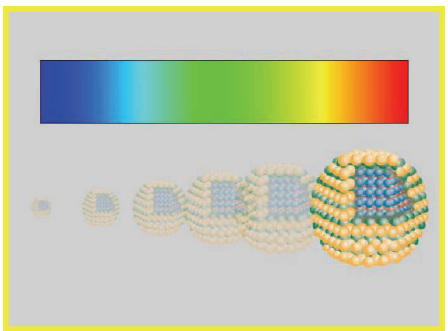

FIGURE 7.103 Quantum dots. Quantum dots change color with size because additional energy is required to "confine" the semiconductor excitation to a smaller volume.

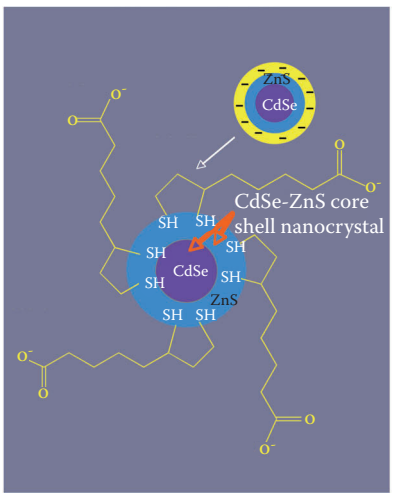

FIGURE 7.104 Nanocrystal with CdSe core and a ZnSe shell. The surface is derived with dihydrogenlipoic acid (DHLA) groups that terminate with negatively charged carboxyl groups. The addition of this coat makes the particles water soluble. To conjugate quantum dots to biomolecules, avidin or protein-G with a positively charged tail may be conjugated to the negatively charged DHLA coat.

the core from oxidation and prevents the CdSe from leeching into the surrounding solution.

Compared with traditional organic dyes such as rhodamine 6G and fluorescein, CdSe nanocrystals show similar or lower quantum yields at room temperature. The lower quantum yields are compensated by their larger absorption cross-sections and much reduced photobleaching rates. Bawendi and coworkers[48] estimated that the molar extinction coefficients of CdSe QDs are about 10^5–10^6 M^{-1} cm^{-1}, depending on the particle size and the excitation wavelength. Chan and Nie[47] estimated that single ZnS-capped CdSe QDs are ~20 times brighter and ~100–200 times more stable than single rhodamine 6G molecules (see also comparison of dyes and QDs in Table 7.19). CdSe cores with ZnS shells are the best QDs for bioapplications with an easily reproducible chemistry and a wide range of emissions.

QDs are generally negatively charged, owing to the colloid stabilizer molecules adsorbed on their surface.[49] These stablizers include hydrophobic tri-*n*-octylphosphine oxide (TOPO), which strongly coordinates to the surface metal atoms, whereas tri-*n*-octylphosphine (TOP) and tributylphosphine (TBP) are weakly bound. These surface stabilizers prevent flocculation in organic solvents and must be replaced with surface stabilizers for use of the same particles in aqueous environments. A few different methods for making nanocrystals water soluble are available. Methods include derivatizing the surface with mercaptoacetic acid or dithiothreitol, encapsulating in phospholipid micelles, derivatizing the surface with dihydrogenlipoic acid (DHLA; groups that terminate with negatively charged carboxyl groups, as shown in Figure 7.104), and coating them with amine-modified polyacrylic acid. In yet another approach, Alivisatos et al.[50] use a silica/siloxane coating for creating water-soluble, ZnS-capped CdSe QDs. During their process, 3-(mercaptopropyl) trimethoxysilane (MPS) is directly adsorbed onto the nanocrystals, and the TOPO molecules are displaced. A silica/siloxane shell is formed on the surface by the introduction of a base and hydrolysis of the silanol groups. The addition of these coats makes the particles water soluble, and therefore more useful for biological applications.

The water-soluble QDs are now ready to be conjugated to all sorts of biomolecules. The surface area of a single QD is large enough to bind multiple biomolecules. Two to five protein molecules and 50 or more small molecules (such as oligonucleotides or peptides) may be conjugated to a single 4-nm QD. To attach QDs to biomolecules in a simple

Table 7.19 Comparison of Organic Dyes and Quantum Dots

Organic Dye	Quantum Dot
Broad absorption and emission profiles spectrum	Broad absorption but narrow emission. Sharper spectrum (FWHM ~25–40 nm)
Low photobleaching threshold. Fades quickly ~100 ps	High resistance to photobleaching and photo and chemical degradation ~5–40 ns
Unstable	Stable output over time (100 times more stable)
One dye excited at a time	Multicolor imaging
Low quantum yield (usually smaller than quantum dots)	High quantum yield. Fluorescent yield is 20 times larger
	Can be made water soluble
	Requires much less sample preparation
Large Stokes shifts come with low molar extinction coefficients	Excited at one wavelength for multiple colors
Can diffuse through cell walls	QDs cannot diffuse through cell walls
Smaller	Bulkier
	Large Stokes shifts
	Wide range (UV-IR)
	High molar extinction coefficient (~10–100 times organic)

electrostatic fashion, avidin or protein-G with a positively charged tail may be conjugated to the negatively charged DHLA coat of a QD. Other scenarios for QD to biomolecule conjugation are illustrated in Figure 7.105. In general, one deals with reactive functional groups, including primary amines, carboxylic acids, alcohols, and thiols. Bioconjugated QDs are finding more and more applications, including DNA hybridization, multiplexed optical encoding, and high-throughput analysis of genes and proteins, immunoassays, and in vivo cellular imaging. Some important advantages of QDs for the latter application are the extremely high photostability of QDs, which allows real-time monitoring or tracking of intracellular processes over long periods (minutes to hours); the ability to use multicolor nanocrystals to simultaneously image multiple targets; and the fact that nanocrystals are believed to be less toxic to the cell than organic dyes. This will allow, for example, viral particles to be followed in vivo, drug molecules to be analyzed in biological systems, and tumor cells to be tracked in real time.

Micro- or nanobeads filled with QDs, as shown in Figure 7.105e, constitute one of the most fascinating new applications of QDs. In this configuration, polystyrene or latex beads are filled with QDs of various combinations of color and intensity (by using different concentrations of the same QD). Specific capturing molecules such as peptides, proteins, and oligonucleotides are then covalently linked to the beads and thus are encoded by the beads' spectroscopic signature, like a barcode on a product. The use of six colors and 10 intensity levels could, in theory, encode 1 million protein or nucleic acid sequences. A single light source is sufficient for reading all the QD-encoded beads. To determine whether an unknown analyte is captured, conventional assay methodologies may then be applied.[51] Because large numbers of barcode variations are possible, each perhaps specific to a different DNA sequence, the application of QD-encoded beads to DNA microarray assays is obvious. Traditional DNA microarrays are composed of short DNA oligomers attached to an inert substrate (glass slide) and typically contain a grid of 10^5–10^6 features (spots), each with a different DNA molecule (a DNA probe) at a known location in the grid. Fluorescently labeled target DNA or RNA hybridizes to these complementary probes. The hybridized array is scanned with a laser to check for a fluorescent signal for each spot, and because we know where each DNA probe is located, we know which ones hybridize successfully. In the case of QD-encoded beads,

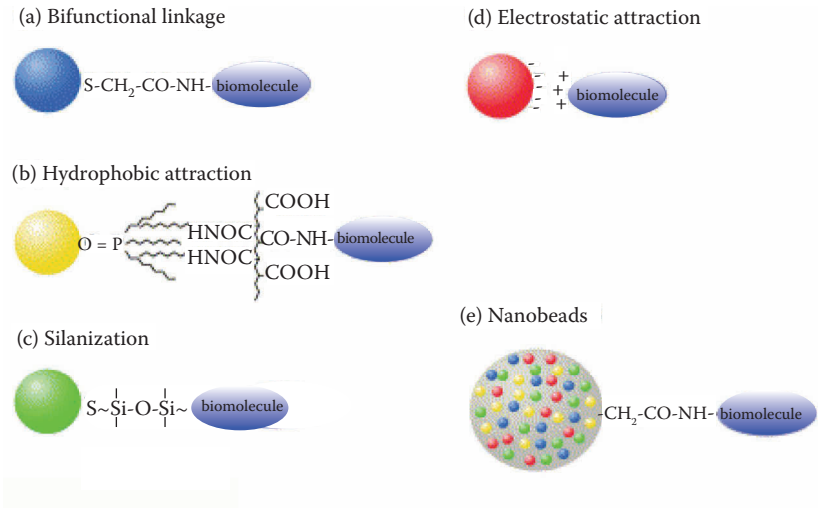

FIGURE 7.105 Quantum dot-biomolecule conjugation schemes. (a) Use of a bifunctional ligand such as mercaptoacetic acid for linking QDs to biomolecules. (b) Tri-*n*-octylphosphine oxide (TOPO)-capped QDs bound to a modified acrylic acid polymer by hydrophobic forces. (c) QD solubilization and bioconjugation using a mercaptosilane compound. (d) Positively charged biomolecules are linked to negatively charged QDs by electrostatic attraction. (e) Incorporation of QDs in microbeads and nanobeads. (From Chan, W. C. W., D. J. Maxwell, X. Gao, R. E. Bailey, M. Han, and S. Nie. 2002. Luminescent quantum dots for multiplexed biological detection. *Curr Opin Biotechnol* 13:40.[46])

multiplexed assays are simply created by mixing the appropriate beads in a solution rather than placing them on a solid surface. We do not need a grid location anymore because each particle comes with its own barcode. One can envision these 3D liquid arrays (Figure 7.106) as the successors of the current generation of gene chips (e.g., see the Nanogen DNA chip in Volume II, Figure 8.51). These new liquid "bar-coding" technologies have the potential to offer significant advantages over current planar chip devices, such as faster binding kinetics (3D vs. 2D), decreased hybridization time, more massive parallel processing, and ease of adding new targets. These novel multiplexed multicolor assays are being developed for massive parallel biosensing and analytical detection.

An entirely different bar-coding principle was developed by Natan and coworkers[52] and uses metallic nanobars. These authors report the development of metallic nanobarcodes for multiplexed bioanalysis. Fluorescence is still used for target detection, but the barcodes are read by measuring the reflectivity differences between different metals. See also the BeadArray™ from Illumina further below in Figure 7.120.

It is still unclear how similar technologies, such as encoded nanobars and QD-tagged microbeads and encodable radiofrequency devices, will compete in genomic, proteomic, and clinical diagnostic applications.

From the above, it appears that QDs could eventually constitute a big improvement over fluorescent dyes. Unlike fluorescent dyes, which tend to decompose and lose their ability to fluoresce, QDs maintain their integrity, withstanding many more cycles of excitation and light emission (they do not bleach easily!). Some of the disadvantages associated with QDs are the possibility of their irreversible aggregation and their relatively bulky size (they cannot diffuse through a cell membrane) compared with most organic fluorophores. In Table 7.19, we compare organic dyes with QDs.

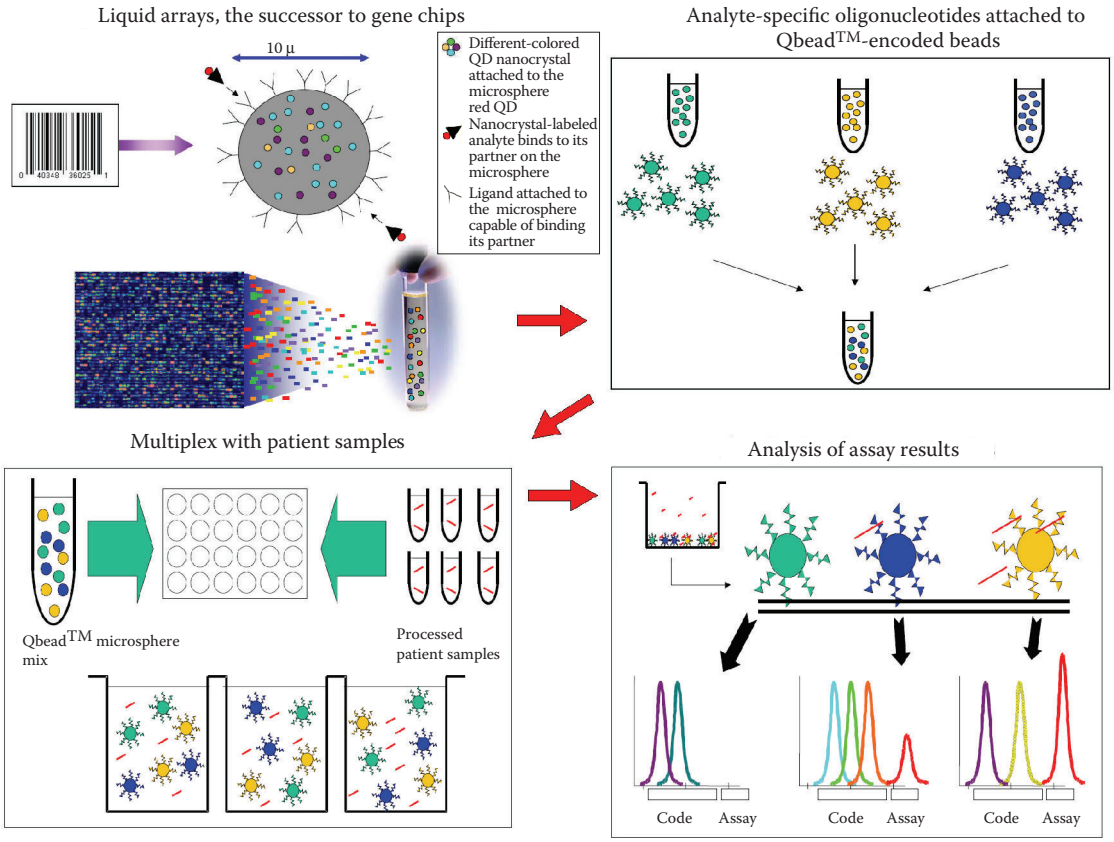

FIGURE 7.106 Spectral barcodes. How to use liquid arrays. The Qbead™ technology is based on the use of QD particles to create spectral barcodes that enable high levels of multiplexing for genetic analysis. As few as 10 assays per well or potentially as many as millions of assays per well may be encoded. Quantum Dot Corporation now known as Invitrogen.

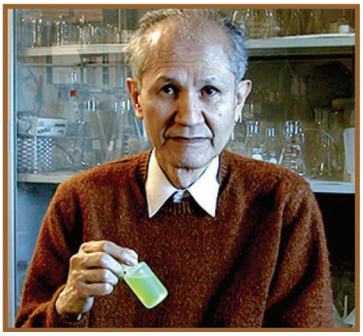

FIGURE 7.107 Dr. Osamu Shimomura.

Fluorescent Proteins As an example of a fluorescent protein, we will focus on green fluorescent protein (GFP). GFP is an intensely fluorescent probe, with a quantum efficiency of approximately 80% and a molar extinction coefficient ε of 2.2×10^4 cm^{-1} M^{-1}. The GFP from the molecular system of the bioluminescent jellyfish *Aequorea victoria* is making an impact on biotechnology today. It was Osamu Shimomura who first noticed GFP in 1962 (Figure 7.107) (http://en.wikipedia.org/wiki/Green_fluorescent_protein). At first, a mere footnote in a scientific paper about a small, bioluminescent jellyfish called *Aequorea aequorea*, or *A. victoria* as the natives from the Bay of Puget Sound call it, the study of this jellyfish's glow became Shimomura's life's work.

The gene encoding GFP was first isolated from the photocytes in the umbrella of the jellyfish *A. victoria*, which was then cloned and introduced into cells of other species. The structure of the GFP molecule, along with a picture of the *A. victoria* jellyfish, is shown in Figure 7.108. This extremely stable protein is made up of 238 amino acids. Its fluorescent properties are unaffected by prolonged treatment with 6 M guanidine HCl, 8 M urea, or 2-day treatment with various proteases such as trypsin, chymotrypsin, or papain. The excitation maxima of GFP are at 395 nm (A state) and 470 nm (B state), and its peak emission is at 509 nm.

The structure of the GFP protein is a marvel of molecular engineering. Looking like a glowing green lantern, it consists of an outer coat, which is a symmetrical large barrel made up of 11 strands of β-pleated sheets. The barrel even has a top and bottom lid made up by shorter protein helices. A much longer helix is centered inside this barrel, and the chromophore itself is nestled in the middle segment of this helix. The cylinder has a diameter of 30 Å and a length of 40 Å. The GFP molecule emits green light when activated by blue or UV light. In vivo, in the jellyfish, there is a radiationless energy transfer from aequorin (AEQ), a bioluminescent protein (see below) present in the same jellyfish that emits at 469 nm to excite GFP, which in turn then emits at 509 nm. This is possible because of the overlap between the emission spectrum of AEQ and the excitation spectrum of GFP [see bioluminescence resonance energy transfer (BRET) in Figure 7.116].

The mechanism of luminescence emission in GFP involves the formation of an internal chromophore, p-hydroxybenzylidene-imidazolone, by an unusual cyclization of three neighboring amino acid residues (Ser-Tyr-Gly at the 65–67 positions of the primary

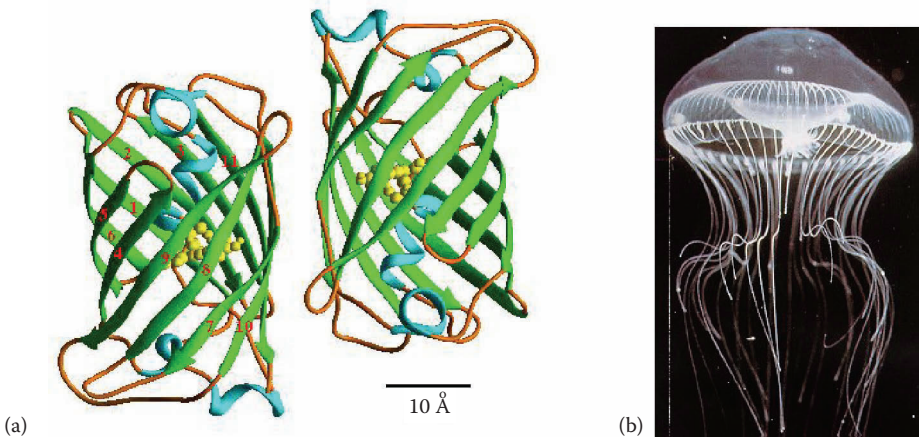

FIGURE 7.108 (a) The overall shape of the GFP protein. Eleven strands of sheet (green) form the walls of the cylinder; short segments of helices (blue) cap the top and bottom of the β barrel (can). (b) The *Aequorea victoria* jellyfish.

sequence). While the wild-type GFP emits in the green region, by introducing amino acid changes in the region close to the chromophore, all types of GFP color variants can be made. This enables the production of GFP variants (mutants) with tailor-made optical properties. Miyawaki et al.[53] have combined the protein calmodulin and the peptide M13 (binds to calmodulin on exposure to Ca^{2+}) with GFP and produced an optical sensing probe for Ca^{2+} with a detection limit in the 100 to 10 billionth of a mol per liter. The sensitivity range depends on the calmodulin mutant used. The spatial resolution of this fluorescent probe is good enough to allow one to compare concentrations of Ca^{2+} between different compartments of one cell.

In 1994, Chalfie et al.[54] coupled the gene for GFP to the gene of another protein of interest. This technique is known as *gene fusion*. The resulting gene fusion, or protein chimera, is then transferred to an organism (e.g., bacterial, yeast, or mammalian cell) so that the latter may produce a protein of interest (protein chimera) that combines the characteristics of both partner protein molecules.[54] After transfer of this target gene into the organism, one can measure the success of the gene transfer simply by shining UV light on the transformed cells. If the cells produce green light, it indicates that the transfer has occurred. GFP has been used to produce animals [e.g., fruit flies, zebrafish, mice, a dog (http://www.ekac.org/transgenic.html), and a bunny (http://www.ekac.org/gfpbunny.html)], as well as plants that light up brightly (see Figure 7.109). This fluorescence can be generated either in the whole animal or plant, or just in some desired part of the organism, such as the cells in a tumor.

FIGURE 7.109 Alba, the fluorescent bunny. (From http://www.ekac.org/gfpbunny.html.)

Further developments have made it possible for the GFP to blink intermitently.[55] This was the first demonstration of light switching of molecules induced at room temperature and of monitoring this switching on a molecule-by-molecule basis.[56] Applications in optoelectronic devices and computing are obvious future targets for GFP. Another protein that is often mentioned in the context of molecular computing and optical switching, bacteriorhodopsin,* requires the measurement of absorbance of a large number of molecules; thus, it appears less efficient for these applications. For more GFP literature, see http://www.imb-jena.de/www_sbx/gottfried/gfp/gfp_literature.html. Books on GFP are listed at http://pantheon.cis.yale.edu/~wfm5/gfp_gateway.html.

Chemiluminescence and Bioluminescence

Chemiluminescence Emission of light by matter (luminescence) has always been known to humans: lightning, the aurora borealis, and light emission by bacteria in the sea or by decaying organic matter are common natural phenomena. Scientific investigation of the luminescence phenomena began with a discovery by Vincenzo Casciarolo, a Bolognian shoemaker and alchemist who in 1603 prepared, serendipitously, an artificial phosphor known as the *Bolognian stone* (or Bolognian phosphor), which glows after exposure to light. Chemi- and bioluminescence measurements with luminometers have become extremely popular in recent years. A luminometer consists of a sample chamber, a detector [usually a photomultiplier tube (PMT)], a signal processing method, and a signal output display. In chemiluminescence, the light emission (sometimes called *cold light*†) is caused by a chemical reaction in which chemical energy is converted to light energy.

* Bacteriorhodopsin (BR) is a photon-driven ion pump. BR is a seven-helical transmembrane protein with a retinal cofactor. It is found in the bacterium *Halobacterium salinarium*, where it converts light to a proton gradient, which in turn is used by a second membrane protein called *ATP synthase* to generate chemical energy in the form of ATP. ATP is then used by the cell to drive a multitude of vital processes. Bacteriorhodopsin movies can be found at http://www.utexas.edu/depts/pharmacology/gonzales/brhod.html.

† To create light, another form of energy must be supplied. The two common ways are incandescence and luminescence. Incandescence refers to the emission of light from heat energy, e.g., the tungsten filament of an ordinary incandescent light bulb glows "white hot."

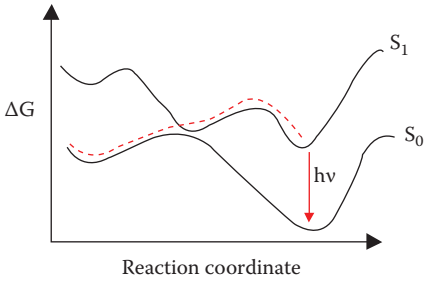

FIGURE 7.110 Chemiluminescence occurs when the ground state of one molecule crosses with the excited state of a rearranged or fragmented molecule.

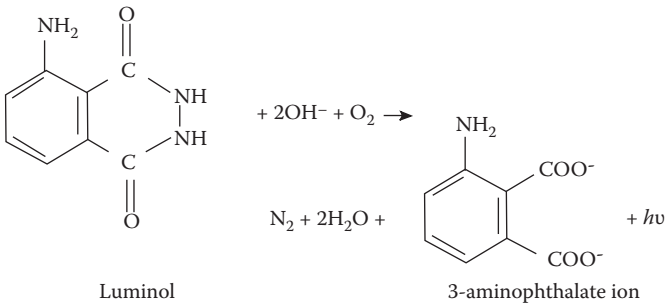
Chemiluminescence occurs when the ground state of one molecule crosses with the excited state of a rearranged or fragmented molecule, as sketched in Figure 7.110.

These reactions can occur in the gas and liquid states and can last from less than a second to more than a day. Reagents containing the group —CO—NH—NHR react with oxygen, hydrogen peroxide, and many other oxidizing compounds to yield chemiluminescent products. A typical example is that of luminol, given as:



Reaction 7.7

When luminol is placed in an alkaline solution with hydrogen peroxide and a catalyst such as iron, manganese, copper, nickel, or cobalt, the luminol is oxidized to 3-aminophthalate ion in the excited state, causing fluorescence. The luminol creates light via oxidation because two oxygen atoms easily replace the two nitrogen atoms. As this reaction occurs, nitrogen gas is discharged, leaving the luminol in an excited state and releasing additional energy as light. Amino acids, fructose, glycerols, thiols, and serum albumin can also react with luminol to produce an intense light. No excitation source is needed to produce the glow, and a PMT is used to measure and detect low amounts of light in a simple luminometer.

The most important and well-known use of luminol is in the field of forensic science. Blood, which is slightly alkaline, contains cells, water, enzymes, proteins, and hemoglobin. Hemoglobin reacts with the luminol, allowing for the detection of very small amounts of blood. Once an area is suspected to have blood (even if the area has been cleaned) luminol can be applied. The lights are turned off, and after a few seconds a glow appears (Figure 7.111). Many other organic compounds can be oxidized using enzymes such as uricase and oxygen to yield hydrogen peroxide:

$$\text{uric acid} + O_2 \xrightarrow{\text{uricase}} \text{allantoin} + H_2O_2 \qquad \text{Reaction 7.8}$$

The hydrogen peroxide can then be detected with luminol (Reaction 7.7). Examples of compounds that are often detected in this manner are glucose, cholestereol, choline, uric acid, amino acids, aldehydes, and lactate. Biosensors with enzymes immobilized on optical fibers have been developed for the in situ detection of many compounds using this principle.

Another well-known chemiluminescence system is Cyalume from American Cyanamid. In this case a simplified format of the reaction is given as:

$$\text{phenyl oxalate ester} + H_2O_2 \rightarrow \text{intermediate}$$
$$(I) + \text{products I} + \text{flurophor}(F) \rightarrow F^* + \text{products}$$
$$F^* \rightarrow F + h\nu$$

Reaction 7.9

The same reaction is reproduced in Figure 7.112. Here, the phenyloxalate ester is shown, and the reactive intermediate (*I*) is dioxetane. The excited molecule can also transfer energy to another molecule, which then emits light. Different fluorophores (*F*)

FIGURE 7.111 Blood detection using luminol.

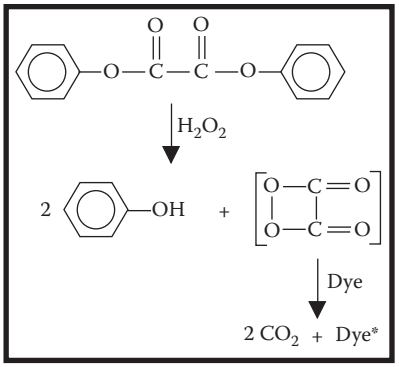


FIGURE 7.112 Oxalate ester in contact with H_2O_2 makes the reactive intermediate dioxetane (*I*). This intermediate reacts with a variety of dyes to give different colors.

reacting with intermediate *I* give different colors used in "glow-in- the-dark" light sticks (Figure 7.113). For red light, rhodamine B is used; the common green comes from 9,10-*bis*(phenylethynyl) anthracene; 9,10-diphenylanthracene results in blue.

A "glow-in-the-dark" light stick is a plastic tube with a glass vial inside. To activate such a light stick, one bends the plastic stick, which breaks the glass vial containing the hydrogen peroxide. This allows the hydrogen peroxide that was inside the glass to mix with the chemicals in the plastic tube. Once these substances contact each other, a reaction sets in that might last as long as 12 hours. When mixed with hydrogen peroxide and a dye, phenyl oxalate gives a quantum yield of 5%, which is not as efficient as a firefly (see below) but still very useful.

One of the widest analytical implementations of chemiluminescence is in the detection of NO or O_3.

FIGURE 7.113 Oxetane intermediate reacts with a variety of dyes to give different colors in light sticks. Plastic tubes have a glass vial inside that breaks on bending and lets the reagents react.

Together they react to produce electronically excited NO_2^*, which emits light throughout the red and near-infrared spectral regions (600–2800 nm):

$$NO + O_3 \rightarrow NO_2^* + O_2$$
$$NO_2^* \rightarrow NO_2 + h\nu \qquad \text{Reaction 7.10}$$

Using an excess of either component, one can detect trace amounts of the other. For example, ozone from an electrogenerator can be drawn together with an atmospheric sample into a reactor, where chemiluminescence is monitored by a photomultiplier in a luminometer. Linearity is obtained for NO concentrations from 1 ppb to 1%. This is the method of choice for measuring NO concentrations from ground level to altitudes up to 20 km. Atmospheric ozone is detected by chemiluminescence, resulting from the reaction of ozone with rhodamine B adsorbed on a silica gel. This reaction has a linear response in the range of 1–400 ppb. Ozone is also detected by the chemiluminescence from its reaction with ethylene.

Bioluminescence Bioluminescence is a type of chemiluminescence where the production and emission of *cold light* in a living organism is the result of a chemical reaction. Bioluminescence is caused by enzymes and other proteins present in the organism. Because it is a biochemically driven reaction/phenomenon, there is no need for excitation sources. These proteins can be used as markers or reporters of other biochemical processes in biomedical research. It is found in many marine animals, both invertebrate (e.g., some cnidarians, crustaceans, squid) and vertebrate (some fishes), in some terrestrial animals (e.g., fireflies, some centipedes), and in some fungi and bacteria (see Table 7.20).

The two insets in the heading of this chapter—a shrimp vomiting a bioluminescent substance to keep a predator at bay and a firefly—are examples of bioluminescence. The anglerfish lives more than a mile deep in the ocean. On her forehead, the female has a "fishing rod" tipped with a lighted "artificial worm" that she dangles over her mouth to attract her next meal. Deep-sea predators, like the anglerfish, need their own light to attract both prey and

TABLE 7.20 Organisms in Nature That Are Bioluminescent

Group	Features of Luminous Displays
Bacteria	Organisms glow constantly; system is autoinduced
Fungi	Mushrooms and mycelia produce constant dim glow
Dinoflagellates	Flagellated algae flash when disturbed
Coelenterates	Jellyfish, sea pansies, and comb jellies emit flashes
Annelids	Marine worms and earthworms exude luminescence
Mollusks	Squid and clams exude luminous clouds and have photophores
Crustacea	Shrimp, copepods, ostracodes; exude luminescence; also have photophores
Insects	Fireflies (beetles) emit flashes; flies (Diptera) glow
Echinoderms	Brittle stars emit trains of rapid flashes
Fish	Many bony and cartilaginous fish are luminous; some use symbiotic bacteria; others are self-luminous; some have photophores

mates. Fireflies also use their flashes to attract mates. The pattern differs from species to species. In one species, the females sometimes mimic the pattern used by females of another species. When the males of the second species respond to these "femmes fatales," they are eaten! The organism itself, or certain symbiotic bacteria living in the organism, can control the light emission. In a firefly, about 100% of the ATP energy is converted into light. By comparison, a normal electric light bulb gives off only 10% of its energy as light, whereas the rest is wasted as heat. Molecular details vary from organism to organism, but each involves a luciferin, a light-emitting substrate; a luciferase, an enzyme that catalyzes the reaction; ATP, which is the source of the energy; and molecular oxygen, O_2:

$$\text{luciferin} + \text{luciferase} + \text{ATP} \rightarrow$$
$$\text{luciferyl adenylate-luciferase} + \text{pyrophosphate}$$
$$\text{luciferyl adenylate-luciferase} + O_2 \rightarrow$$
$$\text{oxyluciferin} + \text{luciferase} + \text{AMP} + h\nu$$

Reaction 7.11

For a simplified reaction scheme, see Figure 7.114. Firefly luciferase was originally prepared by extraction of firefly tails and purified by crystallization. Luciferases and luciferins from different bioluminescent organisms might differ greatly. Today genetic cloning of various luciferases allows for its recombinant production. Genetic engineering of the luciferases and luciferins can extend both the performance and capabilities of bioluminescence.

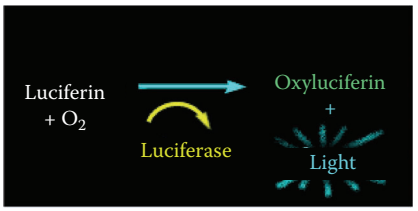

FIGURE 7.114 Luciferin is the substrate and luciferase the enzyme that catalyzes the reaction; ATP (not shown) is the source of energy. Molecular oxygen O_2 is also needed.

The more ATP available, the brighter the light. In fact, firefly luciferin and luciferase are commercially available for measuring the amount of ATP in biological materials (e.g., Millipore's Milliflex Rapid). A well-designed luminometer can detect as little as 0.6 pg of ATP or 0.1 fg of luciferase with six decades of linearity.

Sometimes the luciferin and luciferase (as well as a cofactor such as oxygen) are bound together in a single unit called a *photoprotein*. This molecule can be triggered to produce light when a particular type of ion is added to the system (frequently calcium ions) (see Figure 7.115). This mechanism can be used for a very sensitive Ca^{2+} detector. An example of such a photoprotein is aequorin.

Aequorin, like green fluorescent protein (GFP), is a photoprotein native to the jellyfish *A. victoria* (see Figure 7.108). Aequorin is composed of two distinct units, apoaequorin and an organic chromophore known as *coelenterazine*, a molecule belonging to the luciferin family. In the presence of molecular oxygen, the two components of aequorin reconstitute spontaneously, forming the functional protein.

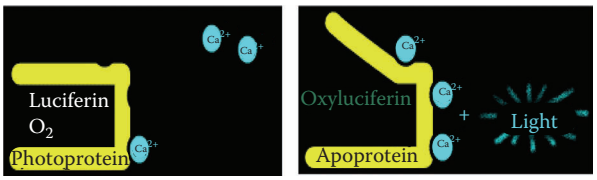

FIGURE 7.115 Luciferin, luciferase, and oxygen are bound together in a photoprotein.

Aequorin emits a flash of blue light (469 nm) that lasts 3–10 s on exposure to calcium ions, which produces a direct, ultrasensitive signal that can be measured with a luminometer:

$$\text{Aequorin} + 2Ca^{2+} \rightarrow$$
$$\text{blue fluorescent protein: } 2Ca^{2+} + CO_2 + h\nu$$

Reaction 7.12

When conjugated to other proteins, such as antibodies or streptavidin, or to small molecules such as biotin, the aequorin conjugates can be used as detection labels in bioluminescence-based assays (BIAs). Adding a calcium salt solution and measuring the amount of light produced during the bioluminescent reaction determines the amount of label present. Because of this calcium-dependent light emission, the aequorin complex has been used as an intracellular Ca^{2+} indicator.

The jellyfish *A. victoria* contains two photoactive proteins. In bioluminescence resonance energy transfer (BRET), a radiationless energy transfer takes place from aequorin, which emits at 469 nm (blue), to the GFP (see Figure 7.116), which then emits at 509 nm, i.e., the green light of the jellyfish (Figure 7.108).

Aequorin can be microinjected into cells or introduced into cells by complementary DNA (cDNA) transfection (see Volume III, Chapter 2 on nature as an engineering guide). An additional tool is provided by the targeting of aequorin to specific compartments of the cell (see Brini et al., 1999)[65] by introducing in the cDNA codes for targeting the protein to specific localities. Similar to GFP, AEQ-cDNA attached to a promoter provides a useful reporter gene.

Scaling in Chemiluminescence and Bioluminescence Earlier, we saw that fluorescence and absorption both scale with path length b, so that both techniques scale badly when miniaturizing the sample path. In the case of fluorescence, the situation is a bit better than for absorption because one can at least turn up the number of incoming photons to increase the signal intensity (see Equations 7.137 and 7.144). In chemiluminescence there is no path length, b, dependence, and intensity, I_{CL}, is only a function of the chemiluminescence efficiency, Φ, and the rate of production of the activated complex (intermediate), c^*:

$$I_{CL} = \phi \frac{dc^*}{dt} \tag{7.148}$$

Luminometers are considerably simpler than fluorescence instrumentation; they need no excitation source—the chemical reaction provides the input energy—and because emitters are usually single wavelength, they also need no wavelength selection device (filter or spectrophotometer). Essentially one only needs a light detector, a sample holder, and a mixing system (e.g., to add the Ca^{2+}; see Reaction 7.12). The latter could be further simplified through the use of a microfluidic system (e.g., see the CD-based fluidic system described in Chapter 6 and Volume III, Chapter 5). Spectral overlap between acceptor and donor excitation is of no concern, and photobleaching by an excitation source is avoided. Chemiluminescent

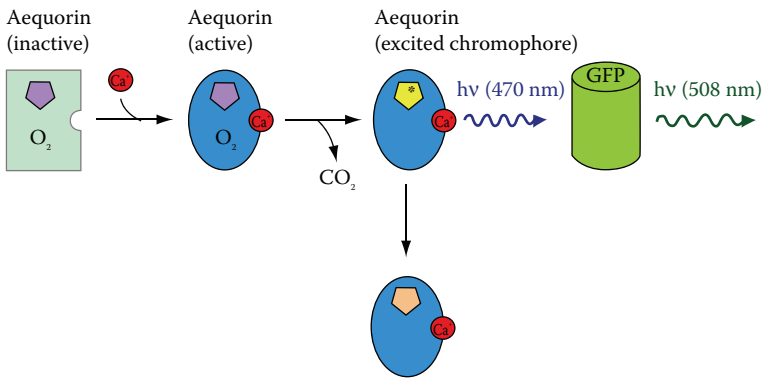

FIGURE 7.116 Bioluminescence resonance energy transfer (BRET) in *Aequorea victoria* from aequorin to GFP.

reactions can be carried out in front of the detector for higher photon collection. Perhaps the most important advantages of chemiluminescence are its high specificity—very few reactions result in light emission—and its very high sensitivity because there is no stray light. Chemiluminescence may be up to 1,000 times more sensitive than fluorometry and 100,000 times more sensitive than absorption spectroscopy. In some instances single molecules have been detected. Bioluminescence is just an extremely efficient subclass of chemiluminescence, and it provides better reliability because the enzyme is naturally evolved to protect the photon emitter. Disadvantages of chemiluminescence include the limited number of donor acceptor pairs available, i.e., Renilla luciferase, bacterial luciferase, firefly luciferase, and aequorin, and the fact that the emission spectra of bioluminescent proteins are broad.

Phosphorescence

Phosphorescence is the emission of photons with a change in spin multiplicity. Because the process violates the spin selection rule, it should not be allowed, but selection rules are broken, and phosphorescence is commonly observed. More specifically, phosphorescence, as we saw above, occurs when the molecule returns to the electronic ground state from the excited triplet state by emission of a photon (i.e., a radiative transition between states of different multiplicities) (see Figures 7.90 and 7.91). Because the transition is spin forbidden and is often slow (i.e., long lifetime, with τ in the 10^{-4}–10-s range), it is also referred to as *delayed luminescence* or *afterglow*. It occurs at much longer wavelength compared with fluorescence. Phosphorescence is susceptible to O_2 and collisions with solvent molecules. Triplet states are rapidly deactivated under these conditions. Because of the long radiative lifetime of phosphorescent transitions, internal conversion and other radiationless transfers of energy compete so effectively with phosphorescence. For many molecules it is only observed at low temperatures or in rigid frozen media (e.g., solvent mixtures at 77 K) and in the absence of oxygen. As illustrated in Figure 7.117, photon absorption occurs between electronic levels with the same spin multiplicity.

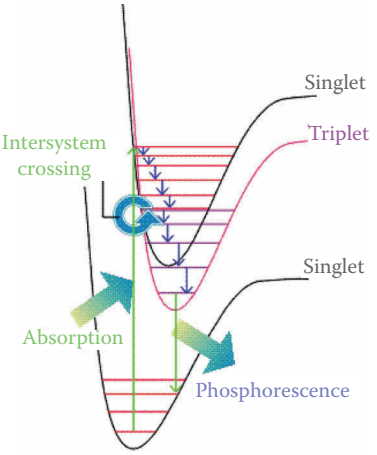

FIGURE 7.117 The phosphorescence process.

The radiationless transition between states of different multiplicity, shown here, is known as *intersystem crossing* (ISC). This may be followed by phosphorescence (weak emission from a long-lived state) to the ground electronic state. Fluorescence is measured much more often than phosphorescence because the lifetime of fluorescence (10^{-8}–10^{-4} s) is shorter than the lifetime of phosphorescence (10^{-4}–10^{2} s), allowing other processes to occur before a molecule has a chance to phosphoresce, thus making fluorescence more likely than phosphorescence.

Example Optoanalytical Devices

Introduction

To be able to compare electrochemical with optical sensors, we explore some examples of optical sensors here, just as we did for electrochemical sensors earlier in this chapter. Common types of optical sensors include fiberoptic, planar waveguide, evanescent wave, interferometric, and surface plasmon resonance (SPR). Under fiberoptic sensors, one further distinguishes between extrinsic and intrinsic sensors and direct and indirect ones. In an extrinsic optic fiber sensor, the fiber is only used as a transmission channel to take light to and from the sensing elements. In an intrinsic sensor, the fiber itself acts as a sensing element; a portion of the optical fiber cladding is removed and replaced with a chemically selective layer. The sensor is then placed directly into the media to be analyzed. Interaction of the analyte with the chemically selective layer creates a change

in absorbance, reflectance, fluorescence, or light polarization. A direct fiberoptic sensor measures the intrinsic optical properties of the analyte, and an indirect sensor measures the absorbance or fluorescence of an immobilized indicator dye or label. Planar waveguides are media in which the optical propagation is confined to a plane instead of a cylindrical fiber. Typical materials used for waveguides include plastic $\lambda > 450$ nm, glass $\lambda > 350$ nm, fused silica $\lambda < 350$ nm, and germanium crystals $\lambda > 1{,}000$ nm. The essential feature in interferometric sensing is the modulation of interference behavior by analyte binding. For example, the illumination of transparent thin-film coatings on reflective surfaces produces the so-called *Fabry-Pérot fringes*—alternating high- and low-intensity features—in which the resulting reflection spectrum and binding of an analyte to such film will shift these interference fringes. Evanescent wave sensors use the interaction with the electromagnetic field that extends a very short distance away from the surface of the light-guiding medium. The interaction of the evanescent wave with the sensing layer is used to get information on the analyte binding. It can involve IR (vibrational), UV-visible (electronic) absorption band, or Raman spectroscopic transitions. Surface plasmon resonance operates on the same principle as evanescent wave sensing, except that the planar waveguide is replaced by a metal/dielectric interface. Surface plasmons are electromagnetic waves that propagate between a metal and a dielectric material.

We encountered several of these types of optical sensors already in Chapter 5, where we introduced evanescent waveguide-type and SPR sensors. Additional optical sensors we review here are a fiberoptic-based continuous immunosensor, an interferometric immunosensor, a fiberoptic-based nanobead array for detection and analysis of DNA sequences, and PEBBLEs (**p**robes **e**ncapsulated **b**y **b**iologically **l**ocalized **e**mbedding) nanosensors. PEBBLEs is a general term that describes a family of matrices and nanofabrication techniques used to miniaturize optode technologies, thus filling a niche that lies between micro-optodes and free molecular probes.

Continuous Immunosensors—Optodes

A fiberoptical chemical sensor (FOCS) is often called an *optode* (also optrode), a word derived from optical electrode. An optode measures changes in the optical properties of a coating or membrane caused by the analyte. The sensors generally have a fiber for the light source and a return fiber to a spectrometer. If the sensor uses a phase change, it has a reference fiber and a sensing fiber. If the analyte is present, the optical parameter of the sensing fiber is changed. This creates a phase difference between the light traveling through the two fibers. If intensity is measured, instead of phase difference, the optode has an important advantage over electrochemical sensors in that no reference is needed.

The sensor consists of three main parts: a light source, optode, and detector. The main part of the sensor, the so-called optode, contains an appropriate indicator that changes its optical properties in dependence on the analyte. In basic fiberoptic sensor configurations, the active sensing region of the optical fiber may be located either on the end facet of the fiber (end-fiber configuration), on the side of the fiber (side-fiber configuration), or as an interrupting porous section inserted in the fiber (interrupted-fiber configuration). The end-fiber configuration is commonly applied for absorbance, luminescence, or fluorescence sensors, using the fiber as a light guide to and from the sample. The side-fiber configuration is usually applied for sensing schemes based on evanescent field measurements using the fiber as a waveguide and as the active transducer in sections with removed cladding. The interrupted-fiber configuration incorporates the active sensing region directly in the fiber by introducing a porous section. Thus, direct absorbance measurements are facilitated along with a large surface area. The fiberoptic immunosensor sensor shown in Figure 7.118 is an end-fiber configuration.

A key issue with immunosensors is their seemingly inherent irreversibility. Barnard and Walt.[57] introduced an ingenious way to make an immunoassay continuous by using the controlled release of labeled antibodies to maintain sensitivity. They used fluorescein-labeled antibody (F-Ab) and Texas Red-labeled immunoglobulin G antigen (TR-Ag) in a competitive immunoassay based on Förster

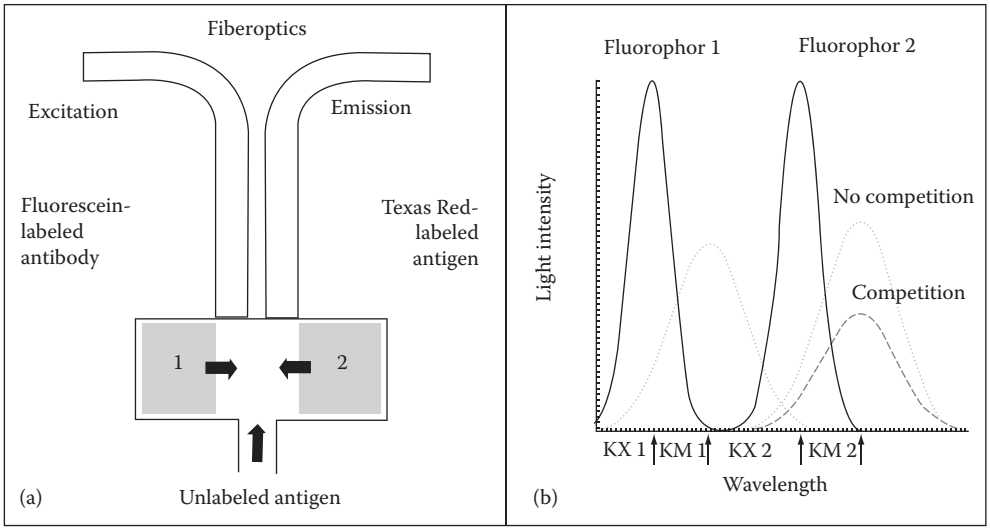

FIGURE 7.118 A new approach to immunosensing. A continuous immunomeasurement is enabled by implementing a polymer-release mechanism. Labeled antibody and antigen are released from polymer reservoirs, and fluorescence is measured by fiberoptics (a). The fluorescence emission from the second fluorophore (Texas Red) is reduced when unlabeled antigen competes with the reaction (b). (From Barnard, S. M., and D. R. Walt. 1991. Chemical sensors based on controlled release polymer systems. *Science* 251:927. With permission.[57])

resonance energy transfer (FRET) (see Figure 7.101). When the antibody (Ab) and antigen (Ag) bind, the two fluorophor labels are very close to one another, allowing nonradiative transfer of energy. When the fluorescein molecule is excited by light, it donates energy to the Texas Red fluorophor, enhancing its fluorescent light emission. To circumvent the irreversibility of the immunoassay, these researchers used a controlled-release delivery system capable of sustaining a constant release of fresh immunochemicals as shown in Figure 7.118. Specifically, they used ethylene-vinyl acetate as the controlled-release delivery system of reagents into the reaction chamber, i.e., the sensing region of the optical fiber. Unlabeled Ag diffused into the reaction chamber and competed with the Ag-TR for the available binding sites on the F-Ab, and bound species diffused out of the reaction chamber while a constant release of reagents maintained a constant concentration of fresh reagents in the reaction chamber. The fluorescence changes induced by the competition reaction were used to calculate the amount of unlabeled antigen in the sample solution. In cases where response time is not very critical but continuous monitoring is of major importance, this technique seems promising. A micromachined version of the sensor, shown in Figure 7.118, seems imminently feasible. This could involve micromachining a reaction chamber, release polymer reservoirs, and a waste dump, all connected with flow channels, and a window in the reaction chamber for the fiberoptics. Plastic injection molding or photoformed glass would be good approaches here.

Interferometric Immunosensor

The interferometric immunosensor the author and collaborators developed at SRI International is based on Langmuir-Blodgett technology.[58] As early as 1936, Irving Langmuir and Katherine Blodgett developed, in a most ingenious way, a method to measure film thickness comprising a small fraction of a wavelength of light. It consisted of building multilayers of barium stearate on a slide using a series of steps in a staircase fashion, as shown in Figure 7.119a. The method they used is known today as the Langmuir-Blodgett deposition method (see Volume II, Figure 8.13 in for a typical setup). Since then, much progress has been made in automating this deposition technology. The difference in thickness of two adjacent steps, as shown in Figure 7.119a, corresponds to a double layer of stearate (approximately 48 Å) and forms an interference-based color gauge that tracks thickness increases. When a film of unknown thickness is coated on the

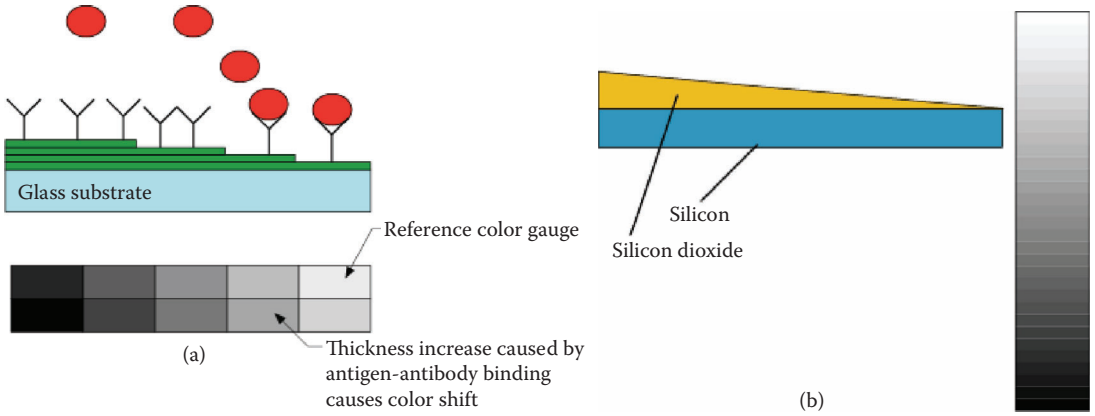

FIGURE 7.119 Optical immunosensors. (a) Staircase made by Langmuir-Blodgett technology (additive technique) or etching (substractive technique); (b) wedge made by pulling sample out of an etchant (substractive technique).

steps and is compared with an uncoated slide with steps, the eye can measure differences of thickness by means of color comparison down to about 10 Å. Greater sensitivity is obtained by illuminating films with sodium light rather than white light. Differences of thickness equal to 5 Å have been made plainly visible to the eye this way. This means that adsorbed layers of molecules or atoms having an optical thickness of 5 Å can be made visible to the eye without the aid of optical apparatus and can be measured with a probable error of about 2.5 Å. Some preliminary experiments were carried out with this simple step technique in the Madou laboratory while he was at SRI International laboratory at SRI International. When albumin was adsorbed on one-half of the staircase slide, the slide then was exposed to antialbumin. A thickness increase was observed via a color shift. What does this mean from the biosensor point of view? For many years, ellipsometers have been used to detect the deposition of antibody onto antigen preadsorbed on a flat reflecting surface. In this way, any molecule with a molecular weight greater than 60,000 (e.g., viruses, antibodies, proteins) could be detected. The ellipsometer is a very involved and expensive instrument (see Volume III, Chapter 6), whereas the system described above can perform the same task in a simple and inexpensive way. However, as pointed out earlier, the Langmuir-Blodgett deposition is a difficult manufacturing proposition. Fortunately, steps can also be built using etching techniques and using inorganic materials with optimum refractive indices for maximum interference effect.[58] Later, we found yet a better way to make interference slides: a substrate pulled at a uniform rate from an etchant solution forms a continuous optical wedge, making for a more elegant and faster manufacturing option than either Langmuir-Blodgett or staircase etching (Figure 7.119b). We believe the wedge approach is an excellent illustration of how micromachining could benefit immunosensor development by making inexpensive and disposable optical transducers possible. Whereas the wedge approach is more appropriate for the detection of larger molecules, the detection of smaller molecules is accomplished more easily with the electrochemical approach.

Bead Arrays for Detection and Analysis of DNA Sequences

Conventional DNA microarrays are manufactured by spotting or synthesizing probes at known locations onto 2D substrates, as we review in Volume II, Chapter 8 on chemical-, photochemical-, and electrochemical-based forming. Above, we discussed 3D liquid arrays (Figure 7.106) as an alternative for these planar gene chips with the idea of conjugating biomolecules to beads that are filled with various combinations of quantum dot (QD) types at various concentrations that can be used as "barcodes." Here we consider yet another option for DNA assaying, one that is already commercialized by Illumina (a San Diego biotech company) and is vying against Affymetrix, the industry pioneer, and other rivals, including Agilent Technologies, GE Healthcare, NimbleGen Systems, ParAllele BioScience, and Perlegen Sciences.

Illumina's BeadArray™ technology is based on the random self-assembly of a bead pool onto a patterned substrate.[59] The patterned substrate may be an etched flat surface (glass or Si) or a bundle of fiberoptic fibers with etched cavities to accommodate one bead per fiber. Illumina's fiber bundle-based chip-making process is illustrated in Figure 7.120.

This elegant design starts by making a pool of hundreds of thousands of tiny glass beads (3-µm diameter), each batch coated with one (among 1500) type of oligonucleotide, DNA fragments that will seek and latch onto a specific sequence of a DNA sample. Each bead has only one type of oligonucleotide attached to it but consists of hundreds of thousands of copies. Next, the batches of beads are mixed to form a mixed "pool" (see Figure 7.120, panel 1). When a bundle of 50,000 optical fibers is dipped into this pool (Figure 7.120, panel 2), a single bead adheres to the end of each fiber (Figure 7.120, panel 3). The beads occupy the wells in a random distribution, and each bead is represented by, on average, about 30 instances within the array. An array of 8 × 12, or 96 fiber bundles (i.e., 96 independent arrays) with 50,000 light-conducting strands per bundle, is constructed to be compatible with standard microtiter plates used to carry out sample preparation and enzymatic steps before exposure of the beads in the array to the sample (Figure 7.120, panel 4). As a part of the array manufacturing process at the company, a decoding process is implemented to map the precise location of a specific bead type on the array.[59]

The decoding strategy involves sequential hybridization of differentially labeled probes to an address site on the array.[59] The differential labeling uses three states: carboxyfluorescein (FAM), labeled green; cyanine 3 (Cy3), labeled red; and not labeled. During any given cycle of the process, a bead is green, red, or blank. Dye-labeled oligonucleotides hybridize to the address sequence of each probe type in the hybridization or "decoding" process (Figure 7.121). Labeled decode oligonucleotides are hybridized to the arrays at high concentrations, which allows for rapid (several minutes) hybridizations, followed by washing to remove nonspecific signal and background. If one assigns a number to each state—0 to blank, 1 to green, and 2 to red—then each cycle of the process generates a trinary digit. If we look at one hypothetical probe, then the first round may be red, which generates 2 for the first digit. The second round is green and generates 1, so the number is now 21. The third round is red, so the number is now 212. Each round just adds a new digit to the

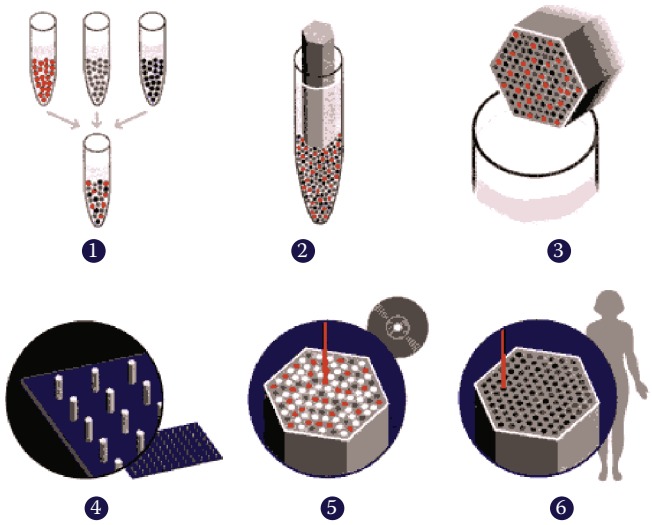

FIGURE 7.120 Illumina's BeadArray technology is based on the random self-assembly of a bead pool on fiber bundles; see text. (From Gunderson, K. L., S. Kruglyak, M. S. Graige, F. Garcia, B. G. Kermani, C. Zhao, D. Che, T. Dickinson, E. Wickham, J. Bierle, et al. 2004. Decoding randomly ordered DNA arrays. *Genome Res* 14:870.[59])

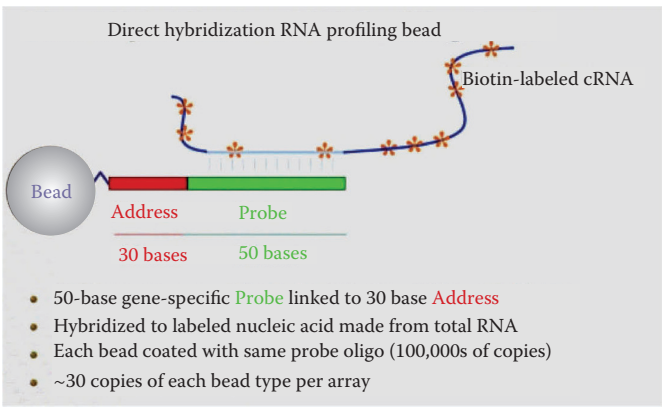

FIGURE 7.121 Gene-specific probes are attached to beads, which are then assembled into arrays. For simplicity, the diagram only shows one oligomer attached to the bead; actual beads have hundreds of thousands of copies attached per bead. The 50-base gene-specific probe is attached to a 30-base address. (From Gunderson, K. L., S. Kruglyak, M. S. Graige, F. Garcia, B. G. Kermani, C. Zhao, D. Che, T. Dickinson, E. Wickham, J. Bierle, et al. 2004. Decoding randomly ordered DNA arrays. *Genome Res* 14:870.[59])

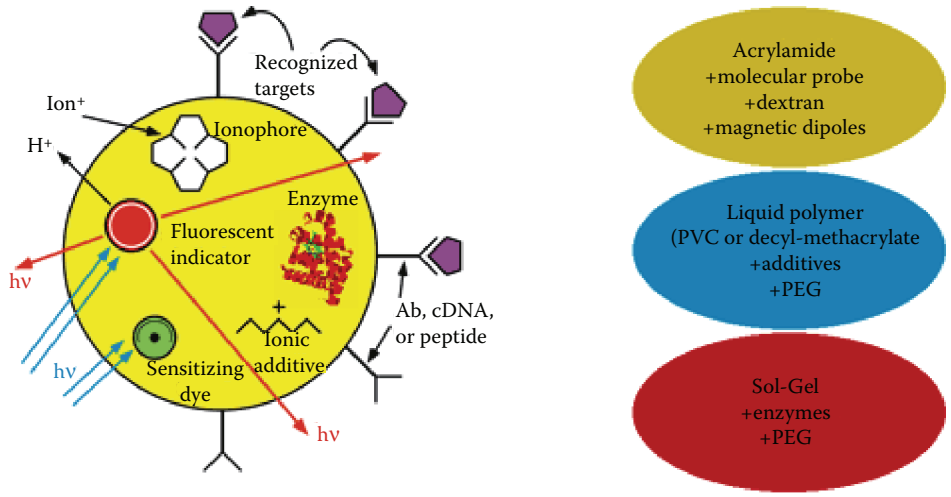
number. This continues until there are sufficient digits to uniquely identify each probe. One digit can uniquely identify three probes (0, 1, or 2). Two digits can uniquely identify nine probes (00, 01, 02, 10, 11, 12, 21, 22, or 23). Three digits can identify 27 probes (we will leave anything further as an exercise for the reader!). Rehybridization continues until there are sufficient data to unambiguously determine the identity of each bead. The physical location of each bead type is thus mapped by using a decoding algorithm[59] that tracks oligonucleotides successfully hybridizing to a specific address. With this compiled information, the physical location of each bead is mapped, and this unique map of all the oligo on the chip is stored on a CD-ROM that is shipped to the customer with the chip. The decoding process also serves as a quality control step for each feature of each array. The address sequences are designed to have no significant homology to genomic sequences within the species queried. Customers put all this to work by dipping the array into a specially treated DNA sample. As the sample wets the beads, each oligo looks for the unique DNA sequence it is built to detect. If the sequence is present, the oligo chemically binds to it and then lights up when a finely focused laser is beamed through the array; if the sequence is absent, the oligo stays dark. The resultant array is compared with the unique map on the CD-ROM to determine which oligonucleotide-bead combination is in each well. The decoded arrays may be used for a number of applications, including gene expression analysis and genotyping.

A high degree of miniaturization can be achieved by exploiting the intrinsic size of the beads and patterned substrate. For example, the density of a randomly assembled 300-nm diameter bead array is more than 40,000 times higher than a typical spotted microarray.[60]

PEBBLE Sensors

With most electrochemical electrodes and optodes, when it comes to penetrating individual live cells, even the introduction of a submicrometer sensor tip causes biological damage. Individual molecular probes (free sensing dyes), on the other hand, are physically small enough to enter biological cells without damage. Unfortunately, they often suffer from chemical interference between the probe and the cellular components. To solve this problem, Kopelman[61] developed PEBBLE (**p**robes **e**ncapsulated **b**y **b**iologically **l**ocalized **e**mbedding) nanosensors. These are nanoscale spherical devices consisting of sensor molecules entrapped in a chemically inert matrix, as shown in Figure 7.122a. PEBBLE is a general term that describes a family of matrices and nanofabrication techniques used to



(a) (b)

FIGURE 7.122 (a) PEBBLE (**p**robes **e**ncapsulated **b**y **b**iologically **l**ocalized **e**mbedding) nanosensors. (b) Three different matrices are commonly used depending on the sensor materials. (http://www.umich.edu/~koplab/index.htm.)

miniaturize optode technologies, thus filling a niche that lies between micro-optodes and free molecular probes (naked indicator dye molecules). PEBBLEs are designed specifically for minimally invasive analyte monitoring in viable, single cells with applications for real-time analysis of drug, toxin, and environmental effects on cell function. The main classes of PEBBLE nanosensors are based on matrices of polyacrylamide hydrogel, sol gel silica, and cross-linked decyl methacrylate (Figure 7.122b).[62] These matrices have been used to fabricate PEBBLE nanosensors for H^+, Ca^{2+}, K^+, Na^+, Mg^{2+}, Zn^{2+}, Cl^-, O_2, NO, glucose, etc. that range from 30–600 nm in size.

The protective coating of a PEBBLE eliminates interferences, such as protein binding and/or membrane/organelle sequestration, which might alter dye response. Conversely, the nanosensor matrix also provides protection for the cellular contents, enabling dyes that might usually be toxic to cells to be used for intracellular sensing. In addition, the inclusion of reference dyes allows quantitative, ratiometric fluorescence techniques to be used. A number of delivery methods of PEBBLE nanosensors to single cells have been tried, including gene gun, picoinjection, liposomal delivery, and sequestration (phagocytosis and pinocytosis) into macrophages. The gene gun can best be thought of as a shotgun for nanoparticles. The gene gun can be used to deliver one to thousands of PEBBLEs per cell into a large number of cells very quickly (http://www.umich.edu/~koplab/research2/analytical/NanoScaleAnalysis.html). Cell viability is excellent: 98% viability compared with control cells. Commercially available liposomes can also be used to deliver PEBBLEs to cells. In this case, liposomes are prepared in a solution of PEBBLEs and then placed in the cell culture, where they fuse with the cell membranes and empty their contents (the PEBBLE-containing solution) into the cell. Dourado and Kopelman[63] detailed the specific advantages of these types of nanoscale dimension optical sensors. They argue that the absolute detection limit decreases with the PEBBLE radius r as r^3 (good!), and the response time is reduced as r^2 (good!). The signal-to-noise (S/N) ratio, on the other hand, decreases with r (bad!), but at least not with r^3 (luckily!) under standard working conditions. Other features that improve as sensors get smaller include required sample volume, invasiveness, spatial resolution, dissipation of heat in sensor and/or sample, toxicity, and materials cost. Features that typically worsen include fluorophore leaching and photodamage to sensor and/or sample.

Comparison of Optical versus Electrochemical Sensors

In this chapter, we gave examples of both optical and electrochemical immunosensors. In Table 7.21, pros and cons of both approaches are summarized. Several features make electrochemical techniques attractive in immunosensing (especially of small molecules). Because accuracy is achieved

Table 7.21 Comparison of Optical and Electrochemical Immunosensors

	Optical	Electrochemical
Instrument cost	Often expensive	Always inexpensive
Sensor cost	Fair	Low
Turbid solutions	Problematic	Usually no problem
Dynamic range	Limited	Very wide
Selectivity	Good	Fair
Sensitivity	Very good	Good
Simplicity of method	Often simple	Simple
Color	Sometimes problematic	No problem
Species size	Better for larger molecules	Better for smaller molecules
Electromagnetic interference (EMI)	No	Yes
Resistance to radiation and corrosion	Yes	No
Cross-talk	No	Yes
Ambient light	Problem (must be modulated)	No problem
Response curve	Sigmoidal	Nernstian (potentiometric) or linear

independent of color and turbidity of the solution, rapid measurements are often obtained with less tedious sample preparation. In principle, analysis of a whole range of analytes in matrices as complex as whole blood can be done. Electrochemical probes are easy to use as analytical tools for measuring ions and neutral molecules, typically in a range of 1 M to 1 μM. Examples of even wider dynamic ranges also exist. Coupled with chemical amplification (enzyme or liposome), lower detection limits of picomoles per liter have been attained. In addition, the sensor is inexpensive. Using optical techniques, one partner of the immunochemical complementary pair is typically immobilized onto a surface with some optical characteristics modified when binding takes place. In optical sensing, the signal is not subject to electrical interference, no reference electrode is required, and simultaneous measurement of two or more analytes is possible by measuring at two or more wavelengths. Whereas classical optical assays rely mostly on absorption spectroscopy, luminescence in the form of fluorescence or phosphorescence (depending on the excited state being single or triplet) is more important for immunosensors. Electrochemical detection tends to be better for small molecules, whereas optical techniques are better suited for large molecule detection.

From a more global perspective, comparing electrochemical with optical methods, we start by pointing out again that electrochemical methods are not affected by color and turbidity of the solution, are very low cost, and have the potential to do elemental speciation (e.g., Fe^{2+} vs. Fe^{3+}).

Questions

7.1: Show how the Butler-Volmer expression leads to an ohmic resistance at low over-potentials.
Thanks to Dhondup Pemba, UC Irvine

7.2: What is a Jablonski diagram?
Thanks to Elisa Morganti, UC Irvine

7.3: Calculate the decay time or ring-down time in cavity ring-down spectroscopy (CRDS).
Thanks to Arezoo Motavalizadeh Ardekani, UC Irvine

7.4: How does the electric double layer (EDL) arise and what are the four theoretical models that attempt to describe the structure of the EDL?
Thanks to Derek So, UC Irvine

7.5: Are ISFETs potentiometric or amperometric devices? Explain the difference between the two types of devices. What does MOSFET stand for and what are the differences between the electrical circuits of an ISFET and a MOSFET?
Thanks to Han Wu, UC Irvine

7.6: In infrared absorption spectroscopy one measures the absorption of the infrared radiation at specific wavelengths that match the energy of vibrational transitions of a molecule. Raman spectroscopy is a complementary technique also based on vibrational transitions. In what ways does Raman spectroscopy differ from infrared (IR) spectroscopy and what advantages does it offer over IR spectroscopy?
Thanks to Kiavash Koko, UC Irvine

7.7: Explain how the Fermi level of a metal electrode regulates electron transfer from the metal electrode to the redox molecules in solution
Thanks to Neil Olson, UC Irvine

7.8: What are two typical optical absorption spectrometers? Explain how they work. Compare these two types.
Thanks to Omid Rohani, UC Irvine

7.9: How do absorbance spectroscopy and fluorescence differ experimentally, and consequently what benefits does fluorescence have to offer?
Thanks to Christopher Clawson, UC Irvine

7.10: Match the following terms with the appropriate definitions:

(1) Fluorophore	(a) Crystals composed of materials from periodic groups II-VI, III-V, or IV-VI and can be conjugated to biomolecules

(2) Stokes shift	(b) Method used to measure the ability of a molecule to move around in a cell over time
(3) FRAP	(c) Intense fluorescent probe used in many biological studies
(4) Quantum dots	(d) Difference in wavelength between fluorescence excitation maximum and the fluorescence emission maximum
(5) Green Fluorescent Protein	(e) Molecule that can be excited by light to emit fluorescence

Thanks to Youssef Farhat, UC Irvine

7.11: Given the concentration of Cu^{2+} in a first solution, design an amperometric sensor to measure the concentration of any other unknown Cu^{2+} solution.
Thanks to Chuan Zhang, UC Irvine

7.12: What is the most commonly used type of spectroscopic technique? How does one representative technique of this type work? Does it scale well in the micro domain compared to other spectroscopic techniques?
Thanks to Irena Aleksieva, UC Irvine

7.13: What are the advantages of using ultra-micro electrodes (UMEs)?
Thanks to Megan Jacks, UC Irvine

7.14: The Ag/AgCl reference electrode is an electrode of the first or second kind? How is the potential of this electrode fixed constant?
Thanks to Mary Amasia, UC Irvine

7.15: Derive absorbance using $dP = -Pc\beta dx$, where c = molar concentration, P = light intensity, β = probability of a photon being absorbed.
Thanks to Kim Bui, UC Irvine

7.16: What does it mean that the standard reduction potential is an intensive property?
Thanks to Kevin Ko, UC Irvine

7.17: Why is the miniaturization of a reference electrode such a challenge?
Thanks to Michelle Tu, UC Irvine

7.18: Given the following galvanic cell and half reactions:
$Au^{3+} + 3e^- \rightarrow Au \qquad E^0 = 1.50$
$Tl^+ + e^- \rightarrow Tl \qquad E^0 = -0.34$
Determine the following:
(a) Overall cell reaction and E^0_{cell}
(b) $\Delta G°$ for the cell reaction at 25°C
(c) Calculate E_{cell} at 25°C when $[Au^{3+}] = 1.0 \times 10^{-2}$ M and $[Tl^+] = 1.0 \times 10^{-4}$
Thanks to Andrew Sumarto, UC Irvine

7.19: There are two carbon electrodes arranged in an electrochemical cell. On one hydrogen is evolving and on the other Ag is being deposited. 1 h after passing current, 95 cm^3 H_2 (g) (19°C, 99.19 KPa) is collected on the hydrogen electrode, while 0.8368g Ag is deposited on the Ag electrode. Use the given information to calculate the current through the circuit.
Thanks to Xi Wang, UC Irvine

7.20: Match each term with the proper definition:
Thanks to Muhammad Uneib, UC Irvine

7.21: What's the ratio of the van der Waals forces between two atoms at a distance of 1 nm and the same atoms at a distance of 3 nm?
Thanks to Elaheh Shekaramiz, UC Irvine

7.22: Under what conditions do oxide semiconductors or nonoxide semiconductors with a native oxide fail to function as pH sensors?
Thanks to Geethika Alapati, UC Irvine

7.23: Explain the differences between electrodes of the first kind and electrodes of the second kind.
Thanks to Nelson Jen, UC Irvine

7.24: Draw the equivalent electrical circuit of a metal/electrolyte interface with the electrode at a potential so that a redox reaction occurs.

7.25: Calculate the potential of a battery with a Zn bar in a 0.5 M Zn^{2+} solution and Cu bar in a 2 M Cu^{2+} solution.

7.26: Show in a cyclic voltammogram the transition from kinetic control to diffusion control and why it really happens.

7.27: Derive how the capacitive charging of a metal electrode depends on the potential sweep rate.

7.28: Calculate the potential difference between two Pt electrodes immersed in two different solutions connected via a salt bridge. The first solution has 1 M KCl and 10^{-1} M Fe^{2+} and the second has 1 M KCl and 10^{-5} M Fe^{3+}.

7.29: What are the requirements of a good reference electrode? What is a double junction reference electrode, and in what cases is it useful?

7.30: Define sensitivity, detection limit, and selectivity in an analytical method.

7.31: What is the effect of the following parameters on the quantum yield of fluorescence?
(a) Raising the temperature.
(b) Adding a heavy atom to the solvent.
(c) Lowering solvent viscosity.
(d) What is the physical process that makes phosphorescence rare?

7.32: In the last few years, applications of quantum dots have become increasingly popular among analytical chemists. Quantum dots are now commercially available for a variety of applications, and many examples of their uses can be found in the literature. Briefly describe what quantum dots are and describe their applications.

7.33: Briefly state the difference between fluorescence and phosphorescence.

7.34: In potentiometry:
(a) What is a "junction potential"?
(b) What does the acronym ISE stand for?
(c) What are the components of ISEs?
(d) Give an example of an ISE.

7.35: How does Raman spectroscopy work?
Thanks to Elisa Morganti, UC Irvine

7.36: In a fluorescence measurement setup, which emitted photons are monitored? Why?
Thanks to Omid Rohani, UC Irvine

7.37: Define photobleaching. Identify an analytical technique that uses photobleaching and describe what kind of information it can provide about the membrane of a cell.
Thanks to Kiavash Koko, UC Irvine

7.38: What problem of conventional multipass approaches does cavity ring-down spectroscopy (CRDS) overcome, and how does it do this?
Thanks to Christopher Clawson, UC Irvine

7.39: What are fluorescence, chemiluminescence, and bioluminescence spectroscopy? Give an example of each technique. Why are chemiluminescence and bioluminescence spectroscopy preferred over fluorescence spectroscopy?
Thanks to Irena Aleksieva, UC Irvine

Couette shear flow, 448–449
3D vector equations, 437
Hagen–Poiseuille's law, steady duct pipe flow, 449–450
hydrostatics, 446
momentum equation
convective fluid transport, 441
falling sphere (I), viscid regime, 443
heat transfer problem, 441
scaling parameters, 442–443
total change of momentum, 442
x-momentum, 442
unidirectional flow, two infinite plates, 447–448
viscid, inviscid, and Froude flow
Boltzmann's constant, 444
diffusion constant, 444
drag coefficient, 444–445
falling sphere (II), inviscid flow, 445
Froude number, 446
gravitational forces, 446
Reynolds number, 444–445
Near-field diffraction, 302–303
Near-field scanning optical microscopy (NSOM). *See* Plasmonic applications 3
NEMs. *See* Nano-electromechanical systems

O

Optical properties of metals
conductors, EM radiation
absorption coefficient, 361
AC conductivity, plasma, 361
complex dielectric constant, 361
penetration/skin depth, 362
reflectance, 360–361
Drude–Lorentz theory
bound and conduction electrons, 363
free electrons and interband transitions, 364
ITO, 365
photon energy, 364
effective dielectric constant, 360, 363
energy *vs.* reflectance, 360
nanoparticles
absorption spectrum, 369
alchemists, 367
aspect ratio, 369–370
electromagnetic radiation, 367–368
electromagnetic wave interaction, 367
electron density, 368
energy absorption, 368
extinction coefficient, 369
gold and silver, 367
gold nanocages, 370
localized plasmons, 367
Lycurgus Cup, 366
metal shell, 370
nanoshell resonance frequency, 370
parameter α, 368
particle size, 367
quantum effects, 365–366
Renaissance pottery, 366
resonance, 369
resonance frequency and condition, 370–371
scattering, 368
surface plasmon bands, 367

plasma frequency, 359–360
reflectance curves, 360
surface plasmon applications II, 370, 372–373

P

Particle distributions functions
average interparticle spacing, 160
Bose–Einstein distribution, 162–163
de Broglie temperature, 160
Fermi–Dirac distribution
Boltzmann approximation, 160
electronic velocity vector component distribution, 161–162
energy and temperature, 161
exclusion principle, 160
Fermi energy, 161
Fermion and boson particle, 160–161
function of temperature, 161
heat capacity, 162
Pauli's principle, 160
thermal de Broglie wavelength, 159–160
Photodiode, 250–251
Photoelectric effect
classical wave model, 97
Einstein's light particles photons, 98–99
experimental setup, 97
frequency of incident light, 97–98
Planck's hypothesis, 98
Photoluminescence
fluorescence
analytical chemistry and scaling, 604–605
autofluorescence, 603
excited singlet and triplet states, 601–602
fluorescence quantum yield and lifetime, 603
fluorescent proteins, 613–614
fluorophores (*see* Fluorophores)
Franck–Condon principle, 602
Jablonski diagrams, 601
light-emitting phenomena, 602
quantum dots (*see* Quantum dots)
radiative processes, 601
reagent background, 603
singlet ground state, 601–602
spectrofluorometers and microplate readers, 604
Stokes law, 602
Stokes shift, 603
phosphorescence, 619
2D and 3D Photonic crystals manufacturing
holographic lithography, 409
inverse opal, 408
LPCVD, 409
macroporous silicon, 408
microwave range, 407–408
self-assembled silica opals, 409
synthetic opals, 408
two-photon lithography, 409
Yablonovite, 407
Photonics
beyond Maxwell
Einstein's general relativity, 348–349
Einstein's special relativity, 347–348
Lorentz transformation, 345–347
diffraction and image resolution
Abbe's limit, 304–306
far field and near field, 302–303
image definition, 303–304
Rayleigh's limit, 306–308
Galilean transformation, 299–300
lasers
masers, 423–426
quantum mechanics, 426–431
light interaction, small particles
geometric scattering, 397
light scattering, 386–388
Mie scattering-elastic scattering, 395–397
plasmonic applications 3, 397–402
Raman scattering-inelastic scattering, 392–395
Rayleigh scattering-elastic scattering, 388–391
light polarization, 311–312
Maxwell's equations
Ampère's law, 314–315
birefringence-double refraction, 326–328
characteristic vacuum and medium impedance, 323–324
curl equations, 318
Dirac's quantum field theory, 313
dispersion relation, 324–325
electromagnetic waves (*see* Electromagnetic (EM) waves)
electrostatics and magnetostatics, 318–319
Faraday's law, 316–317
Gauss and Stokes theorems, 313–314
Gauss' law for electric fields, 315–316
Gauss' law for magnetic fields, 316
mathematical formulation, 317
permittivity, 317
plane wave propagation, 318–319
plane wave solutions (*see* plane wave solutions)
plasmonics (*see* Plasmonics)
ray optics, 312
refractive index, 313
right-and left-handed materials, 325–326
time varying equations, 317–318
vector fields, 313
wave equations (*see* Wave equations, medium)
nature of light
cellular phones, 301
EM spectrum, 300–301
EM vibration, 300
EM wave formation, 301–302
far field and near field, 301
field lines, 301
gravitational lensing, 302
Maxwell's description, 300
plane waves, 301
visible light, 301
optical properties of materials
classification, 349
dielectrics (*see* Lorentz model for dielectrics)
Drude–Lorentz model (*see* Drude–Lorentz model)
generalized dispersion relation, 376–378
Lorentz model for semiconductors, 378–386
metals (*see* optical properties of metals)
microscopic origin, frequency dependency, 349–350
quantum dots *vs.* metal nanoparticles, 386
photons *vs.* electrons
applications, 413–414
Bloch invention, 405
Coulomb potential, 404
dispersion relationships, 404
lattice structure, 404–405
Maxwell's equations, 402–403
photonic bandgap, 405–407
photonic crystal optic fibers, 411–413
photonic crystals defect, 409–411
2D and 3D photonic crystals manufacturing, 407–409
prism effect, 411–412
wavelength, 402, 404
μ-ε quadrant and metamaterials
dispersion equation, 416
EM properties, 414–415
ideal lens, 420–423
left-handed materials, 416–420
plane representation, 416–417
right-hand rule, 416
reflectance and total internal reflectance, 310–311
refraction
refractive index, 309–310
Snellius law, 308–309
Planck constant, 109–110
Planck's hypothesis, 98
Plane wave equations, 70–71
Plane wave solutions
E⊥B⊥k, 322–323
E⊥k and B⊥k, 322
media with charges/current, 323
propagation, 321

Plasmon bands. *See* Surface plasmon bands
Plasmonic applications 3
  applications, 401–402
  diffraction limit break
    aperture-based proximal probes/tips, 399–400
    electron microscope, 397
    high-resolution imaging, 398
    lensless optics, 398
    light detection, 398
    local field enhancement technique, 400–401
    luminescent quantum dot imaging, 400
    near-field and far-field imaging, 397–398
    NSOM tip, 398–399
    perturbation, 400
    scattering based NSOM, 399
    SNOM, 398
    surface plasmon radiation, 400
  pros and cons, 401
Plasmonics
  applications
    AC current, 344
    information transmission, 343
    lithography, 345
    local electric fields, 345
    optical fibers, 343–344
    photonic device, 344–345
  bulk plasmons, 338–339
  EELS, 338
  localized plasmons, 343
  plasmon, 338
  polaritons types, 338
  subwavelength resolution, 337
  surface plasmons
    decay lengths, 343
    dielectric constant, 340, 342
    dispersion, 341–342
    eigenmodes, 339–340
    excitation methods, 342
    localized surface mode, 340
    metal/dielectric interface, 339
    momentum, 341
    optical frequencies, 341
    permittivity, 341
    polarization charges, 339–340
    p-polarization, 339
    quantum mechanics, 339
    transverse electric and magnetic field, 339–340
    wave vector, 340–341
Point spread function (PSF), 306–307
Poisson equation, 316
Polarizing/Brewster polarizing angle, 312
Polaroid, 312
Potentiometric sensors
  EGFET, 588
  ISFET
    CHEMFETS, 585
    Debye shielding, 586–587
    gate dielectrics, 586
    IC compatibility and drift, 587
    MOSFET, 585–586
    need for reference electrode, 586
    pH sensitivity, 585
  potentiometric immunosensors
    direct binding/label-less assays, 591
    DNA probes, 588
    ELISA, 589–590
    GOx enzyme, 589
    heterogeneous assay, 590
    immunoassay, 588–589
    micromachined potentiometric immunosensors, 591–593
    noncompetitive/sandwich assay, 590
    sensitivity, 590–591
    SWNTs, 590
Pseudoplastics, 437

Q

Quantum confinement
  bulk materials
    Brillouin zones, 165–169
    density of States, 169–172
    electronic conductivity, 172–175
    Fermi surface, 164–165
  DOS function, 164
  quantum dots (*see* Quantum dots)
  quantum wells (*see* Quantum wells)
  quantum wires (*see* Quantum wires)
  reduced-dimensional material geometries, 164
Quantum dots (QDs), 384
  BeadArray™, 612
  biomolecule conjugation schemes, 611
  CdS and ZnSe dots, 609
  CdSe QDs, 609–610
  colloid stabilizer, 610
  definition, 608
  density of states function, 189–190
  DNA microarray assays, 611
  electronic conductivity, 190–191
  Fermi surfaces and Brillouin zone, 188–189
  3-(mercaptopropyl) trimethoxysilane, 610
  vs. organic dyes, 610
  quantization, 188
  RSD, 609
  spectral barcodes, 612
Quantum electron dynamics, 209
Quantum mechanics and lasers
  photonic crystal, 431
  quantum cascade lasers
    degree of freedom, 431
    electron transitions, 430
    Esaki tunnel diode, 427
    GaAs, 428
    minibands formation, 430–431
    MOCVD, 428–429
    quantum well, 429
    resonant tunneling diode, 427–428
    superlattice, 428–429
  quantum confinement, 426–427
Quantum numbers
  fourth quantum number, electron spin, 106
  magnetic number, 105–106
  principal quantum number, 104–105
  properties, 107
  second quantum number, 105
Quantum wells
  density of states
    bound-state energies, 179
    1D confinement, 177–178
    2D electron gas, 178
    frequency dependence, 179
    optical transitions, 178–179
  electronic conductivity, 179–180
  Fermi surfaces and Brillouin zone, 177
  GaAs and $Al_xGa_{1-x}As$ layer, quantization
    blue shift, 177
    electron energy levels, 176–177
    electronic conductivity, 179–180
  Schrödinger's equation
    charge carriers, 128
    HEMT, 128
    one dimension, 127
    semiconductor heterostructures, 128
    Sommerfeld's mathematical model, 125
Quantum wires
  density of states function, 182–183
  electronic conductivity
    Bloch's theorem, 183
    conductance quantization, 186
    density of states, 183–184
    one-dimensional wire, 184–185
    quantized resistance, 185
    Van Hove singularities, 184
  Fermi surface, 182
  quantization
    2D quantum gas, 180–181
    energy dispersion function, 181
    $GaAs/Al_xGa_{1-x}As$ heterojunction, 181
    square cross-section, 182

R

Radiation pressure, 329
Radio detecting and ranging (RADAR), 7
Raman (inelastic) scattering
  advantages, Raman spectroscopy, 393
  chemical adsorption, 395
  decay curves, 394–395
  disadvantages, 393
  field and signal enhancement, 393
  gain, 394
  molecules polarizability, 392

physicist, Chandrasekhara Venkata Raman, 392
Raman shift, 392
Raman spectrum of CCl_4, 392
Raman *vs*. IR spectroscopy, 392–393
SERS, 393
Stokes lines, 392
total enhancement factor, 393–394
wavelength discovery, 392
Randles–Sevcik equation, 580
Random access memory (RAM), 10–11
Rayleigh's limit
Airy pattern, 306
circular aperture diffraction, 306
Fraunhofer diffraction patterns, 307
lens magnification, 307–308
lithography resolution, 308
numerical aperture, 308
PSF, 306–307
Rayleigh criterion, 307–308
small circular aperture, 307–308
smallest object radius, 307
Ray optics. *See* Geometric optics
Reciprocal space
definition, 57–58
diffraction pattern, 56
Ewald construction, 59–60
explicit algorithm, 58–59
graphical presentation, 57
Relative permittivity, 350
Relative standard deviation (RSD), 609
Reynolds number
hydraulic diameter, 454
hydrodynamic layer thickness, 454–455
intermolecular viscous forces, 454
laminar/turbulent flow, 453–454
mobile machines, 454
Right-handed materials (RHMs), 325–326
Rutherford experiment, 101–102

S

Scanning near-field optical microscopy (SNOM), 398
Scanning tunneling microscope (STM), 21
Schrödinger's equation
Born and von Karman's periodic boundary condition, 124–125
cat-like state of matter, 209–210
finite-depth potential wells, 134–136
finite height barriers, 136–137
free electrons, infinitely large 3D piece of metal, 124
free particles, wave function, 123–124
Hamiltonian, 116
harmonic potential wells, 140–141
infinitely deep, finite-sized 1D potential wells
boundary conditions, 125–126
dispersion function, 126–127
eigenfunctions, 126
energy levels, 126
probability distribution, 127
quantum wells (*see* Quantum wells)
Sommerfeld's mathematical model, 125
wave number, 126
infinitely deep, finite-sized 2D potential wells
vs. 1D potential wells, 129–130
quantum wires, 130–131
wave functions and energies, 129
infinitely deep, finite-sized 3D potential wells
energy levels, 131
k-states, 131–132
quantum dots, 132–133
wave vectors, 131
interfaces, 139–140
plausibility, 119–121
TISE, stationary states, 122
tunneling, 137–139
two-dimensional representation, 116
wave function interpretation, 121–122
zero point energy, 133–134
Sedimentation potential, 538
Severinghaus sensor, 563
SHE. *See* Standard hydrogen electrode
Silicon in integrated circuits
Apple I and II, 11
Babbage, analytical engine, 7
business, 13
Colossus coding and deciphering machine, 7
Crookes experiment, 5
crystal set radios, 6
De Forest, Lee, 6
Edison effect, 5–6

Shockley, Bardeen, and Brattain invention, 8
transferred resistance, 8
types of components, 9–10
vacuum tubes, 6, 12
von Neumann, John, 8
Silicon single crystal (SSC)
crystal growth
Czochralski (CZ) crystal pulling method, 225–226
float zone crystal growth, 226
monocrystalline silicon wafer, 227
silicon boules, 226–227
wafer flats, 226–227
crystallography
diamond-hexagonal silicon, 216
diamond-type lattice, 216
energy bandgap difference, 216
FCC lattices, 216
MEMS structure, 217–218
silicon substrates, 217
silicon wafers, 217
diffusion
activation energy, 231–232
boundary condition, 230
diffusion coefficient, 232
dopant diffusivities, 232
dopant surface concentration, 230–231
drive-in diffusion, 231
Fick's first law, 229
Fick's second law, 229
gaseous doping, 229–230
gradients, 230
impurity profile, 232
vs. ion implantation, 233
lateral diffusion, 232
mechanisms, 229
oxide film, 228
two-step junction formation, 231
wafer coating, 228–229
extrinsic *vs*. intrinsic semiconductors, 227–228
ion implantation, 229, 233–234
mechanical sensors
elasticity constants, 277–278
piezoresistivity, 281–285
residual stress, 278–279
stress-strain behaviors, 275–277
MEMS, biocompatibility, 290–293
optical properties, 288–289
[100]-oriented silicon, 218–222
[101]-oriented silicon, 222–223
oxidation
Bruce Deal–Andy Grove model, 238
field oxidation, 240
fluxes, 238
gas-phase oxidation method, 237–238
gate oxide thickness, 245
high-pressure oxidation, 240
kinetics, 241–242
LOCOS process, 240–241
nonthermal methods, 242–243

oxide thickness color, 239
parabolic law, 239
semiconductors, 237
shallow trench isolation, 240
silicon and oxide thickness, 238
silicon dioxide growth, 237
silicon dioxide thickness *vs.* growth time, 238–239
thermal oxides, 239
thermal SiO_2, properties, 243–245
ultrathin oxides, 240
structure and conductivity, 222–225
thermal properties, 288
transistors (*see* Transistors)
Single-wall carbon nanotubes (SWNTs), 590
Solar cells, 251–252
Solid-state p-n junction diode, 246
Sound navigation and ranging (SONAR). *See* Radio detecting and ranging
Specific heat capacity, 89–90
SSC. *See* Silicon single crystal
Standard hydrogen electrode (SHE), 545–546
Stern potential, 536
Streaming potential, 537
Surface-enhanced Raman scattering (SERS), 393
Surface plasmon bands, 367

T

Thermal conductivity, 90–93
Thermalization process, 381–382
Time-independent Schrödinger equation (TISE), 122
Tin-doped indium oxide (ITO), 365
Transistors
bipolar junction transistor
vs. BiCMOS, 255
vs. CMOS, 255
elements, 254
high *vs.* low-resistance circuit, 255–256
planar process, 254–255
p-n diodes, 254
bipolar transistors, 254–256
FinFET approach, 273
MOSFETS (*see* Metal-oxide-semiconductor field-effect transistor)
Traveling wave dielectrophoresis (TWD), 490–491

U

Ultramicroelectrodes (UME)
advantages, 583
CNT arrays, 583
Cottrell equation for planar diffusion, 582
diffusion layer thickness, 581–582
diffusion-limited current, 582
Kelgraf electrode, 583
LIGA process, 584
microelectrodes, 582–583
nonlinear diffusion, 584
types, 581
UV/VIS absorption spectroscopy, 595–598

V

Valence band maximum (VBM), 379
Van der Waals forces
definition, 524
dipole-dipole interactions
hydrogen bonding, 526–528
Keesom equation, 524–525
dipole-induced dipole interactions, Debye, 525
dispersion forces, 524
induced dipole-induced dipole, dispersive/London forces, 525–526
solid surfaces
energy of adhesion, 530
Hamaker constants, 530
interaction potentials, 531
for molecules, 529
sphere-plane interaction, 531–532
surface energy, 530–531
A/V ratio, 532
types, 524
Velocity of charge carriers, 156–157
Vertical cavity surface-emitting lasers (VCSELs), 426
Voltammetry, 553–554
Voltammogram, 553

W

Wave equations, medium
with charges and currents, 320–321
without charge/current, 319–320
Wave velocity, 309
Working electrode, 552
Worldwide IC and electronic equipment, 32–33

X

X-ray diffraction
Bragg's law, 49–50
discovery, 48
electron density map, ATP, 49
electron density/molecular structure image, 49–50
Fourier transform, 49
Laue equations
connection with Bragg's law, 52–53
diffraction angles, 50
Henry and Bragg, 52
incident x-ray beam scattering, 51
magnitude of vector, 53
reflection, 52
sodium deoxyribose nucleate, 53
two cones, 51
two scattering atoms, 50–51
von Laue's photography, 52
pattern, 48–49
phase problem, 49
x-ray intensity and structure factor
Fraunhofer diffraction patterns, 54
Fresnel diffraction patterns, 53–54
interference, 55
lost phase regeneration, 54
phase problem, 54, 56
scattering, x-ray, 54
spatial frequency spectrum/harmonic analysis, 54
wave amplitude, 54–55
wave vector, 56
$y = \sin^2 Mx/\sin^2 x$ plot, 55–56

Z

Zener diode, 252
Zero point energy (ZPE), 541–542

I dedicate this third edition of Fundamentals of Microfabrication to my family in the US and in Belgium and to all MEMS and NEMS colleagues in labs in the US, Canada, India, Korea, Mexico, Malaysia, Switzerland, Sweden and Denmark that I have the pleasure to work with. The opportunity to carry out international research in MEMS and NEMS and writing a textbook about it has been rewarding in terms of research productivity but perhaps even more in cultural enrichment. Scientists have always been at the frontier of globalization because science is the biggest gift one country can give to another and perhaps the best road to a more peaceful world.

Roadmap

Manufacturing Techniques for Microfabrication and Nanotechnology consists of three parts and ten chapters.

In Part I, we review different forms of lithography, detailing those that differ most from the miniaturization processes used to fashion integrated circuits (ICs). Chapter 1 starts with a short historical note about the origins of lithography, followed by a description of photolithography, including developments that have allowed the printing of the ever-shrinking features of modern ICs. After reviewing the limits of photolithography, we detail alternative next-generation lithographies (NGEs) in Chapter 2, including extreme ultraviolet (EUV), x-ray, and charged-particle (electron and ion) lithographies, followed by lithography techniques in the early research and development (R&D) stage. Lithography approaches in the R&D stage include very thin resist layers and block copolymers, zone plate array lithography (ZPAL), quantum lithography (two-photon lithography), and proximal probe-based techniques such as atomic force microscopy (AFM), scanning tunneling microscopy (STM), dip-pen lithography (DPL), near-field scanning optical microscopy (NSOM), and apertureless near-field scanning optical microscopy (ANSOM). Also considered are holographic lithography, plasmonic lithography, and lithography with superlenses ("Pendry's dream"). As an example of a lithography method that is capable of patterning resist on nonplanar substrates (e.g., patterning a resist on the surface of a cylinder) we detail soft lithography.

In Part II we deal with material removal processes, and additive technologies are the focus of Part III. We review gas and vapor phase dry etching processes, including chemical, physical (purely mechanical), and chemical-physical (mostly chemical with some mechanical assist) in Chapter 3. Chapter 4 consists of two parts: one covers wet *chemical etching* and the other *wet bulk micromachining*, the latter being chemical etching as well but optimized for the manufacture of ICs, nano-, and micromachines. Chapter 5 discusses thermal removing techniques where thermal energy, provided by a heat source, melts and/or vaporizes material from the work piece. Examples of thermal techniques covered in this chapter are electric discharge machining (EDM) (including μ-EDM), laser- and electron-beam machining (LBM and EBM), and plasma arc cutting. In Chapter 6, we cover traditional and nontraditional mechanical removing techniques. Traditional mechanical material removing technologies covered are mechanical precision machining and abrasive wheel machining. In nontraditional mechanical machining, we deal with ultrasonic drilling, electrolytic in-process dressing (ELID) grinding, water jet, abrasive water jet, abrasive jet machining, and focused ion-beam milling (FIB). Also in this chapter, we highlight recent developments toward miniaturized mechanical manufacturing equipment, the so-called desktop factories.

In Part III we cover additive (forming) processes, where materials are added, usually in a selective manner, to a work piece or a device under construction. Physical vapor deposition processes (PVD) and chemical vapor deposition (CVD) are topics of Chapter 7. In the same chapter we survey thin film properties and detail surface micromachining, an important application of thin film deposition techniques. In surface micromachining, features are built up, layer by layer, on the surface of a substrate (e.g., a single-crystal silicon wafer). Dry etching defines the surface features in the x,y-plane, and wet etching releases them from the plane by undercutting. In surface micromachining, shapes in the x,y-plane are unrestricted by the crystallography of the substrate. In Chapter 8 we discuss additive chemical, photochemical, and electrochemical processes. The chemical forming methods covered in Chapter 8 are geared toward BioMEMS applications. In photochemical forming, photoenergy solidifies a material into a 3D shape, as illustrated in rapid prototyping and microphotoforming (stereolithography). In the case of electrochemical forming, the energy at the work piece is electrochemical. Chapter 9 covers thermal forming techniques where thermal energy provided by a

heat source "transforms" a material as in crystallization, sintering, alloying, annealing, decomposition, and pyrolizing. Replication methods based on plastic molding and LIGA—a sophisticated type of replication technique combining x-ray lithography with electroplating and plastic molding—are discussed in Chapter 10. Plastic molding techniques include RIM, thermoplastic injection molding (IM), and compression molding or hot embossing.

Note to the Reader: *Manufacturing Techniques for Microfabrication and Nanotechnology* was originally composed as part of a larger book that has since been broken up into three separate volumes. *Manufacturing Techniques for Microfabrication and Nanotechnology* represents the second volume in this set. The other two volumes include *Solid-State Physics, Fluidics, and Analytical Techniques in Micro- and Nanotechnology* and *From MEMS to Bio-NEMS: Manufacturing Techniques and Applications*. Cross-references to these books appear throughout the text and will be referred to as Volume I and Volume III, respectively. The interested reader is encouraged to consult these volumes as necessary.

Author

Dr. Madou is the Chancellor's Professor in Mechanical and Aerospace Engineering (MEA) at the University of California, Irvine. He is also associated with UC Irvine's Department of Biomedical Engineering and the Department of Chemical Engineering and Materials Science. He is a Distinguished Honorary Professor at the Indian Institute of Technology Kanpur, India, and a World Class University Scholar (WCU) at UNIST in South Korea.

Dr. Madou was Vice President of Advanced Technology at Nanogen in San Diego, California. He specializes in the application of miniaturization technology to chemical and biological problems (bio-MEMS). He is the author of several books in this burgeoning field he helped pioneer both in academia and in industry. He founded several micromachining companies.

Many of his students became well known in their own right in academia and through successful MEMS start-ups. Dr. Madou was the founder of the SRI International's Microsensor Department, founder and president of Teknekron Sensor Development Corporation (TSDC), Visiting Miller Professor at UC Berkeley, and Endowed Chair at the Ohio State University (Professor in Chemistry and Materials Science and Engineering).

Some of Dr. Madou's recent research work involves artificial muscle for responsive drug delivery, carbon-MEMS (C-MEMS), a CD-based fluidic platform, solid-state pH electrodes, and integrating fluidics with DNA arrays, as well as label-free assays for the molecular diagnostics platform of the future.

To find out more about those recent research projects, visit http://www.biomems.net.

Acknowledgments

I thank all of the readers of the first and second editions of Fundamentals of Microfabrication as they made it worthwhile for me to finish this completely revised and very much expanded third edition. As in previous editions I had plenty of eager reviewers in my students and colleagues from all around the world. Students were especially helpful with the question and answer books that come with the three volumes that make up this third edition. I have acknowledged reviewers at the end of each chapter and students that worked on questions and answers are listed in the questions sections. The idea of treating MEMS and NEMS processes as some of a myriad of advanced manufacturing approaches came about while working on a WTEC report on International Assessment Of Research And Development In Micromanufacturing (http://www.wtec.org/micromfg/report/Micro-report.pdf). For that report we travelled around the US and abroad to visit the leading manufacturers of advanced technology products and quickly learned that innovation and advanced manufacturing are very much interlinked because new product demands stimulate the invention of new materials and processes. The loss of manufacturing in a country goes well beyond the loss of only one class of products. If a technical community is dissociated from manufacturing experience , such as making larger flat-panel displays or the latest mobile phones, such communities cannot invent and eventually can no longer teach engineering effectively. An equally sobering realization is that a country might still invent new technologies paid for by government grants, say in nanofabrication, but not be able to manufacture the products that incorporate them. It is naïve to believe that one can still design new products when disconnected from advanced manufacturing: for a good design one needs to know the latest manufacturing processes and newest materials. It is my sincerest hope that this third edition motivates some of the brightest students to start designing and making things again rather than joining financial institutions that produce nothing for society at large but rather break things.

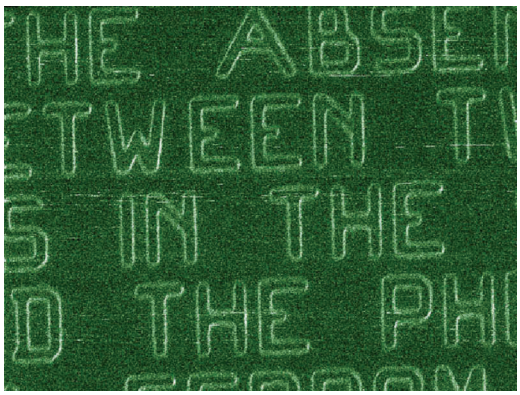
Introduction to Part I

Chapter 1 Photolithography
Chapter 2 Next-Generation Lithographies (NGLs) and Lithography Research

Introduction to Part I

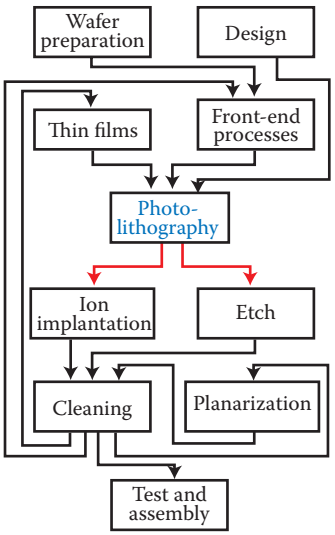
For many miniaturization tasks, lithography, the technique used to transfer copies of a master pattern onto the surface of a solid material such as a silicon wafer, is of central importance. In Part I of this book, we review different forms of lithography, detailing those that differ most from the miniaturization processes used to fashion integrated circuits (ICs). Chapter 1 starts with a short historical note about the origins of lithography, followed by a description of photolithography, including developments that have allowed the printing of the ever-shrinking features of modern ICs. After reviewing the limits of photolithography, we detail alternative next-generation lithographies (NGLs) in Chapter 2, including extreme ultraviolet (EUV), x-ray, and charged-particle (electron and ion) lithographies, followed by techniques in the early research and development stage.



Text by William Gilbert (from De Magnete), written using a 100-keV electron microscope in a common resist (PMMA). The height of each letter is 250 nm. The pattern was then imaged using the same electron microscope. (From http://www.lancs.ac.uk/staff/koltsov/nanoimage.html.)

1

Photolithography



The image of an IC, micro-, or nanomachine pattern is transferred to a substrate in a process known as photolithography. Substrates are first coated with a thin emulsion of photoactive organic material called a *photoresist*. A pattern is then aligned and projected onto the substrate using a light source (e.g., deep UV). Subsequently, the resulting image is developed and inspected.

Introduction

We start this chapter with a short historical note about the origins of photolithography and follow with details on all the steps involved, including resolution enhancement techniques (RET), that have allowed the printing of the ever-shrinking features of modern integrated circuits (ICs). In this photolithography treatise we expand especially on those aspects that are of most importance to microelectromechanical systems (MEMS) and nanoelectromechanical systems (NEMS) and that differ the most from typical lithography processes for IC fabrication.

Historical Note: Lithography's Origins

Within the space of 40 years two developments in photography laid the foundations for the photoresists we use today. In 1782, the Swiss pastor Jean Senebier (1742–1808) of Geneva investigated the property of

certain resins that become insoluble in turpentine after exposure to sunlight. Inspired by Senebier, Nicéphore Niépce, after experimenting with various resins in sunlight, managed to copy an etched print on oiled paper by placing it over a glass plate coated with bitumen (asphalt) dissolved in lavender oil (France, 1822). In so doing, he resurrected an ancient Egyptian embalming technique that involved the use of what is now known as Syrian asphalt. After two or three hours of sunlight, the unshaded areas in the bitumen became hard compared with the shaded areas, which remained more soluble and could be washed away with a mixture of turpentine and lavender oil. Niépce's concoction, we will learn below, corresponds to a negative-type photoresist. Five years later, in 1827 (talk about fast turnaround time!), using strong acid, the Parisian engraver Lemaître made an etched copy of an engraving of Cardinal d'Amboise from a plate developed by Niépce (see (a) on title page of Part I). The latter copy represents the earliest example of pattern transfer by photolithography and chemical milling [i.e., photochemical milling (PCM); see Chapter 4]. The accuracy of the technique was 0.5–1 mm.[1]

The word *lithography* [Greek for the words *stone* (*lithos*) and to *write* (*gráphein*)] refers to the process invented in 1796 by Aloys Senefelder. Senefelder found that stone (he used Bavarian limestone), when properly inked and treated with chemicals, could transfer a carved image onto paper. As a result of the chemical treatment of the stone, image and nonimage areas became oil receptive (water repellent) and oil repellent (water receptive), respectively, attracting ink onto the image area and attracting water on nonimage areas.

Photomasking, followed by chemical processing, led to the photolithography now used in fabricating integrated circuits (ICs) and in miniaturization science. Not until World War II, more than 100 years after Niépce and Lemaître, did the first applications of the printed circuit board (PCB) [also printed wiring board (PWB)], invented in 1943 by the Austrian Paul Eisler, come about. Interconnections were made by soldering separate electronic components to a pattern of "wires" produced by photoetching a layer of copper foil that was laminated to a plastic board. Jack Kilby of Texas Instruments and Robert Noyce of Fairchild Semiconductor developed the first IC in the late 1950s. By 1961, Fairchild Semiconductor had introduced the first commercial IC in which photoetching processes produced large numbers of transistors on a thin slice of Si. Now, ICs are ubiquitous, and we find them in microprocessors, audio and video equipment, dishwashers, garage openers, security systems, automobiles, and so on. With the first ICs, patterns had a resolution not better than 5 μm. Today photolithography, x-ray lithography, and charged particle lithography all achieve submicrometer-printing accuracy. Intel introduced the Prescott Pentium IV chip, an IC chip incorporating 90-nm-sized features using UV photolithography, in the fourth quarter of 2003. Chips based on a 65-nm technology became available in 2006, and the 32-nm node was achieved in 2009.

For details on the projected feature size of future ICs, see the International Technology Roadmap for Semiconductors (ITRS) in Appendix 1A of Chapter 1 in Volume I or on the web at http://public.itrs.net. In the ITRS, technology modes have been defined, i.e., the feature sizes that have to be in volume manufacturing at a fixed date (year of production).

Photolithography Overview

Introduction

The most widely used form of lithography is photolithography. In the IC industry, pattern transfer from masks onto thin films is accomplished almost exclusively via photolithography. The combination of accurate registration and exposing a series of successive patterns leads to complex multilayered ICs. This essentially two-dimensional (2D) process has a limited tolerance for nonplanar topography, creating a major constraint for building non-IC miniaturized systems, which often exhibit extreme topographies. Photolithography has matured rapidly, and its ability to resolve ever-smaller features is constantly improving. For the IC industry, this continued improvement in photolithography resolution has impeded the adaptation of alternative, higher-resolution lithography techniques, such as x-ray lithography. Research during the past 10 years in high-aspect-ratio resist features to satisfy needs of both IC and

non-IC miniaturization is also finally improving dramatically photolithography's capacity to cover wide ranges of topography. Performance of a photolithographic process is determined by its resolution, the minimum feature size that can be transferred with high fidelity; the registration, how accurately patterns on successive masks can be aligned; and throughput, the number of wafers that can be transferred per hour (a measure of the efficiency of the lithographic process).

Photolithography and pattern transfer involve a set of process steps summarized in Figure 1.1. As an example, we use an oxidized Si wafer and a negative photoresist system. For simplicity, not all the steps are detailed in this figure, as they will be covered in the subsequent text. A short preview follows.

An oxidized wafer (Figure 1.1a) is coated with a 1-µm-thick negative photoresist layer (Figure 1.1b). After exposure (Figure 1.1c), the wafer is rinsed in a developing solution or sprayed with a spray developer, which removes the unexposed areas of photoresist and leaves a pattern of bare and photoresist-coated oxide on the wafer surface (Figure 1.1d). The photoresist pattern is the negative image of the pattern on the photomask. In a typical next step after development, the wafer is placed in a solution of HF or HF + NH_4F, meant to attack the oxide but not the photoresist or the underlying silicon (Figure 1.1e). The photoresist protects the oxide areas it covers. Once the exposed oxide has been etched away, the remaining photoresist can be stripped off with a strong acid such as H_2SO_4 or an acid-oxidant combination such as H_2SO_4-Cr_2O_3, attacking the photoresist but not the oxide or the silicon (Figure 1.1f). Other liquid strippers include organic solvent strippers and alkaline strippers (with or without oxidants). The oxidized Si wafer with the etched windows in the oxide (Figure 1.1f) is ready now for further processing, which might entail a wet anisotropic etch of the Si in the etched windows with SiO_2 as the etch mask.

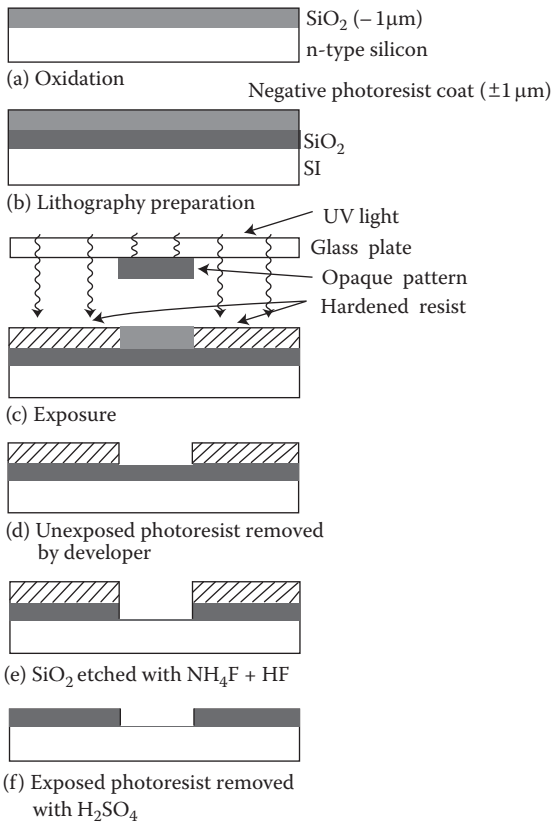

FIGURE 1.1 Basic photolithography and pattern transfer. Example uses an oxidized silicon wafer and a negative photoresist system. Process steps include exposure, development, oxide etching, and resist stripping. Steps (a) through (f) are explained in the text.

Wafer Cleaning and Contaminants: The Clean Room

An important step, even before lithography proper, is wafer cleaning. Contaminants include solvent stains (e.g., methyl alcohol, acetone, trichloroethylene, isopropyl alcohol, and xylene), dust from operators and equipment, and smoke particles. Stains or films may lead to adverse effects during oxidation and evaporation processes. Particulates, chunks of granular matter, may cause undesirable masking effects and scratches on the photomask during contact printing (see Figure 1.6). Solvent stains and other contaminants on a Si wafer can be easily observed in dark field microscopy (see Volume III, Chapter 6 on metrology and MEMS, NEMS modeling). All lithography processes take place inside a semiconductor clean room, which is a specially constructed enclosed area environmentally controlled with respect to airborne particulates, temperature (±0.1°F), air pressure, humidity (from 0.5–5% relative humidity), vibration, and lighting. In Table 1.1, some common sources of clean room contaminants are listed, and in Figure 1.2, the clean room classification system is elucidated. In a Class 1 clean room, the particle count does not exceed 1 particle

TABLE 1.1 Some Common Clean Room Contaminant Sources

• Location: a clean room near a refinery, smoke stack, sewage plant, cement plant spells big trouble
• Construction: the floor is an important source of contamination. Also, items such as light fixtures must be sealed, and room construction tolerances must be held very tight
• Wafer handling: transfer box
• Process equipment: never use fiberglass duct liner; always use 100% polyester filters, eliminate all nonessential equipment
• Chemicals: residual photoresist or organic coatings, metal corrosion
• Attire: only proper attire and dressing in the anteroom
• Electrostatic charge: clean room must have a conductive floor
• Furniture: only clean room furniture
• Stationary: use ballpoint pen instead of lead pencil, only approved clean room paper
• Operator: no eating, drinking, smoking, chewing gum, or makeup of any kind

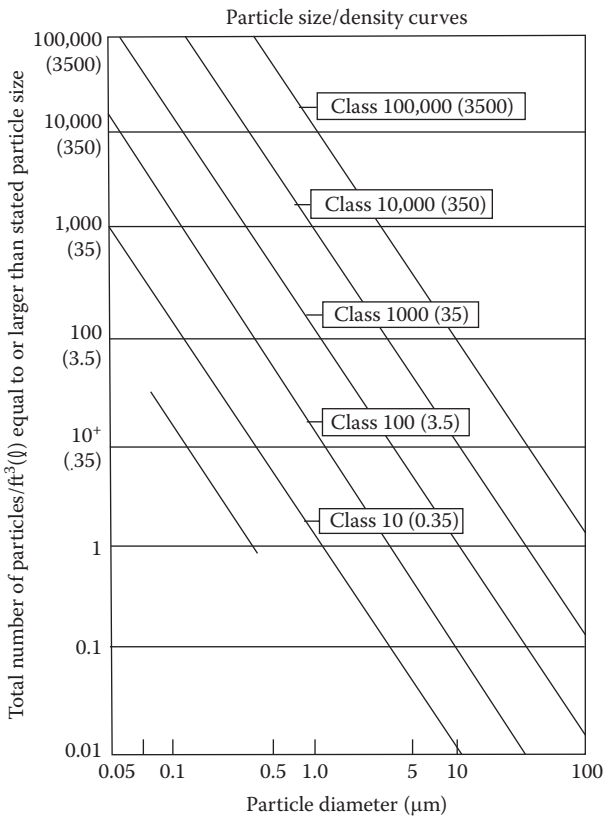

FIGURE 1.2 U.S. Federal Standard 209b for clean room classification. The bottom solid line shows the definition of Class 1. (From Cunningham, J.A. 1992. The remarkable trend in defect densities and chip yield. *Semicond Int* 15:86–90. With permission.[2])

per cubic foot with particles 0.5 μm and larger, and in a Class 100 clean room, the particle count does not exceed 100 particles per cubic foot with particles 0.5 μm and larger. The allowable contamination particle size in IC manufacture has been decreasing hand in hand with the ever-decreasing minimum feature size. With a 64-kB dynamic memory chip [dynamic random access memory (DRAM)], for example, one can tolerate 0.25-μm particles, but for a 4-MB DRAM, one can only tolerate 0.05-μm particles. The smallest feature sizes in these two cases are 2.5 and 0.5 μm, respectively. As a reference point, a human hair has a diameter of 75–100 μm (depending on age and race); tobacco smoke contains particles ranging from 0.01–1 μm; and a red blood cell ranges from 4–9 μm.

Example 1.1

Problem: If a 125-mm diameter wafer is exposed for 1 minute to an air stream under a laminar-flow condition at 30 m/min, how many dust particles will land on the wafer in a Class 10 clean room?

Solution: In a Class 10 clean room, there are 350 particles (0.5 μm or larger) per cubic meter. The air volume that passes over the wafer in 1 min is (30 m/min) × π(0.125 m / 2)^2 × 1 min = 0.368 m^3. The number of dust particles (0.5 μm or larger) contained in that air volume is 350 × 0.368 = 128 particles. Therefore, if there are 200 IC chips on the wafer, the particle count amounts to one particle on each of 64% of the chips. Fortunately, only a fraction of the particles that land on the surface of the wafer adhere to the wafer surface, and of those only a fraction are at a circuit location critical enough to cause a failure. However, the calculation demonstrates the importance of the clean room.

Many different dry and wet methods for wafer cleaning currently in use are listed below. RCA1 and RCA2, developed by W. Kern in 1965 while working for the Radio Corporation of America (RCA), which are well known, use mixtures of hydrogen peroxide and various acids or base followed by deionized (DI) water rinses. Others include vapor cleaning; thermal treatment, for example, baking at 1000°C in a

Table 1.2 Wet versus Dry Cleaning Attributes

Attribute	Wet	Dry
Particle removal	+	–
Metal removal	+	–
Heavy organics, i.e., photoresist	+	–
Light organics, i.e., outgassed hydrocarbon residues	+	+
Throughput	+	–
Process repeatability	+	+
Water usage	–	+
Process chemical cleanliness	–	+
Environmental impact, purchase, and disposal cost	–	+
Single wafer use applicability	–	+

Dry cleaning usually requires wet followup. UV ozone can effectively remove light organic contamination.[3]
Source: Iscoff, R. 1991. Wafer cleaning: can dry systems compete? *Semicond Int* 14:48–54. With permission.[3]

vacuum or in oxygen; and plasma or glow discharge techniques, for example, in Freons with or without oxygen. Mechanical methods include ultrasonic agitation, polishing with abrasive compounds, and supercritical cleaning. Ultrasonic cleaning, which is excellent for removing particulate matter from the substrate, is unfortunately prone to contamination and mechanical failure of deposited films. Attributes of wet versus dry cleaning techniques are compared in Table 1.2. Except for environmental concerns, wet etching still outranks other cleaning procedures.

The prevalent RCA1 and RCA2 wet cleaning procedures are as follows:

- RCA1: Add 1 part of NH_3 (25% aqueous solution) to 5 parts of DI water; heat to boiling, and add 1 part of H_2O_2. Immerse the wafer for 10 minutes. This procedure removes organic dirt (resist).
- RCA2: Add 1 part of HCl to 6 parts of DI water; heat to boiling, and add 1 part of H_2O_2. Immerse the wafer for 10 minutes. This procedure removes metal ions.

The second RCA cleaning process is required to keep oxidation and diffusion furnaces free of metal contamination. Both cleaning processes leave a thin oxide on the wafers. Before a further etch of the underlying silicon is attempted, oxide must be stripped off by dipping the wafer in a 1% aqueous HF solution for a very short time. Water spreads on an oxide surface (hydrophilic) and beads up on a bare Si surface (hydrophobic). This behavior can be used to establish whether any oxide remains.

In most IC labs, processing a wafer previously exposed to KOH is not allowed as it is feared that the potassium will spoil the IC fabrication process. In more lenient environments, carefully cleaned wafers using RCA1 and RCA2 are allowed.

Supercritical cleaning (Figure 1.3) with CO_2 is especially suited for microstructure cleaning.[4] These fluids possess liquid-like solvative properties and gas-like diffusion and viscosity that enable rapid penetration into crevices with complete removal of organic and inorganic contaminants contained therein. During wet cleaning of surface micromachined structures, thin, mechanical microstructures tend to stick to one another or to the substrate through surface tension (stiction) (Chapter 7). Consequently, dry vapor phase and supercritical cleaning with low or no surface tension are preferred.

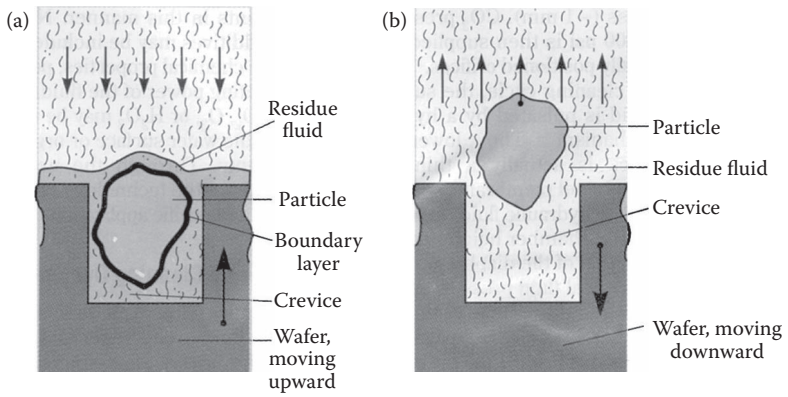

FIGURE 1.3 (a) Wet cleaning. (b) Supercritical cleaning.

Vapor phase cleaning also uses significantly fewer chemicals than wet immersion cleaning.[5]

We will learn more about the emerging importance of supercritical fluids as developers for completely dry resist processes further below.

Wafer cleaning has become a scientific discipline in its own right with journals such as *Microcontamination* and *The Magazine for Ultraclean Manufacturing Technology*, books such as *Handbook of Contamination Control in Microelectronics: Principles, Applications and Technology*[6] and the *Handbook of Semiconductor Wafer Cleaning Technology*,[7] and dedicated conferences (e.g., the Microcontamination Conference). Visit the Semiconductor Subway (http://www-mtl.mit.edu/semisubway.html) for frequent updates in this important area.

Silicon-Based Device Manufacturing Costs

The manufacturing of a Si-based device involves many processing steps, and each step adds to the cost of the finished wafer/device. In the most general terms, the finished wafer costs depend on the number of masks used, the complexity of the devices, and the clean room requirements. The costs increase with the number of layers in a device in a nonlinear fashion as defects are introduced in each new layer, but with each new layer more defects accumulate in the underlying layers as well. Cost per device/chip further increases the smaller the feature size because of more stringent requirements for the lithography steps and overall process control. In first world countries, an added concern is that semiconductor fabrication processes are highly toxic; therefore, environmental and worker protection laws need to be considered. In the case of an IC fab, the current cost is in the $2–3 billion range. A typical fab line occupies one city block and employs a few hundred workers. The most profitable period is typically in the first 18 months to 2 years. It is important to note that for large-volume ICs, packaging and testing constitute the largest costs, and that for low-volume ICs, design costs may swamp out the manufacturing costs. In the case of non-IC micro- and nanomachines, testing and packaging become yet more significant contributors to costs. Moreover, standardization is much more difficult, and multiphysics design software packages required for these devices are not yet sophisticated enough.

In Table 1.3 we list the relative costs of IC production processes (does not include design, test, and packaging); lithography is the most expensive step (at 35%), and cleaning adds another 20%.

Variability in the IC manufacturing processes listed in Table 1.3 can lead to deformations or nonconformities in finished products. The product yield is defined as the percentage of devices or circuits that meet a nominal performance specification. One distinguishes between a functional (hard) yield (e.g., opens, shorts, particles) and a parametric (soft) yield (e.g., speed, noise, immunity, power consumption). Functional yield is affected by the presence of defects. Defects result from a number of random sources such as contamination from equipment or processes, handling, mask imperfections, and airborne particles. Functional yield Y is a function of A_c, a critical area in which, if a defect occurs, it has a high probability of inducing a fault, and D_0, the density of defects per unit area, or:

$$Y = f(A_c, D_0) \tag{1.1}$$

This relation depends on circuit geometry, density, feature sizes, number of processing steps, and so on, and is sometimes represented as:

$$Y = \frac{1 - e^{-D_0 A_c}}{D_0 A_c} \tag{1.2}$$

Manufacturing issues that influence hard yield Y include photoresist shrinking/tearing, variations in material deposition, variations in temperature, variations in oxide thickness, impurities, variations between lots, variations across the wafer, and so on.

Table 1.3 Relative Costs of IC Production Processes

Manufacturing Process Step	Percentage of Wafer Processing Cost per Square Centimeter*
Lithography	35%
Multilevel materials and etching	25%
Furnaces and implants	15%
Cleaning/stripping	20%
Metrology	5%

*Excludes packaging, test, and design costs.

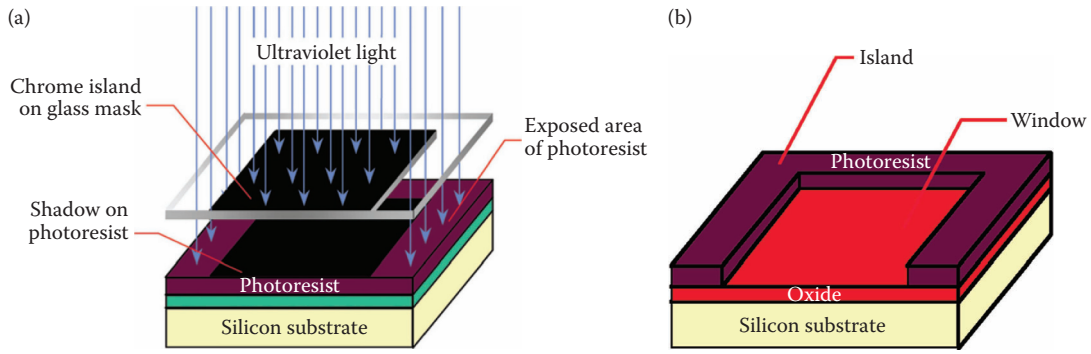

FIGURE 1.4 (a) Photomask in an exposure setup. (b) Resulting pattern in case a negative photoresist is used.

The parametric yield measures the "quality" of functioning systems. Even in a defect-free manufacturing environment, random process variations can lead to varying levels of system performance. Parametric yield may include variations in threshold voltage (because of oxide thickness, ion implantation, poly variations), variations in R, C (because of changes in doping or poly-Si, metal variations in height and width), and shorts and opens (because vias are not cut all the way through, or undersized vias that have too much resistance or oversized vias that short).

Masks

Standard Photolithography Masks

The stencil used to repeatedly generate a desired pattern on resist-coated wafers is called a *mask*. In typical use, a photomask—a nearly optically flat glass [transparent to near ultraviolet (UV)] or quartz plate (transparent to deep UV) with an absorber pattern metal (e.g., an 800-Å-thick chromium layer)—is placed above the photoresist-coated surface, and the mask/wafer system is exposed to UV radiation (Figure 1.4). The absorber pattern on the photomask is opaque to UV light, whereas the glass or quartz is transparent. The absorber pattern on the mask is generated by e-beam lithography, a technique that yields higher resolution than photolithography. In e-beam lithography, a pattern drawn on a computer-aided design (CAD) system is exposed onto the mask. Like resists, masks can be positive or negative. A *positive* or *dark field* mask is a mask on which the pattern is clear with the background dark. A *negative* or *clear field* mask is a mask on which the pattern is dark with the background clear. A light field or dark field image, known as *mask polarity* (Figure 1.5), is then transferred to the semiconductor surface. This procedure results in a 1:1 image of the entire mask onto the silicon wafer.

Masks making direct physical contact (also referred to as *hard contact*) with the substrate are called *contact masks*. Unfortunately, these masks degrade faster because of wear than noncontact, proximity masks (also referred to as *soft contact masks*), which are slightly raised, e.g., 10–20 μm, above the wafer. The defects resulting from hard contact masks on both the wafer and the mask make this method of optical pattern transfer unsuitable for **v***ery* **l***arge* **s***cale* **i***ntegration* (VLSI) manufacturing. In VLSI, ICs have between 100,000 and 1 million components, and in **u***ltra***l***arge* **s***cale* **i***ntegration* (ULSI), there are more than 1 million circuit elements on a single chip. In 2005, Intel began manufacturing computer chips with an average feature size of 65 nm (the so-called *65-nm technology node*, see Volume I, Appendix 1A). This new generation of chips has more than half a billion transistors and constitutes a ULSI chip.

We review hard contact masks because they are still used in research and development, in mask making itself, and for prototyping. Contact mask

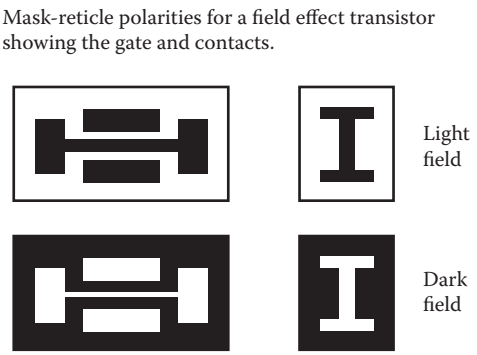

FIGURE 1.5 Light field and dark field.

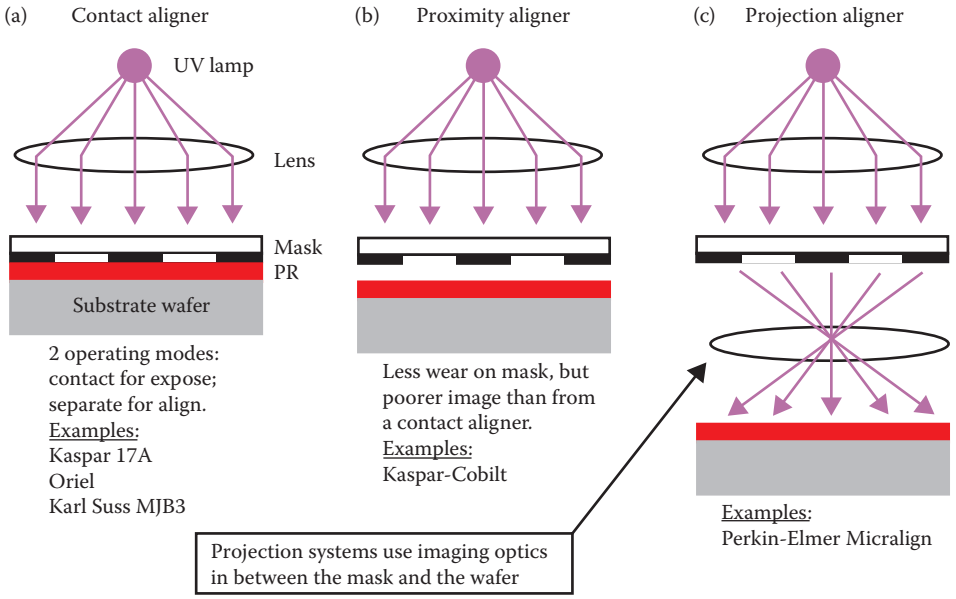

FIGURE 1.6 (a) Contact printing, (b) proximity printing, and (c) projection printing.

and proximity mask printing are collectively known as *shadow printing*. A more reliable method of masking is *projection printing*, where, rather than placing a mask in direct contact with (or in proximity of) a wafer, the photomask is imaged by a high-resolution lens system onto the resist-coated wafer. In the latter case, the only limit to the mask lifetime results from operator handling. The imaging lens can reduce the mask pattern by 1:5 or 1:10, making mask fabrication less challenging. In Figure 1.6, we compare contact, proximity, and projection lithography, and example commercial systems are listed also.

The design of electron beam-generated masks for ICs and miniaturized machines is generally fairly straightforward and requires some suitable CAD software and a platform on which to run it (Figure 1.7). Electron-beam lithography is maskless and is discussed later in this chapter; mask design and suitable CAD software will be addressed in Volume III, Chapter 6.

Gray-Tone Lithography Masks

As described above, photolithography constitutes a binary image transfer process: the developed pattern consists of regions with resist (1) and regions without resist (0). In contrast, in grayscale lithography, the partial exposure of a photoresist renders it soluble to a developer in proportion to the local exposure dose, and as a consequence, after development, the resist exhibits a surface relief.

Gray-tone masks (GTMs), letting varying amounts of light pass through, are of great potential use in

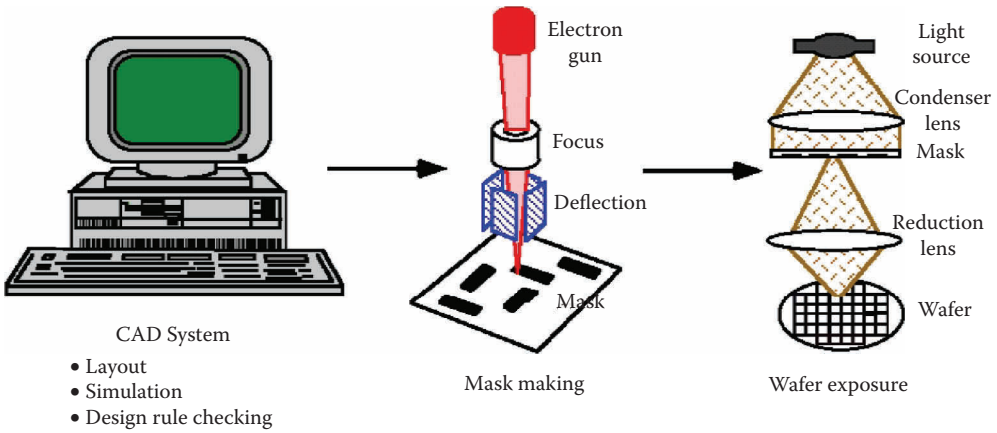

FIGURE 1.7 E-beam writing of a photomask and subsequent projection printing.

miniaturization science as they allow for the mass production of micromachines with varying topography. The possibility of creating profiled micro-3D structures offers tremendous additional flexibility in the design of microelectronic, optoelectronic, and micromechanical components. In optical integrated circuits (OICs), for example, GTMs can be used for the fabrication of tapered waveguides, gratings with saw tooth profiles (blazed gratings), microlenses, and so on.[8] As an example of GTM use, in Figure 1.8, we show experiments with a Rohm and Haas dual-tone resist.[9,10] The right-hand path in Figure 1.8a

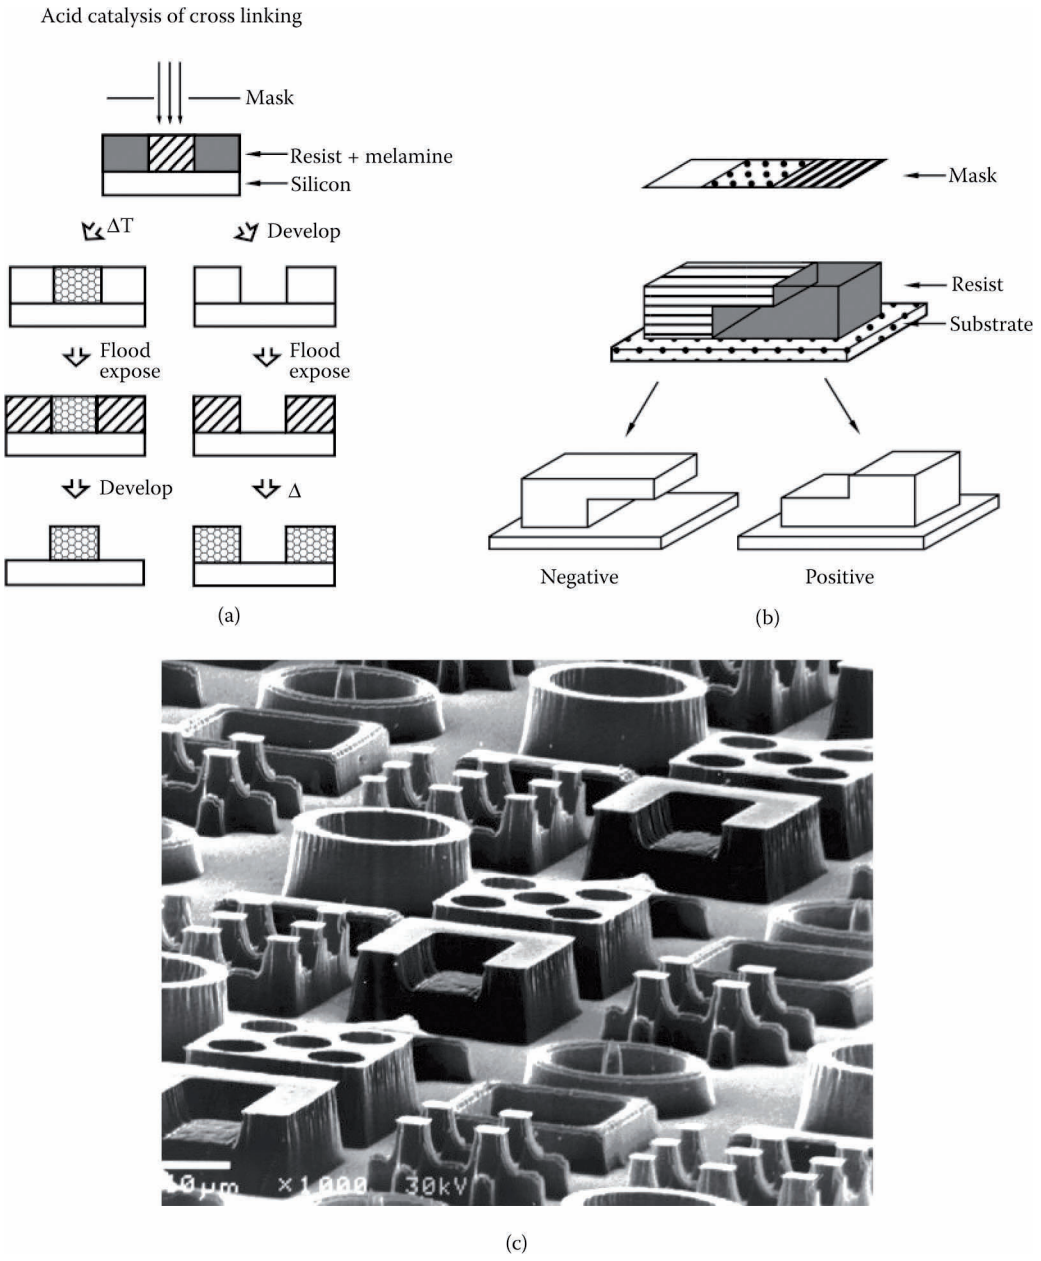

FIGURE 1.8 Rohm and Haas dual-tone resist. (a) Process options for Rohm and Haas dual-tone resist. The right-hand path produces positive-tone images in which the remaining resist is cross-linked and does not flow when exposed to temperatures above the T_g of the novolak-base resin. The left-hand path provides thermally stable negative-tone images. (b) Exposure of the Rohm and Haas resist with a mask exhibiting nominally 0% transmission, 50% transmission, and 100% transmission allows generations of patterns with controlled variations in thickness and/or overhangs and cantilevered structures. (c) Example of the types of features that can be printed using the Rohm and Haas resist. Note the structures with full thickness and 50% thickness. (Courtesy of Drs. Feely, Rohm, and Haas. Feely, W. E. 1988. *Technical digest: solid state sensor and actuator workshop.* Hilton Head Island, SC: IEEE.[9])

produces positive-tone images in which the remaining resist is cross-linked and does not flow when exposed to temperatures above the T_g of the novolak-base resin. The left-hand path provides thermally stable negative-tone images. The mask used here has only 0% or 100% transmission fields. Exposure of the same Rohm and Haas resist with a GTM, exhibiting nominally 0% transmission, 50% transmission, and 100% transmission, allows generations of patterns with controlled variations in thickness and/or overhangs and cantilevered structures. An example of the types of features that can be printed using the Rohm and Haas resist with a GTM is shown in Figure 1.8c. Note the structures with full thickness and 50% thickness.

The fabrication of 3D components by gray-tone technology is performed in three principal steps. The first and most critical step deals with the realization of the GTM itself. The challenge in this step is the definition of zones of variable optical transmission that represent the various gray levels. In a second step, the wafers are exposed, and the light intensity modulation by the gray-tone areas on the mask generates depth variations in the photoresist (Figure 1.9). The profile in the photoresist can also be transferred proportionally into the substrate during a third step, i.e., a dry etching step.[11]

For each substrate/resist combination, the dry etching process has to be established to obtain resist/substrate selectivity close to 1:1.

One approach to make multilevel photoresist patterns directly, without a physical mask, is by variable-dose e-beam writing, in which the electron dosage (current × dwell time) is varied across the resist surface.[13] Variable-dose e-beam writing is slow and costly, and GTMs are a desirable alternative, especially if high throughput production is required. A laser writer can produce the same result but at a lower resolution.

Possible methods for making variable transmission masks include magnetron sputtering of amorphous carbon onto a quartz substrate. Essentially any transmittance (T) desired in the $0\% < T < 100\%$ can be achieved by controlling the film thickness (t) in the $200\text{ nm} > t > 0\text{ nm}$ range with subnanometer precision.[14] Perhaps more elegantly, gray levels may be created by the density of dots that will appear as transparent holes in a chromium mask. These dots are small enough not to be transferred onto the wafer because they are below the resolution limit of the exposure tool. In a CAD program, the dot matrices associated with the gray levels are then combined with the 2D geometries to define the final 3D structures. Both electron-beam and laser-beam pattern generators have been used for manufacturing GTMs. The electron-beam pattern generator is better adapted to this application because of its flexibility and higher resolution.[11] Optimization of the exposure and the development parameters improves the resist depth and profile. The resist profile may then be

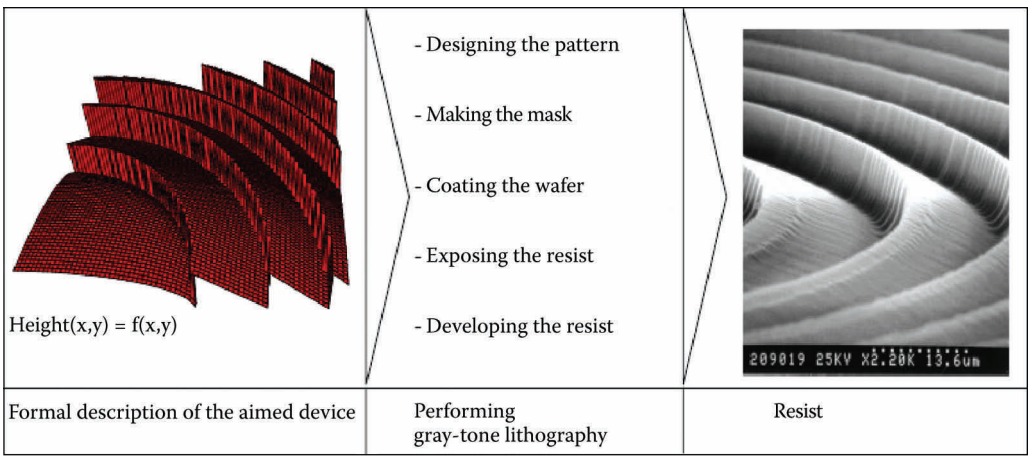

FIGURE 1.9 Process flow chart for transferring the image on a gray-tone mask into a substrate. Gray-tone lithography is an inexpensive one-step lithographic method to fabricate 3D microstructures using a raster-screened (gray-tone) photomask. (Reimer, K., R. Engelke, U. Hofmann, P. Merz, K.T.K.v. Platen, and B. Wagner. 1999. *MF-Conf., micromachine technology for diffractive and holographic optics*. Santa Clara, CA: SPIE.[12])

used directly; it may function as a mold; or it is conformally transferred into the substrate using plasma etching with controlled selectivity. Figure 1.10 shows a blazed grating proportionally transferred from a patterned resist to the underlying fused silica. Blazed gratings with a period of 16 μm and 8 μm covering a surface of 3×3 mm^2 were fabricated with an eight-level GTM. A reflection grating in which the grooves are asymmetric with respect to the surface normal is said to be blazed. A blazed grating is used to direct the light only into the diffracted order of interest with high efficiency. From the atomic force measurements of the grating profile shown here, the distribution of light in the various diffraction orders was computed and found to be in agreement with the experimental optical measurements. Compared with multiple mask techniques, the GTM approach allows the realization of different depths from the same GTM.

Another attractive way to implement grayscale lithography is with high-energy beam-sensitive (HEBS) glass. HEBS glass turns dark on exposure to an electron beam; the higher the electron dosage, the darker the glass turns. In HEBS glass, a top layer, a couple of micrometers thick, contains silver ions in the form of silver-alkali-halide $(AgX)_m$ $(MX)_n$ complex nanocrystallites that are about 10 nm or smaller in size and are dispersed within cavities of the glass

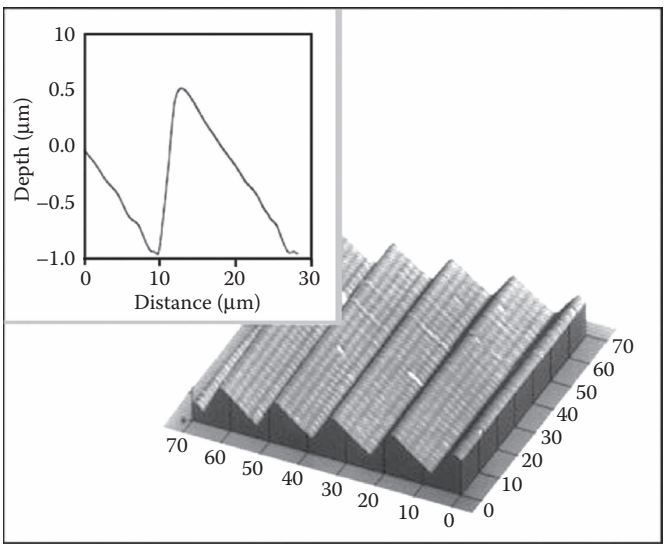

FIGURE 1.10 Atomic force microscope profile of a 16-μm pitch blazed grating in fused silica: the grating was proportionally transferred from resist to fused silica. A sawtooth (blazed) profile notably increases the efficiency of an optical grating.

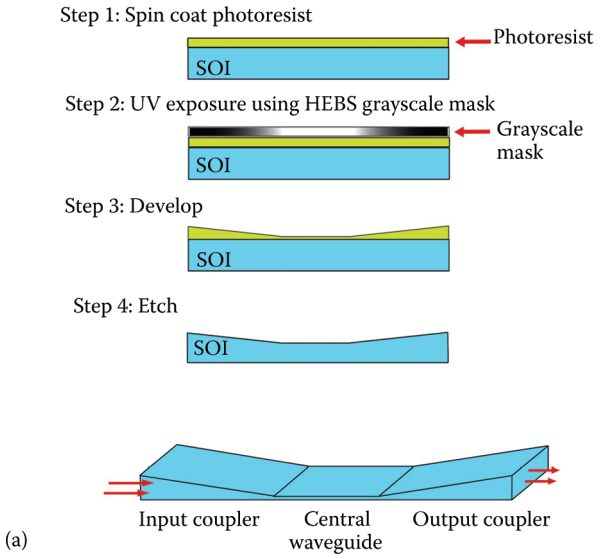
SiO_4 tetrahedron network. Chemical reduction of the silver ions produces opaque specks of silver atoms on exposure to a high-energy electron beam (>10 kV). A key part in the development of a grayscale process is the characterization of the resist thickness as a function of the optical density in the mask for a given lithographic process. It is desirable to use photoresists that exhibit a low contrast to achieve a wide process window (see "Contrast and Experimental Determination of Lithographic Sensitivity," this chapter). Ideally, the resist response can be linearized to the optical density within the mask. Using an HEBS glass mask, Sure et al.[8] fabricated 3D silicon tapers to couple light from an optical fiber into an optical waveguide for an OIC. Fabrication involves writing a single grayscale mask in HEBS glass with a high-energy electron beam, UV grayscale lithography, and inductively coupled plasma etching (see Figure 1.11a).[8] In Figure 1.11b we show an example HEBS mask for the fabrication of an array of lenses (http://www.canyonmaterials.com).

Inexpensive Masks and Maskless Optical Projection Lithography for Research and Development

In miniaturization science, one often is looking for low-cost and fast-turnaround methods to fabricate masks. This may involve manually drawn patterns on cut-and-peel masking films and photoreduction, affording fast turnaround without relying on outside photomask services. Alternatively, it may involve direct writing on a photoresist-coated plate with a laser plotter (~2-μm resolution).[15] Simpler yet, using a drawing program such as Canvas® (Deneba Systems, Inc.), Freehand® (Macromedia, Inc.), Illustrator® (Adobe Systems, Inc.), or L-Edit® (Tanner Research, Inc.), a mask design can be created on a computer and saved as a Postscript® file to be printed with a high-resolution printer on a transparency.[16] A common laser printer has a resolution of 72 lines per inch (lpi) and between 300 and 1200 dots per inch (dpi) (see Figure 1.12). The average dot size for a 1200-dpi printer is 21 μm, and if we print a vertical line approximately 100 μm wide with this printer, approximately 5 dots make up the 100-μm width, but the space between successive lines of 5 dots is 332 μm. Thus, this vertical



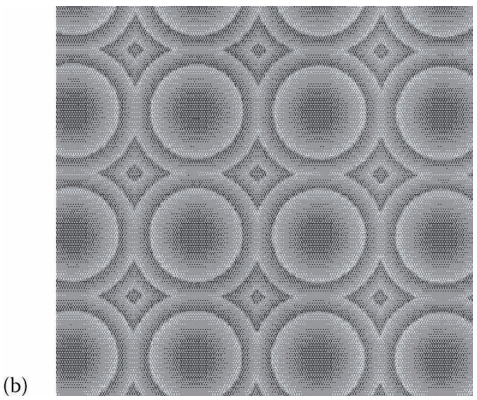


FIGURE 1.11 (a) Fabrication steps for a silicon taper. (Sure, A., T. Dillon, J. Murakowski, C. Lin, D. Pustai, and D.W. Prather. 2003. Fabrication and characterization of three-dimensional Si tapers. *Optics Express* 11:555–61. Drawing by Mary Amasia.[8]) (b) HBS mask for the fabrication of a diffractive microlens array (http://www.canyonmaterials.com).

line will look like a dotted line. Using a typesetting type of printing can avoid these resolution problems (16,000 dpi).

The transparency with the printed image may then be clamped between a presensitized chrome-covered mask plate (i.e., a vendor such as Nanofilm has preapplied the resist) and a blank plate to make a traditional mask from it. After exposure and development, the exposed plate is put in a chrome etch for a few minutes to generate the desired metal pattern, and the remaining resist is stripped off. Simpler yet, the printed transparency may be attached to a quartz plate to be used as a mask directly.

Lithography is still mostly carried out using masks, but because of problems caused by masks, such as expense and time in fabricating them, contamination introduced by them, their disposal, and the difficulties in their alignment, research into maskless optical projection lithography (MOPL) is growing rapidly and broadly. One MOPL approach already on the market (http://www.intelligentmp.com) is based on the digital micromirror device (DMD) chip from Texas Instruments Inc. (TI) and relies on the same spatial light modulation technology used in digital light processing projectors and high-definition television (see Chapter 7, Example 7.10). Enormous simplification of lithography hardware is feasible by using the movable mirror arrays in a DMD chip to project images on the photoresist. This technique is capable of fabricating micromachined elements with any surface topography and can, just like e-beam lithography or laser writing, be used for

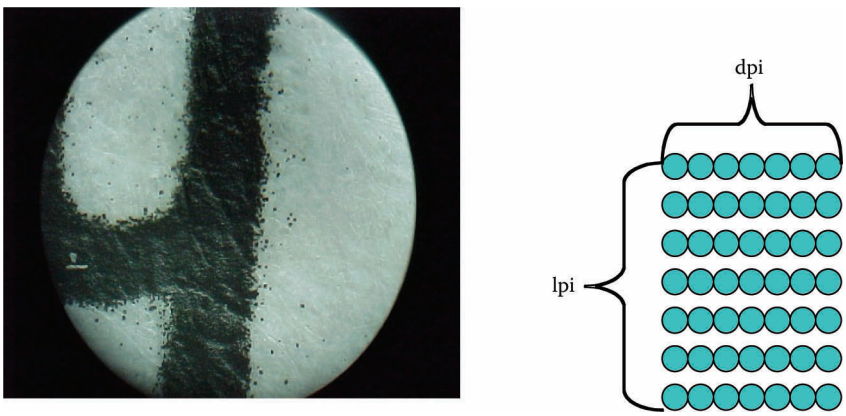

FIGURE 1.12 Laser printer resolution. Image of a laser-printed letter. Note the scatter of small dots. Technology is not so precise as to place dots in a straight line, and the effective dpi might be partially the result of overspray. (From Dr. James Lee, Ohio State University.)

implementing maskless binary and grayscale lithography. The resolution of DMD-based maskless photolithography (about 5 μm) is significantly less than with e-beam lithography (0.25 μm) or laser writers (<1.0 μm), but it is a parallel technique, and for many applications, i.e., in microfluidics, the lower resolution might not be an obstacle. Using DMD technology, on-chip electronics, in conjunction with a control computer, can generate a pattern by turning individual mirrors "on" or "off." DMD chip's micromirrors are mounted on tiny hinges that enable them to tilt either toward the light source in the projection lens (ON) or away from it (OFF) (see Example 7.10), creating a light or dark pixel on the projection surface. The bit-streamed image code entering the semiconductor directs each mirror to switch on and off at a rate of up to 10,000 times/s. This pattern is then demagnified and focused on the wafer to expose the photoresist while light from the remaining off mirrors is deflected away from the optics. The use of refractive optics prevents the extension of MOPL to wavelengths much shorter than 157 nm. The unique capability of representing a grayscale is probably the most essential merit of this type of maskless lithography. When a mirror is switched on more frequently than off, it reflects a light gray pixel; a mirror that is switched off more frequently reflects a darker gray pixel. In this way, the mirrors in a DMD system can reflect pixels in up to 1024 shades of gray to convert the video or graphic signal entering the DMD chip into a highly detailed grayscale image. The method to fabricate the micromirrors used in DMDs is based on MEMS and is detailed in Chapter 7 on surface micromachining. In Figure 1.13 we show a photo of Intelligent Micro Patterning's lithography system, the SF-100, based on TI's DMD with a line-width resolution of 5 μm (http://www.intelligentmp.com/SF100Photos.htm).

Maskless zone-plate-array lithography (ZPAL)[17] is another optical maskless technology. This technology operates on the principle of diffraction rather than refraction. Instead of a single large numerical aperture (NA) lens, an array of thousands of nanofabricated Fresnel zone plate lenses is used, each focusing a beam of light onto the substrate. A computer-controlled array of micromechanical spatial-light modulators turns the light to each lens on or off as the substrate is scanned under the array, thereby printing the desired pattern in a "dot-matrix" fashion.

FIGURE 1.13 Intelligent MicroPatterning's SF-100 lithography system based on DMDs (http://www.intelligentmp.com/SF100Photos.htm).

ZPAL is reviewed in Chapter 2 as a nanolithography technique that can be adapted to work with an extreme UV light source.

Photoresist Deposition

Introduction

Lithography is the most expensive step in microelectronics technology, representing up to 35% of the wafer manufacturing cost (see Table 1.3). Within lithography, photoresist coating is one of the more expensive steps. Photoresists may cost $100/L (and it is about $40/gallon for a typical developer), and several of the resist deposition processes used waste significant amounts of material. For silicon ICs, the resist thickness after a prebake (see below for what a prebake does) typically ranges between 0.5 and 2 μm. For miniaturized 3D structures, much greater resist thicknesses are often required, and complex topography might also call for a conformal resist coat over very high-aspect-ratio features. For thick resist coats, techniques such as casting and the use of thick sheets of dry photoresists replace the ineffective resist spinners. For conformal coating, resist spraying or, better yet, electrodeposition (ED) of photoresist might be preferable. In this section we emphasize methods used to deposit liquid photosensitive materials in ICs, MEMS, and NEMS, including spin coating, spray coating, dip coating,

meniscus coating, electrodeposited (electrophoretic) photoresist, and casting methods such as roller, curtain, and extrusion coating. Photoresist coating is an additive technology, and in Chapter 8 we present a broader review of available processes for the deposition of organic films in general, including photoresists and nonphotosensitive organics for applications such as biosensors, membranes, packaging, protein arrays, DNA arrays, and so on. Very thin photoresist coatings (<<1 μm) are reviewed further below under the section on Thin Photoresists, and in Chapter 10 we explore very thick photoresist coatings (>>20 μm) for molding applications. Lamination of dry photoresist films to a substrate and a comparison of wet versus dry photoresists are covered below in the section on Permanent and Dry Resists.

Spin Coating

A common step before spinning on a resist with Si as the substrate is the growth of a thin layer of oxide on the wafer surface by heating it to between 900 and 1150°C in steam or in a humidified oxygen stream (see Figure 1.1a). Dry oxygen also works, but wet oxygen and steam produce faster results. The oxide can serve as a mask for a subsequent wet etch or boron implantation. As the first step in the lithography process itself, a thin layer of an organic polymer, a photoresist sensitive to UV radiation, is deposited on the oxide surface (see Figure 1.1b). The photoresist is dispensed onto the wafer lying on a wafer platen in a resist spinner (see Figure 1.14).[18] A vacuum chuck holds the wafer in place. A speed of about 500 rpm is commonly used during the dispensing step, enabling the spread of the fluid over the substrate. After the dispense step it is common to accelerate to a relatively high speed to thin the fluid to near its final desired thickness. Typical spin speeds for this step range from 1500–6000 rpm, depending on the properties of the fluid (mostly its viscosity), as well as the substrate. This step can take from 10 seconds to several minutes. The combination of spin speed and time selected for this step will generally define the final film thickness. At these speeds, centrifugal force causes the solution to flow to the edges, where it builds up until expelled when surface tension is exceeded. The resulting polymer thickness, *T*, is a function of spin speed, solution

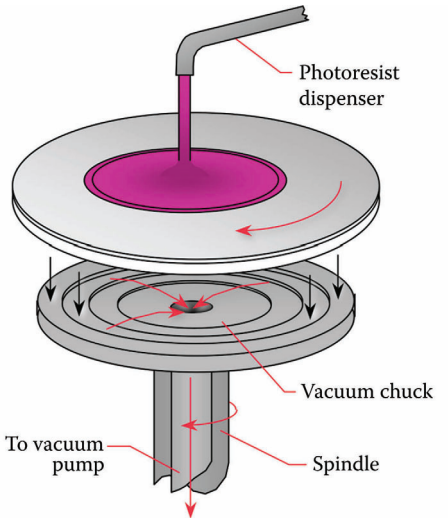

FIGURE 1.14 Resist spinner.

concentration, and molecular weight (measured by intrinsic viscosity). The empirical expression for *T* is given by:

$$T = \frac{KC^{\beta}\eta^{\gamma}}{\omega^{\alpha}} \tag{1.3}$$

where K = the overall calibration constant
C = the polymer concentration in g/100-mL solution
η = the intrinsic viscosity
ω = the number of rotations per minute

Once the various exponential factors (α, β, and γ) have been determined, Equation 1.3 can be used to predict the thickness of the film that can be spun for various molecular weights and solution concentrations of a given polymer and solvent system.[19]

The resist spinning process is of primary importance to the effectiveness of pattern transfer. The quality of the resist coating determines the density of defects transferred to the device under construction. The photoresist film, after application to the substrate, must have a uniform thickness and must be chemically isotropic so that its response to exposure and development is uniform. The coating thickness of the thin, glassy resist film depends on the chemical resistance required for image transfer and the fineness of the lines and spaces to be resolved. The coating process should take place in Class 100 laminar flow air conditions, and a minimum spin time of 30 seconds is necessary for coating uniformity. The

photoresist should also be filtered just before application. The application of too much resist results in edge covering or run-out, hillocks, and ridges, reducing manufacturing yield. Application of too little resist may leave uncovered areas. Optimization of the "regular" photoresist coating process in terms of resist dispense rate, dispense volume, spin speed, ambient temperature, venting of the resist spin station, and humidity presents a growing challenge.

To ensure reproducible line widths and development times in subsequent steps, a resist thickness of 1 μm, with a repeatability of ±10 Å (±0.1%) is becoming the norm. In such cases, even small changes in air draft over the resist-coated substrate could influence the results. In Table 1.4 we present a handy spin coating-troubleshooting chart based on data presented at http://www.brewerscience.com/products/cee/technical/spintheory. In Appendix 1A a more detailed spin coating process troubleshooting list is presented.

Since 2005, computer chips with an average feature size of 65 nm have been on the market, and for these, as well as smaller feature sizes, yet better control over thinner and thinner resist layers is sought. An on-line film thickness monitor, possibly a technique based on reflection spectroscopy, will become essential for statistical process control of such demanding photoresist coatings.[18] The need for an alternative photoresist deposition technique might arise as the amount of waste material generated by spin coating is high, with most of the resist solution (>95%) thrown off the substrate during the spin casting process (the wasted resist must be disposed of as a toxic material). Also inherent to this process is the formation of edge beads, which require an additional removal process (see Figure 1.15a) before subsequent process steps. The edge of a wafer might exhibit resist ridges that are about 10 times the mean thickness on the rest of the substrate. A typical bead removal solution is AZ edge bead remover solvent (http://www.glue.umd.edu/~nima/doc/AZEBRSolventMSDS.pdf). With the current trend toward larger substrate formats, these limitations will be exacerbated. The main obstacle to using spin coating in MEMS is caused by varying topography: deeply etched features cause a physical obstruction to the solution flow, preventing complete coverage and often causing striation or resist thickness variation. For example, resist thickness variations can occur on the near and far sides of a cavity or in cavities at different locations on the substrate. Sizes and shapes of the cavities also have influence on the resist uniformity and coating defects. For substrates with moderate topography, alternative coating techniques, like spray coating (see the next section below), offer better prospects. Wafers with extreme topography, e.g., as encountered in radio frequency-MEMS, require a process with yet higher shape conformality. For the latter application we will see below that ED photoresists are a possible solution.

A good review on spin coating can be found at http://www.brewerscience.com/cee/technical/spintheory.html.

Alternative Photoresist Deposition Methods

In this section, we compare alternatives to spin coating (Figure 1.15a). We follow closely James Webster's treatise of the subject.[20]

Spray Coating In spray coating, the substrates to be coated pass under a spray of photoresist solution. A diagram depicting this process is shown in Figure 1.15b. The spray system includes an ultrasonic spray nozzle that generates a distribution of droplets in the micrometer range. The resist is pushed out of a pressurized tank via a supply pipe to the spray head. The spray head has a defined aperture where the spray mist is formed. The shape of the spray pattern can be adjusted by a secondary air cushion. Compared with electrostatic spraying (see

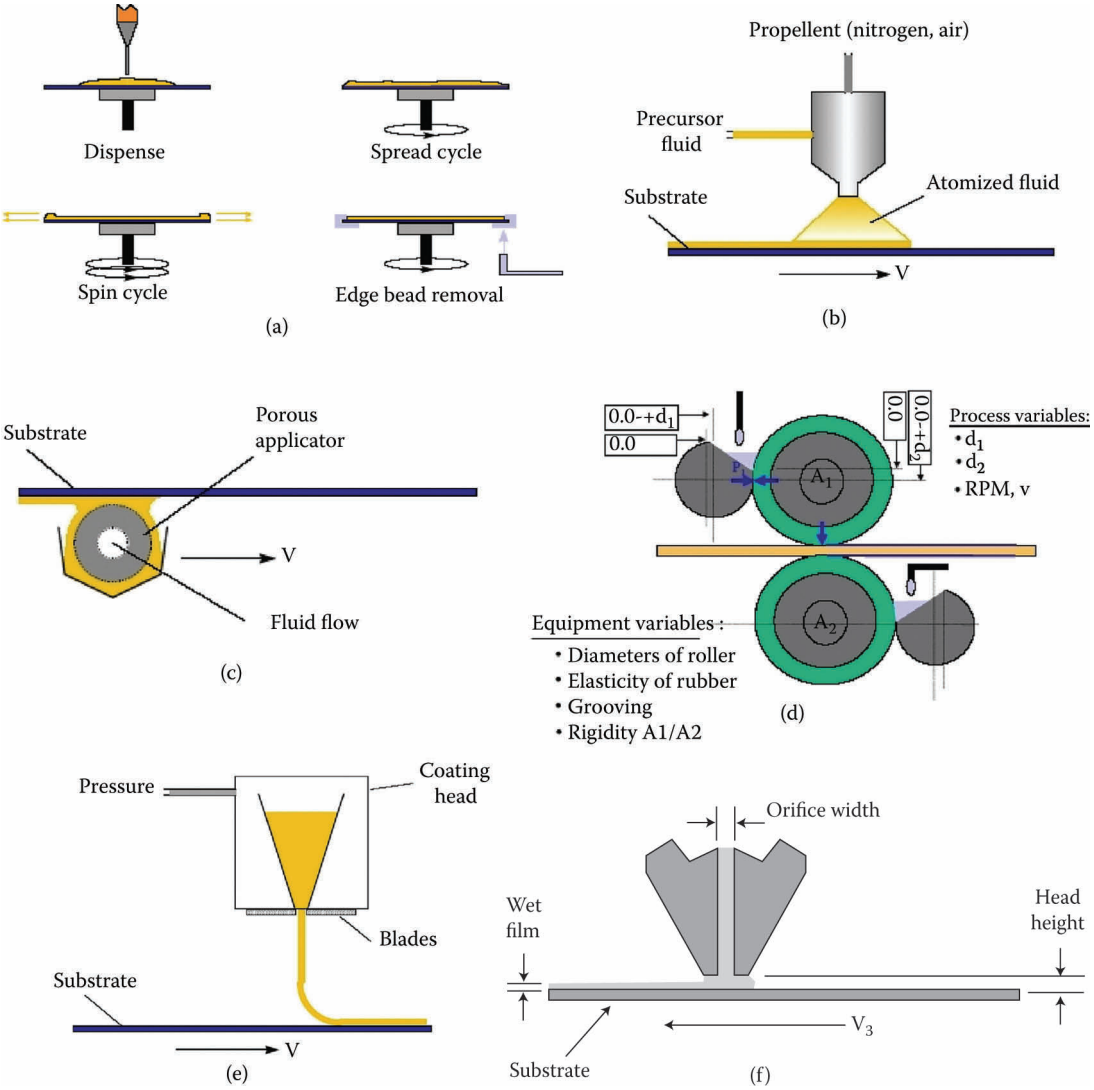

FIGURE 1.15 Photoresist deposition methods: spin coating (a), spray coating (b), meniscus coating (c), roller coating (d), curtain coating (e), and extrusion coating (f) V represents a movement in the direction of the arrow. (Webster, R.J. 1998. *Thin film polymer dielectrics for high-voltage applications under severe environments.* Master's thesis. Virginia Polytechnic Institute and State University.[20])

the coating method described immediately below), the droplets formed in the spray mist are not as small. This can lead to problems in the coating. To avoid the undesired overspray the spray gun must be kept close to the substrate (e.g., 5 cm compared with 30 cm in electrostatic spray). Compared with spin coating, spray coating does not suffer from the resist thickness variation caused by the centrifugal force because the resist droplets are supposed to stay where they are deposited. Spray coating is often used where thicker photoresist films are required, and the uniformity of spray coatings can be held within 5% tolerance when mechanized spray arms are used. Another major advantage is its ability to coat uniformly over nonuniform surfaces, making the technique appropriate for MEMS. During spray coating, the wafer may be rotated slowly while the swivel arm of the spray-coating unit is moved across the wafer. A low spin speed (30–60 rpm) is used to minimize the centrifugal force effects. The rotation allows for resist coverage in all the angles of MEMS cavities. Importantly, sprayed coatings do not have the internal stress forces that are common to spin-coated films. However, control of the deposited film thickness is not as precise as with spin- and extrusion-coated substrates (see last coating method reviewed in this section), and some waste of photoresist solution must be accepted as part of this

processing technique. It is difficult to deposit layers of resist thicker than 20 µm with spray coating. The process can be automated and may coat substrates double-sided.

Electrostatic Spraying Electrostatic spraying or electrodeposition is a variant of spray coating. During the atomization of the resist by air or nitrogen pressure, the droplets formed are given a static charge by applying a large voltage (e.g., 20 kV). The charge causes the droplets to repel each other, maintaining the integrity of the mist of resist formed. Because the droplets follow the electric flux lines, the amount of overspray can be minimized by a set of charged wires keeping the cone of spray to within the desired coating area, thus minimizing overspray. The substrate to be coated can be passed horizontally or vertically through the spray. The latter allows for simultaneous coating on both sides of substrates.

Meniscus Coating Meniscus coating is another viable coating method, especially attractive for large area substrates such as flat panel displays. The method is illustrated in Figure 1.15c. Photoresist solution is pumped through a porous tube (10-µm pores), and a gravity-assisted laminar flow of the liquid is established around the perimeter of the tube. The inverted substrate is made to touch and pass the solution flowing around the tube, and the meniscus of the resist solution adheres to the surface of the moving substrate. Excess fluid that does not adhere to the substrate is collected and recirculated to the coating head. Important process parameters include the separation of the coating head to the substrate, coating velocity, solids content in the resist solution, and evaporation rate of the carrier solvent. These variables control the coating uniformity and thickness. Two important advantages of meniscus coating are the reduction in coating materials loss (only 5–10% loss) and the avoidance of edge buildup (unlike spin coating). Coating techniques involving intimate contact between the substrate and the photoresist supply source, such as meniscus coating or silkscreen printing, lead to good coverage if the adhesion of the resist to the substrate surface is adequate.

Silkscreen Printing Silkscreening can also be used to apply thin, even films of resist for small production runs. Silkscreening of organics is covered in Chapter 8 on chemical, photochemical, and electrochemical-based forming (see Figure 8.10).

Plasma-Deposited Resist Another interesting method is the deposition of resist from the gas phase, i.e., plasma-deposited photoresist. In this method, a monomeric coating precursor is required, which may be evaporated at ambient temperatures and forms a polymer after deposition on the substrate. The latter technique is covered in Chapters Seven and Eight (see for example Figure 8.9).

Electrodeposition (Electrophoresis)[21] Electrophoretic photoresist deposition (ED) is an appropriate technique for the coating of substrates with extreme topography. The ED process requires electrically conductive substrates and electrical biasing during the resist-coating process. The coating solution contains charged micelles comprising resist, solvent, and dye and photoinitiator molecules. The sizes of the micelles are in the 50–200 nm ranges, and coulombic repulsion keeps the particles sufficiently separated to avoid flocculation and settlement. The electrophoretic process was explained in detail in Volume I, Chapter 6; it suffices to mention here that the solution must be rather resistive for a strong enough electrophoretic field to be established. The ED of the photoresist occurs onto a cathodic (negative) or anodic (positive) polarized conductive substrate.[22] In the case of a cataphoretic resist emulsion, the ionized polymer forms positively charged micelles. When the electric field is applied, the positively charged micelles migrate by electrophoresis toward the cathode. When the micelles reach the cathode, their positive surface charges are neutralized by hydroxide ions produced by the electrolysis of water at that electrode. The micelles then become destabilized and coalesce on the surface of the cathode to form a self-limiting, insulating photoresist film. The growth of the film is self-limiting because the resist layer is nonconductive, and once sufficient resist has been deposited to insulate the substrate surface, no further "plating" can occur. Both positive and negative photoresist chemistries for ED are

available (e.g., 2400 ED and Eagle 2100 ED from Shipley Ltd.). Typical coating thicknesses, highly dependent on the voltage and the temperature, are in the range of 5–10 µm, but specific resist systems can be deposited up to about 35 µm on both sides of the substrate simultaneously. The main advantage is that it yields a pore-free deposit of the resist, even at very low thicknesses. Although the most extreme surface topographies can be coated with this technique, this process needs metal plating of substrates and has some associated process complexities, such as the requirement for wafer electrical biasing during the resist-coating process.

Dip Coating In dip coating, one dips the substrate into a solution of liquid resist to apply a coating. The method is simple in that the substrate after cleaning and drying is dipped into a tank containing the photoresist and withdrawn slowly. A thin coating of the resist adheres to the substrate and is fixed by mild baking. The rate of withdrawal and the viscosity and solid contents of the resist are adjusted to obtain the desired thickness. However, it is not possible to get thicknesses greater than about 8–10 µm through this method. The technique does not enable much thickness or uniformity control either, although this method is commonly used in small-volume shops or for odd-sized substrates. The benefits of dip coating are obvious. As a double-sided coating method, all types of formats can be coated. It allows coating thick plates, as well as thin sheets and even wires. Simultaneous coating of multiple sheets increases the productivity significantly. A high and consistent coating quality can be ensured because the few and basic coating parameters can easily be maintained. Dip coating, a process often used to make needle-type biosensors, is covered in more detail in Chapter 8. In the dip-coating process, multiple dip coatings and drying cycles follow each other.

Roller Coating Roller, curtain, and extrusion coating are all variations of directly casting the coating solution on the substrate. Roller coating allows for single- or double-sided coating, and the equipment is less expensive than that used in curtain coating (see next section). Double-sided roller coating is illustrated in Figure 1.15d. Grooved rubber rolls are used to transfer the liquid resist, which is constantly fed into a nip between a doctor bar or roller and the coating roll, to the substrate surface. The pressure between the doctor and coating roller affects the final resist film thickness, as does the pitch of the grooves on the roller, the nonvolatile content of the resist, and the coating roller-to-substrate pressure (see Figure 1.15d). Roller coating can produce very even coatings of low thickness. Excess resist flows back to a sump for recycling via an automatic viscosity controller and filter unit, thus limiting wastage. Roller coaters are often used in-line with a photoresist dryer. The roller-coating technique can also be useful for the application of thick photoresist films to thin substrates. In general, however, it is incapable of producing uniform coatings less than 5 µm in thickness. Other advantages of roller coating include low photoresist waste and adaptability to automation.

Curtain Coating Curtain coating is illustrated in Figure 1.15e; the substrate is moved on a conveyor through a sprayed "curtain" of the resist. The liquid resist is pumped into a head from which the only exit is a thin nip on the head's underside. The resist forced through this nip forms a curtain of resist through which the substrates to be coated are passed. This method can only coat single-sided. The distance from the resist delivery point (the slit) to the substrate is large compared with other coating methods. This method gives high transfer efficiency; however, the thin layer of resist falling through the air results in a significant loss of solvent. Typically, thickness in the 25–60 µm range can be obtained with curtain coating. Undeposited material is recirculated back to the coating head. By careful control of material viscosity, belt speed, and pump speed, reproducible thicknesses can be achieved and maintained over the substrate surface with less than 10% variation in the overall thickness.

Extrusion Coating A method closely related to curtain coating is extrusion coating, as illustrated in Figure 1.15f. In extrusion coating, the extrusion head is positioned at a short, predetermined height above the substrate. Film thicknesses from less than 1 µm to greater than 150 µm in a single coating

pass have been demonstrated with uniformities better than ±3% on substrates up to 350 mm × 400 mm.[20] An important commercial advantage of extrusion coating is that it can be easily integrated into high throughput microelectronic fabrication lines. However, there are some disadvantages associated with extrusion coating, such as the variation in the substrate surface uniformity, which is transferred to the extrusion head during the deposition process. Furthermore, edge beads form along the leading edge of extrusion-coated substrates, although not to the extent encountered in spin-coated films. A thin curtain of the resist is made to fall on the substrate, which is moving horizontally at a controlled rate. As it falls on the substrate, the liquid curtain gently covers it just like a cloth and gets fixed as a film during conveyor movement and drying. This method obviously requires a lot of controls to achieve good results and, if performed well, can yield very satisfactory coatings. It should be noted, however, that coating the two sides of the laminate requires two operations. Control schemes exist in which the fluid flow into the extrusion head and the internal head pressure are measured and passed to a computer that determines the proper motion profile for the extrusion head, thereby improving the uniformity of the coating along the leading edge. The resist extrusion process has been proposed as a lower cost alternative to spin coating for producing highly uniform thin films on large area substrates.

There is no forced drying during roller, curtain, and extrusion coating other than evaporation. Therefore, the coating material has time to flow and planarize over surface features. The degree of coverage into deep features is highly dependent on the surface wettability and the solution viscosity.

A number of the photoresist deposition processes reviewed above are depicted in Figure 1.15.

In Table 1.5, three coating methods of photoresist—spin, spray, and electrodisposition—on large topography MEMS surfaces are compared.[23] Characteristics of each method, as well as advantages and disadvantages, are outlined.

Soft Baking or Prebaking

After resist coating, the resist still contains up to 15% solvent and may contain built-in stresses. Therefore,

Table 1.5 Comparison of Spin Coating, Spray Coating, and Electrodeposition (ED) of Photoresists

	Spin Coating	Spray Coating	ED
Process	Simple Difficult to automate process	Simple Possible for batch production	More complicated (equipment, solution) Batch production
Surface materials	Insulating or conductive	Insulating or conductive	Only on conductive layer Electrical connection to wafer
Parameters	Viscosity Spin speed	Solid content of solution Resist dispensed volume Scanning speed Spray pressure	Voltage Temperature
Photoresist	Several commercially available types	Resist solution with viscosity <20cSt Use much less resist	Special ED resist Resist bath needs frequent refreshing
Resist uniformity	Difficult to control Poor reproducibility Dependent on position of cavities in wafer	Controllable Reproducible Independent on position of cavities	Reproducible and good uniformity (best among three methods)
Suitable application	Transfer patterns to the bottom of etched cavities One level etched and large cavities preferable	Transfer patterns to bottom of etched cavities Cavities with comparable size preferable	Transfer patterns that run in and across cavities Metal patterning preferable

the wafers are soft baked (also pre-exposure baked or prebaked) at 90–100°C for about 20 minutes in a convection oven or at 75–85°C for 1–3 minutes with a vacuum hot plate to remove solvents and stress and to promote adhesion of the resist layer to the substrate. This is a critical step in that failure to sufficiently remove the solvent will affect the resist profile. Excessive baking destroys the photoactive compound and reduces sensitivity. Thick resists may benefit from a longer bake time. The resist thickness, for both negative and positive resists, is typically reduced by 10–25% during soft baking. Hot plating the resist is faster, more controllable, and does not trap solvent like convection oven baking. In convection ovens, the solvent at the surface of the resist is evaporated first, and this can cause an impermeable resist skin, trapping the remaining solvent inside. Therefore, heating in a convection oven must proceed slowly to avoid solvent bursts. On a hot plate, a smooth substrate surface is needed for good thermal contact and heating uniformity, and the hot plate should be perfectly horizontal. In this case, the temperature increase starts at the bottom of the wafer and works upward, more thoroughly evaporating the coating solvent and leading to a generally much faster and more suitable approach for automation. Commercially, microwave heating or IR lamps are also used in production lines. The optimization of the prebaking step may substantially increase device yield.

Exposure and Postexposure Treatment

After soft baking, the resist-coated wafers are transferred to an illumination or exposure system where they are aligned with the features on the mask (see Figure 1.16). For any lithographic technique to be of value, it must provide an alignment technique capable of a superposition precision of mask and wafer that is a small fraction of the minimum feature size of the devices under construction. In the simplest case, an exposure system consists of a UV lamp illuminating the resist-coated wafer through a mask without any lenses between the two. The purpose of the illumination is to deliver light with the proper intensity, directionality, spectral characteristics, and uniformity across the wafer, allowing a nearly perfect transfer or printing of the mask image onto the resist in the form of a latent image.

In photolithography, wavelengths of the light source used for exposure of the resist-coated wafer range from the very short wavelengths of extreme UV (10–14 nm) to deep UV (150–300 nm) to near UV (350–500 nm). In near UV, one typically uses the g-line (435 nm) or i-line (365 nm) of a mercury lamp. The brightness of shorter-wavelength sources is severely reduced compared with that of longer-wavelength sources, and the addition of lenses further reduces the efficiency of the exposure system. For example, the total collected deep UV power for a 1-kW mercury-xenon lamp in the 200–250 nm range is only 30–40 mW; the additional optics absorb more

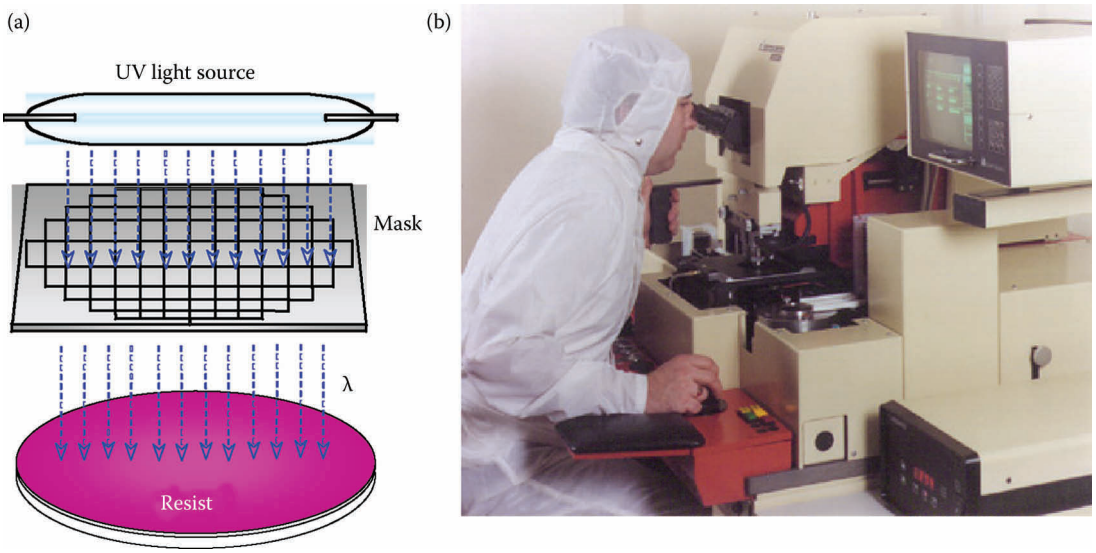

FIGURE 1.16 (a) Exposure of resist-coated wafer to UV light source. (b) An exposure station.

energy of the short wavelengths passing through them. As a consequence, with shorter wavelengths, higher resist sensitivity is required, and newer deep UV sources that produce a higher flux of deep UV radiation must be used. For example, a KrF excimer laser with a short wavelength of 248 nm and a power of 10–20 W at that wavelength is used. In general, the smallest feature that can be printed using projection lithography is roughly equal to the wavelength of the exposure source; in this example, 248 nm would be expected. The same laser, in combination with sophisticated resolution-enhancing techniques (RETs), may be used to produce more advanced circuits with transistor gate features of 160 nm and less. RET methods (see below) enable one to go a bit beyond the conventional Rayleigh diffraction limit. Other exposure systems now available include two deep UV excimer lasers, the ArF at 193 nm and the F_2 at 157 nm, and extreme UV lithography at 13.4 nm. The current generation of lithography uses 193-nm light[24] from ArF lasers. In the case of extreme UV, a plasma or synchrotron source and all-reflective reduction optics (4×) (at this wavelength all materials absorb!) are used. Refractive optical elements are too absorbing at those wavelengths.[25] Extreme UV as a commercial tool is in the exploratory phase only and is discussed in detail in Chapter 2 on next generation lithographies (NGLs). Step and scan printing extreme UV systems are expected to come on-line by the end of this decade. In Figure 1.17 we show the various technologies under investigation for the development of pilot and production lines of large scale integrated (LSI) circuitry.

The incident light intensity (in W/cm^2) multiplied by the exposure time (in seconds) gives the incident energy (J/cm^2) or dose, D, across the surface of the resist film. Radiation induces a chemical reaction in the exposed areas of the photoresist, altering the solubility of the resist in a solvent either directly or indirectly via a sensitizer. During the latent image-forming reaction, the sensitizer in the resist usually *bleaches*; in other words, exposed resist is rendered transparent to the incoming wavelength. This bleaching allows the use of thick films with high absorbency because light will reach the substrate through the bleached resist. The absorbency of the unexposed resist should not reach 40% to avoid degradation of the image profile through the resist depth because

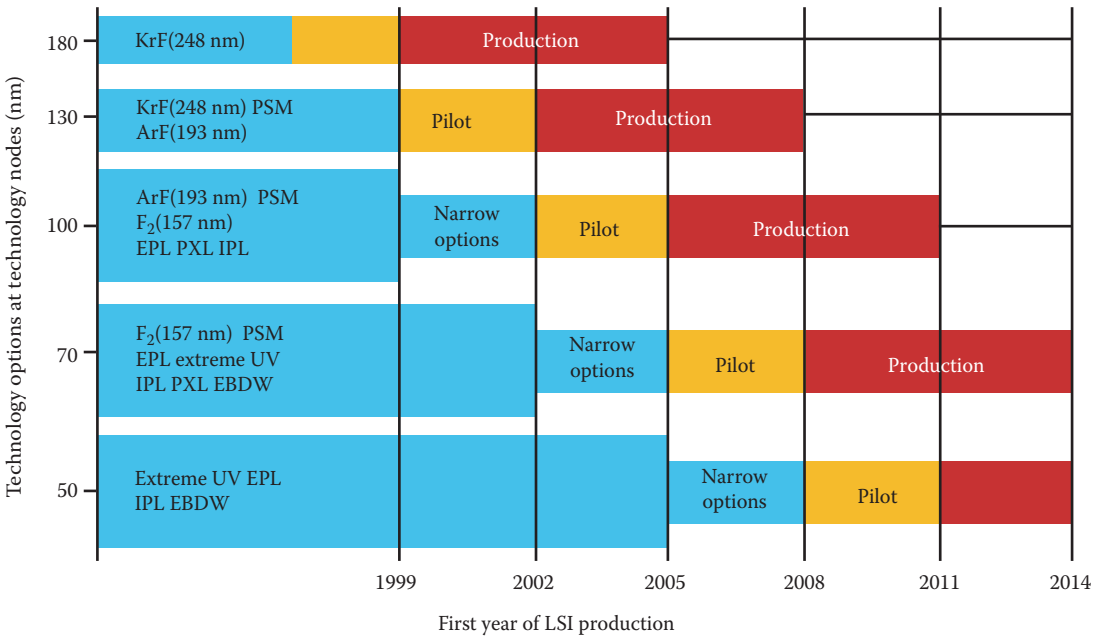

FIGURE 1.17 Various technologies under investigation for the development of pilot and production lines of LSI circuitry. These include KrF (248 nm), KrF excimer laser lithography with wavelength 248 nm; ArF (193 nm), ArF excimer laser lithography with wavelength 193 nm; F_2 (157 nm), F_2 excimer laser lithography with a wavelength of 157 nm; PSM, phase-shifting mask applied to KrF, ArF, and F_2; EPL, electron-projection lithography; PXL, proximity X-ray lithography; IPL, ion-projection lithography; EBDW, electron-beam direct writing. (Ito, T., and S. Okazaki. 2000. Pushing the limits of lithography. *Nature* 406:1027–31.[26])

too large a percentage of the light is absorbed in the top layer. On the other hand, with the absorbency far less than 40%, exposure times required to form the image become too long. The smaller the dose needed to "write" or "print" the mask features onto the resist layer with good resolution, the better the lithographic sensitivity of the resist.

A postexposure treatment of the exposed photoresist is often desired because the reactions initiated during exposure might not have run to completion. To halt the reactions or to induce new ones, several postexposure treatments are in use: postexposure baking (PEB), flood exposure with other types of radiation, treatment with a reactive gas, and vacuum treatment. PEB (sometimes in a vacuum) and treatment with reactive gas are used in image reversal and dry resist development. In the case of a chemically amplified resist, the PEB is most critical. Although reactions induced by the catalyst that forms during exposure take place at room temperature, their rate is greatly increased by baking at 100°C. The precise control of this type of PEB critically determines the subsequent development itself. A PEB improves line-width control by improving adhesion, reduction of scumming (resist left behind after development), increasing contrast and resist profile (higher edge-wall angle), and reducing the effects of standing waves (see Figures 1.69c and 1.70) in regular positive resist. A typical PEB used for the positive resist OCG 895i involves a temperature of 115°C on a hot plate held for 1 minute. Image reversal, dry resist development, and chemically amplified resists will be discussed below.

Development

Development is the dissolution of unpolymerized resist that transforms the latent resist image, formed during exposure, into a relief image that will serve as a mask for further subtractive and additive steps. During the development of an exposed resist, selective dissolving takes place (see Figure 1.1d). Two main technologies are available for development: wet development, illustrated in Figure 1.18, is widely used in circuit and miniaturization manufacture in general, and dry development, which is starting to replace wet development for some of the ultimate line-width resolution applications.

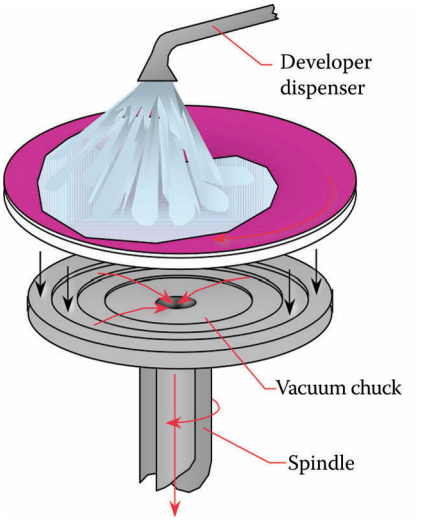

FIGURE 1.18 Wet development.

Wet development by solvents can be based on at least three different types of exposure-induced changes: variation in molecular weight of the polymers (by cross-linking or by chain scission), reactivity change, and polarity change.[27] Two main types of wet development setups are used: immersion (Figure 1.18) and spray developers (Figure 1.19). During batch immersion developing, cassette-loaded wafers are batch-immersed for a timed period in a developer bath and agitated at a specific temperature.

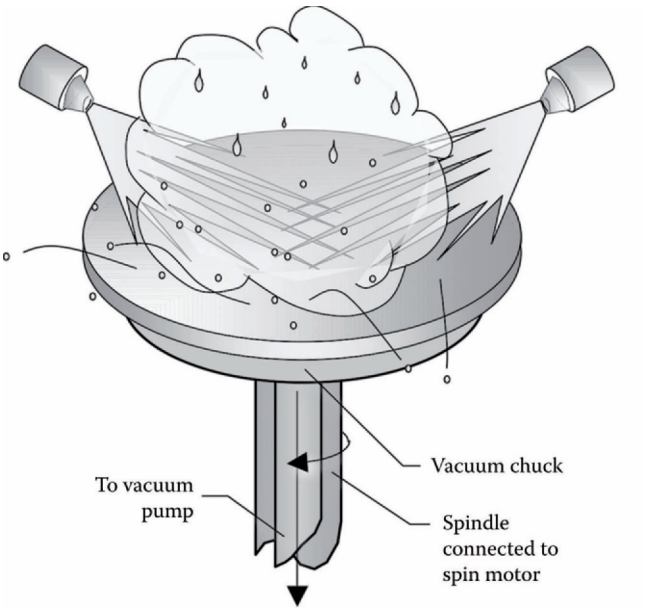

FIGURE 1.19 Spray developer: fresh developing solution is directed across wafer surfaces by a fan-type spraying nozzle. The renewal of developer allows uniform developer strength to be maintained.

During batch spray development, fan-type sprayers direct fresh developing solution across wafer surfaces. Positive resists are typically developed in aqueous alkaline solutions, and negative resists are developed in organic ones. For alkaline developers, simple solutions of NaOH (Shipley 351) or KOH (AZ/Clariant 400K) may be used, but because of the possibility of mobile ion contamination in metal oxide semiconductor (MOS) devices, developers free of metal ions are preferred. The latter are usually tetramethyl ammonium hydroxide (TMAH) based (Shipley CD-26, MF-321, or AZ/Clariant 300-MIF). Each developer has a different dilution, and some require longer development times than others. Developers are generally matched to a type of photoresist. Although they may be interchangeable to some extent, changing the type of developer used in a process will usually change the exposure time necessary to resolve the pattern. It should be noted that all of the above-mentioned alkaline developers etch aluminum. If the micromachine or microchip under construction contains aluminum features, Shipley Microposit Developer Concentrate, a mixture of proprietary alkaline salts (mostly phosphates) with the slowest aluminum etch rate, is a better developer choice.

Aqueous development is highly favored for health reasons. The aqueous development rate depends on the pH of the developer and the temperature, which needs to be controlled to within ±0.5°C.[19] Surfactants and other wetting agents added to the developer ensure uniform wetting, and buffers provide a more stable operating window and a longer lifetime. The more newly developed negative resists also may be developed in aqueous solutions.

The use of organic solvents leads to some swelling of the resist (especially for negative resists) and loss of adhesion of the resist to the substrate. Dry development overcomes these problems, as it is based either on a vapor phase process or a plasma.[28] In the latter, oxygen-reactive ion etching is used to develop the latent image. The image formed during exposure exhibits a differential etch rate to oxygen-reactive ion etching rather than differential solubility to a solvent.[19] Dry developed resists should not be confused with dry film resists, which are resists that come in film form and are laminated onto a substrate rather than spin coated.

With continued pressure by the U.S. Environmental Protection Agency for a cleaner environment, dry development and dry etching (see Chapter 3) are becoming the predominant technologies to use. Dry developed resists, such as the DESIRE process, where the surface of the exposed resist is treated with a silicon-containing reagent, will be discussed below.

Descumming and Postbaking

A mild oxygen plasma treatment, so-called *descumming*, removes unwanted resist left behind after development. Negative and, to a lesser degree, positive resists leave a thin polymer film at the resist/substrate interface. The problem is most severe in small (<1 μm) high-aspect-ratio structures where the mass transfer of a wet developer is poor. Patterned resist areas are also thinned in the descumming process, but this is usually of little consequence.

Before etching the substrate or adding a material, the wafer must be postbaked. Postbaking or hard baking removes residual coating solvent and developer and anneals the film to promote interfacial adhesion of the resist that has been weakened either by developer penetration along the resist/substrate interface or by swelling of the resist (mainly for negative resists). Hard baking also improves the hardness of the film and avoids solvent bursts during vacuum processing. Improved hardness increases the resistance of the resist to subsequent etching steps. Postbaking frequently occurs at higher temperatures (120°C) and for longer times (e.g., 20 min) than soft or prebaking. The major limitation for heat application is excessive flow or melt, which degrades wall profile angles and makes it more difficult to remove the resist. Postbake induces some stress and resist shrinkage. Special care needs to be taken when the baking temperature is above the glass transition temperature, T_g, when impurities are easily incorporated into the resist because of the plastic flow of the resist. Positive resists withstand higher heating temperatures than negative resists, but their stripping proves more difficult. Descumming and postbaking both follow step d in Figure 1.1.

Resist does not withstand long exposure to etchants well. As a consequence, with 1:7 buffered

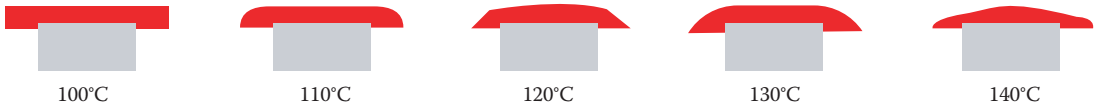

FIGURE 1.20 Tailoring resist sidewalls through resist reflow.

HF (a mixture of 1 part 49% aqueous HF solution and 7 parts NH_4F that is used to strip SiO_2), the postbake sometimes is repeated after 5 minutes of etching to prolong the lifetime of the resist layer (see Figure 1.1e). Also, postbaking should be prolonged before electroplating but is not needed for processes in which a soft resist is desired, e.g., in metal liftoff patterning (see Figure 1.37). As mentioned before, photoresist will undergo plastic flow with sufficient time and/or temperature, and this resist reflow may be used for tailoring resist sidewalls (Figure 1.20).

Resists

The principal components of photoresists are a polymer (base resin), a sensitizer, and a casting solvent. The polymer changes structure when exposed to radiation; the solvent allows spin application and formation of thin layers on the wafer surface; sensitizers control the chemical reactions in the polymeric phase. Resists without sensitizers are single-component or one-component systems, whereas sensitizer-based resists are two-component systems. Solvent and other potential additives do not directly relate to the photoactivity of the resist.

Resist Tone

If the photoresist is of the type called *positive* (also *positive tone*), the photochemical reaction during exposure of a resist weakens the polymer by rupture or scission of the main and side polymer chains, and the exposed resist becomes more soluble in developing solutions (e.g., 10 times more soluble). In other words, the development rate, R, for the exposed resist is about 10 times faster than the development rate, R_0, for the unexposed resist. If the photoresist is of the type called *negative* (also *negative tone*), the reaction strengthens the polymer by random cross-linkage of main chains or pendant side chains, becoming less soluble (slower dissolving). Exposure, development, and pattern-transfer sequences for negative and positive resists are shown in Figure 1.21. Figure 1.22 illustrates chain scission (positive resists) and cross-linking (negative resists).

Positive Resists Two well-known families of positive photoresists are the single component poly (methylmethacrylate) (PMMA) (Figure 1.23) resists and the two-component diazonaphtoquinone (DNQ)

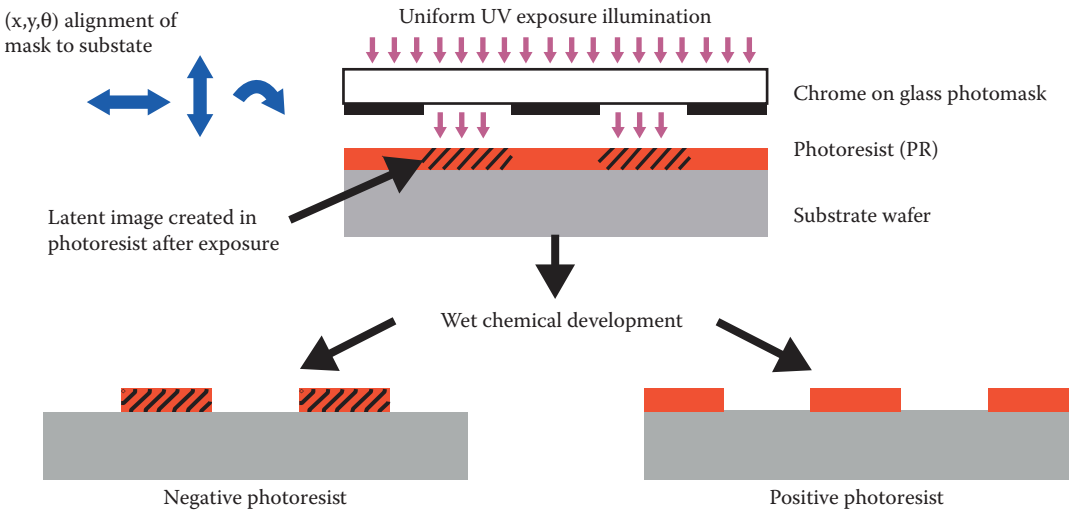

FIGURE 1.21 Positive and negative resist: exposure, development, and pattern transfer. (a) Negative resists remain in the exposed region. (b) Positive resists develop in the exposed region.

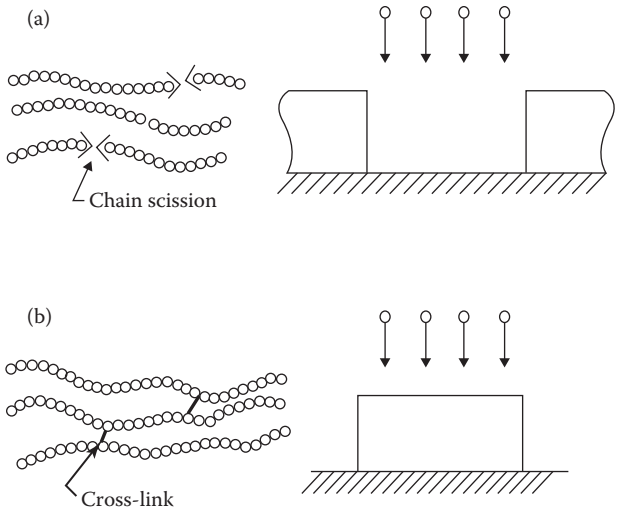

FIGURE 1.22 (a) Polymer chain scission (positive resists) and (b) cross-linking (negative resists).

(Figure 1.24) resists composed of a photoactive component such as DNQ ester (20–50 wt%) and a phenolic novolak resin.

PMMA becomes soluble through chain scission under deep UV illumination. The maximum sensitivity of PMMA lies at 220 nm; at greater than 240 nm the resist becomes insensitive. PMMA resin by itself constitutes a rather insensitive or slow deep UV photoresist requiring doses >250 mJ/cm^2. Exposure times of tens of minutes were required with the earliest PMMAs available.[28] By adding a photosensitizer such as t-butyl benzoic acid, the UV spectral absorbency of PMMA is increased, and a 150-mJ/cm^2 lithographic sensitivity can be obtained. PMMA is also used in electron beam, ion beam, and x-ray lithography. Although the resolution of PMMA is very good, its plasma etch tolerance is very low.

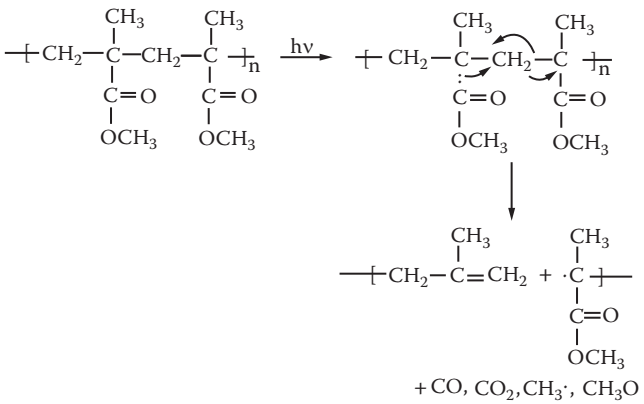

FIGURE 1.23 Poly(methylmethacrylate) or PMMA. Photoinduced chain scission of PMMA resist.

Also, dissociation of PMMA changes the chemistry of a plasma etch and often leads to polymeric deposits on the surface of the substrate.

The DNQ resist system is a "workhorse," near-UV, two-component positive resists, which photochemically transform into a polar, base-soluble product.[24] The hydrophilic novolak resin (N) is in itself alkali soluble because of the OH groups. Diazonaphthaquinone (DQ) is a hydrophobic and nonionizable compound, and when phenolic resins are impregnated with DQ, they become hydrophobic and are rendered insoluble. The addition of 20–50 wt% DQ forms a complex with the phenol groups of the novolak resin and reduces the solubility rate of the unexposed resist to less than 1–2 nm·s^{-1}. During exposure, DNQ undergoes photolysis that destroys the inhibitory effect of DQ on film dissolution (Figure 1.24). The photolysis causes the DNQ to undergo a reaction forming a base-soluble carboxylic acid that can be rapidly developed in aqueous solution of hydroxide ions (e.g., 1% NaOH). In contrast with cross-linked resists, the film solubility is controlled by chemical and polarity difference rather than molecular size. The matrix novolak resin itself is a condensation product of a cresol

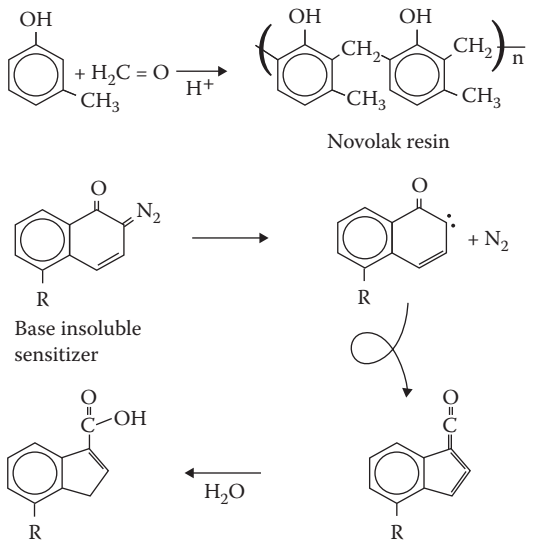

FIGURE 1.24 Phenolic novolak resin and the influence of diazonaphthoquinone ester (DNQ) on it. The novolak matrix resin is prepared by acid copolymerization of cresol and formaldehyde. The base-insoluble sensitizer, a DNQ, undergoes photolysis to produce a carbine, which then undergoes a rearrangement to form a ketene. The ketene reacts with water, present in the film, to form a base-soluble, indenecarboxylic acid photoproduct.

isomer (*para-cresol*) and formaldehyde consisting of hydrocarbon rings with two methyl groups and 1 OH group attached. Phenolic resins are readily cross-linked by thermal activation into rigid forms (bakelite was the first thermosetting plastic). A novolak resin absorbs light less than 300 nm, and the DNQ addition adds an absorption region around 400 nm. The 365-, 405-, and 435-nm mercury lines can all be used for exposure of DNQ. The intense absorption of aromatic molecules prevents the use of this resist at exposing wavelengths less than about 300 nm; at those shorter wavelengths, linear acrylate and methacrylate copolymers have the advantage. Positive attributes of novolak-based resist are that the unexposed areas are essentially unchanged by the presence of the developer. Thus, line width and shape of a pattern are precisely retained. Moreover, novolak is a long-chain aromatic ring polymer that is fairly resistant to chemical attack. Therefore, the photoresist is a good mask for the subsequent plasma etching. Moreover, unlike radical-based systems, it shows no oxygen inhibition.

Most positive resists are soluble in strongly alkaline solutions (a fact which is taken advantage of for stripping of the resist; see Figure 1.1f and text below) and develop in mildly alkaline ones (as shown in Figure 1.1d). Some typical industrially used developers for positive resists are KOH (e.g., a 0.05–0.5 N aqueous solution and a surfactant), TMAH, ketones, and acetates. As mentioned above, besides changing the molecular weight of the resist, radiation-induced reactions may also change the resist's solubility by altering its hydrophilicity (polarity) or its reactivity. Typical casting solvents for positive resists are Cellosolve* acetate, methyl Cellosolve, and aromatic hydrocarbons.

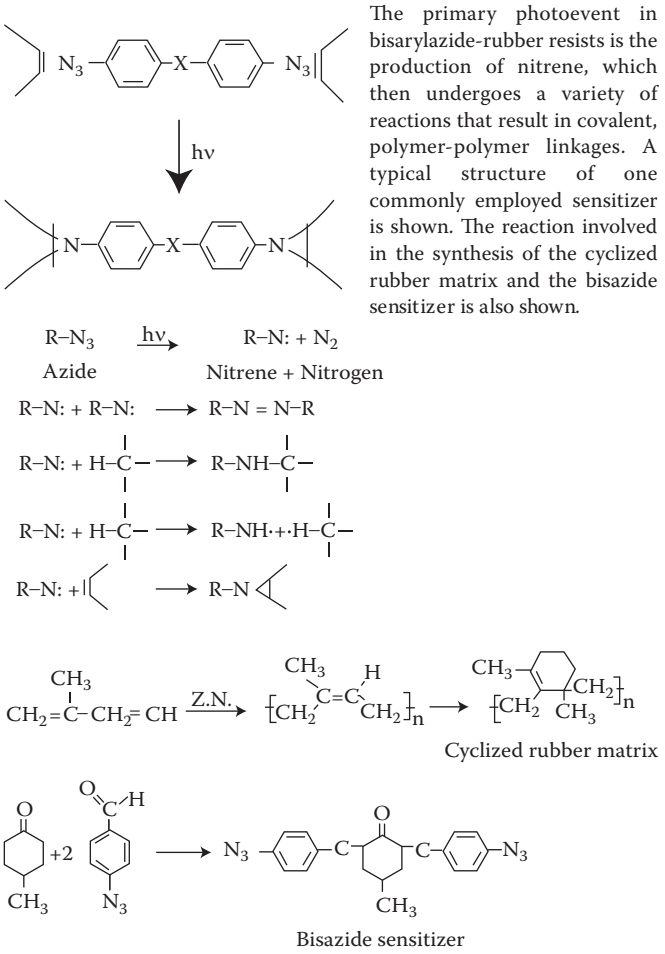
Negative Resists The first negative photoresists were based on free radical-initiated photo cross-linking processes of main or pendant polymer side chains, rendering the exposed parts insoluble. They were the very first types of resists used to pattern semiconductor devices and still comprise the largest segment of the overall photoresist industry, being widely used to define circuitry in printed wiring boards (PWBs).[29] A negative photoresist becomes insoluble in organic (more traditional negative resists) or water-based developers (newer negative resist systems) on exposure to UV radiation. The insoluble layer forms a "negative" pattern that is used as a stencil (usually temporarily) to delineate many levels of circuitry in semiconductors, MEMS, and PWBs. The insolubilization of radiated negative resists can be achieved in one of two ways: the negative resist material increases in molecular weight through UV exposure (traditional negative resists), or it is photochemically transformed to form new insoluble products (newer negative resist products). The increase in molecular weight is generally accomplished through photoinitiators that generate free radicals or strong acids, facilitating polymeric cross-linking or the photopolymerization of monomeric or oligomeric species. Photochemical transformation of negative photoresists may also lead to hydrophobic or hydrophilic groups, which provide another means of inducing preferential solubility between the exposed and unexposed resist film.

Commonly used negative-acting, two-component resists are bis(aryl)azide rubber resists (Figure 1.25), whose matrix resin is cyclized poly(*cis*-isoprene), a synthetic rubber. Cyclized rubber is obtained by acid treatment of poly(*cis*-isoprene), a process that leads to some ring formation in the polymer and stiffens it, thereby raising its glass transition temperature (T_g). For use in a photoresist, a resin should have a molecular weight of around 100,000–200,000 to ensure proper viscosity, melting point, softening point, and stiffness. To get a molecular weight of 100,000 using isoprene (M = 68.12 g/mol), one needs chains of an average length of n = 100,000/68.12 or 1,468 monomer units. This represents a molecule that is too long for proper photolithographic resolution, so the chains need to coil up to make them shorter and to increase the mechanical stiffness of the resist. Therefore, *cis*-isoprene is used to curl up the chains into rings; *trans*-isoprene would not work because of steric hindrance of the CH_3 groups.

The earliest negative photoresists, introduced in the 1960s, were based on the photo cross-linking of

* Cellosolve is a trade name for solvents based on esters of ethylene glycol; these solvents have been identified as possible carcinogens.

Bis(aryl)azide-sensitized rubber resists with cyclized poly(cis-isoprene) as matrix resin



The primary photoevent in bisarylazide-rubber resists is the production of nitrene, which then undergoes a variety of reactions that result in covalent, polymer-polymer linkages. A typical structure of one commonly employed sensitizer is shown. The reaction involved in the synthesis of the cyclized rubber matrix and the bisazide sensitizer is also shown.

FIGURE 1.25 Bis(aryl)azide-sensitized rubber resists with cyclized poly(*cis*-isoprene) as matrix resin. The primary photoevent in bis(aryl)azide rubber resists is the production of nitrene, which then undergoes a variety of reactions that result in covalent, polymer-polymer linkages. A typical structure of one commonly used sensitizer is shown.

"cyclized rubber" using an additive that contained two azide groups such as bis(aryl)azide. When this bis-azide is photolyzed, it loses nitrogen and produces two highly reactive nitrene moieties.

The nitrene intermediates undergo a series of reactions that results in the cross-linking of the resin. The nitrenes can form bonds with the cyclized rubber in a variety of ways, the most common of which is aziridine ring formation. Oxidation of the nitrene intermediate, with oxygen from the ambient or dissolved in the polymer to form azoxy and nitrose products, often competes with the addition and insertion reactions, reducing the extent of the polymer-polymer cross-linking. This phenomenon is called oxygen inhibition. In other words, polymerization can be inhibited by the quenching of the cross-linking reactions through scavenging of the nitrene photoproduct by oxygen. This competing reaction represents a disadvantage, as exposure must be carried out under a nitrogen blanket or in a vacuum. This type of resist was successfully used in the semiconductor industry when printed in "hard contact," minimizing the effect of the oxygen inhibition. With the introduction of soft contact (proximity mode) and off-contact (projection mode), the resist showed severe film thinning (scalping) as a direct consequence of the reduced cross-linking density near the air/polymer interface. Today, cyclic poly(*cis*-isoprene)-based resists play only a small roll in the semiconductor industry.

Another disadvantage of negative resists is that the resolution is limited by film thickness. The cross-linking process starts topside, where the light hits the resist first. Consequently, overexposure is needed to render the resist insoluble at the substrate interface. The greater the desired resist thickness, the greater the overdose needed for complete polymerization and the larger the scattered radiation. Scattered radiation at the resist/substrate interface in turn reduces the obtainable resolution. Moreover, the organic solvent developer swells the cross-linked negative image, which further degrades the resolution. In a practical situation, this leads to a 2–3-μm maximum resolution in a 1-μm-thick resist layer. To improve the resolution of a negative resist, thinner resist layers can be used; however, when using thin layers of negative resist, pinholes become problematic. Xylene is the most commonly used aromatic solvent for negative resists, although almost any organic solvent will do. Aromatic solvent developers may pose environmental, health, and safety concerns. Newer negative resists are water developable.

An example of a commercial, two-component negative photoresist is the Kodak KTFR [an azide-sensitized poly(isoprene) rubber] with a lithographic sensitivity (also photospeed) of 75–125 mJ/cm^2. Negative photoresists, in general, adhere very well to the substrate, and a vast amount of compositions are available (stemming from research and development work in paints, UV curing inks, and adhesives

all based on polymerization hardening). Negative resists are highly resistant to acid and alkaline aqueous solutions, as well as to oxidizing agents. As a consequence, a given thickness of negative resist is more chemically resistant than a corresponding thickness of positive resist. This chemical resistance ensures better retention of resist features even during a long, aggressive wet or dry etch. Negative resists also are more sensitive than positive resists but exhibit a lower contrast (γ smaller; see "Contrast and Experimental Determination of Lithographic Sensitivity," this chapter).

A comparison of negative and positive photoresist features is presented in Table 1.6. This table is not exhaustive and is meant only as a practical guide for selection of a resist tone. The choice of whether to use a negative or a positive resist system depends on the needs of the specific application, such as resolution, ease of processing, speed, and cost. The choice of resist tone will even depend on the specific intended pattern geometry, which is known as the *optical proximity effect*. For example, an isolated single line most easily resolves in a negative resist (higher resolution line), whereas an isolated hole or trench is most easily defined in a positive resist. Because traditional negative resists used to have a line-width limit of only about 2–3 µm and because the industry moved away from organic solvent-based systems in favor of less toxic, water-based developers, positive resists gained in popularity. However, traditional negative resists continue to be used in the production of PWBs and low-cost, high-volume chips

Table 1.6 Comparison of Traditional* Negative and Positive Photoresists

Characteristic	Resist Type	
	Positive Resist	Negative Resist
Adhesion to silicon	Fair (priming required)	Excellent (priming not required)
Available compositions	Many	Vast
Baking	In air (+)	In nitrogen (–)
Contrast γ	Higher, e.g., 2.2	Lower, e.g., 1.5
Cost	More expensive	Less expensive
Developer	Temperature sensitive (–) and aqueous based (Ecologically sound)	Temperature insensitive (+) and organic solvent (–)
Developer process window	Small	Very wide, insensitive to overdeveloping
Influence of oxygen	No (+)	Yes (–)
Liftoff	Yes [usually with multiple layer resist (MLR)]	Yes [even in single layer resist (SLR)]
Mask type	Dark-field: lower defects	Clear-field: higher defects
Opaque dirt on clear portion of mask	Not very sensitive to it	Causes printing of pinholes
Photospeed	Slower	Faster
Pinhole count	Higher	Lower
Pinholes in mask	Prints mask pinholes	Not so sensitive to mask pinholes
Plasma etch resistance	Not very good	Very good
Proximity effect	Prints isolated holes or trenches better	Prints isolated lines better
Residue after development	Mostly at <1 µm and high aspect ratio	Often a problem
Resolution	High	Low (>1 µm)
Sensitizer quantum yield Φ	0.2–0.3	0.5–1
Step coverage	Better	Lower
Strippers of resist over Oxide steps Metal steps	 Acid Simple solvents	 Acid Chlorinated solvent compounds
Swelling in developer	No	Yes
Thermal stability	Good	Fair
Wet chemical resistance	Fair	Excellent

*Newer resist systems are discussed under "Photolithography Resolution Enhancement Technology," this chapter.

because they require only small amounts of sensitizers and therefore are substantially less expensive than positive resists. Moreover, great progress has been made in improving the resolution of new types of water-soluble negative resists. These are used in new generations of ICs and in high-aspect-ratio miniaturized systems.[29,30] In working with different resists, it is also important to be aware of such properties as shelf life, flash point, and threshold limit value (TLV) rating. The flash point is the temperature at which the resist vapors ignite in the presence of an open flame. The TLV is the toxicity rating that specifies the maximum ambient concentration (in parts per million) to which a worker can be safely exposed during a normal workday.

Table 1.7 lists some common positive and negative resists used in various lithography strategies along with their lithographic sensitivities. For charged particles (e-beam lithography and ion-beam lithography), sensitivity is expressed in coulombs per centimeter square (C/cm^2); for photons (optical and x-ray), joules per centimeter square (J/cm^2) is used. Ideally, in charged-particle lithography, one should select a resist with sensitivity in the range of 10^{-5}–10^{-7} C/cm^2, and in photon lithography, 10–100 mJ/cm^2, to minimize the exposure duration.

Resist research and development are producing better resolution in both positive and negative resists. Results have been especially impressive in the latter. Negative resists used to be relegated to low-resolution chips and PWBs, but newer systems offer wider processing latitude and higher resolution. Progress has been so swift that new negative resists are now used in advanced complementary metal oxide silicon (CMOS) logic device manufacture. Several of these new negative resists also enable very high-aspect-ratio microfabrication.

Finally, in Table 1.8, we list the development of photoresists as they keep up with the scale of integration in ICs. In the inset of Table 1.8, we show the photoresist evolution with the type of lithography. In this inset, SCALPEL, ion-projection lithography, and x-ray lithographies are next generation lithographies (NGLs) that will be reviewed in Chapter 2; PSM stands for phase-shifting masks and OAI for off-axis illumination, two resolution-enhancing techniques (RETs) that are reviewed further below.

Permanent Resists and Dry Resists

Permanent Resists Resists typically are removed (stripped) once they have served their function as temporary stencils. Some negative resists, hardened through UV exposure, are used as permanent components of miniature devices. Two prominent examples in this category are polyimide and SU-8-based resists.

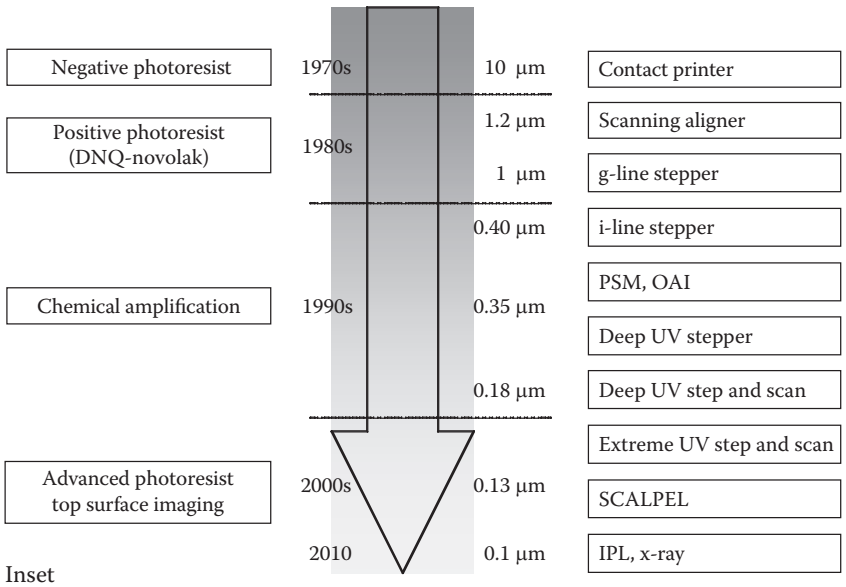
Polyimides are a class of polymers synthesized from two monomers: a dianhydride and a diamine.

Table 1.7 Typical Negative and Positive Photoresists and Their Lithographic Sensitivity

Class of Resist	Resist Name	Tone (Polarity)	Lithographic Sensitivity
Optical	CAMP-6 (OCG)	Positive	100 mJ/cm^2
	APEX-E (IBM and Shipley)	Positive	75 mJ/cm^2
	Kodak 747	Negative	9 mJ/cm^2
	AZ-1350J	Positive	90 mJ/cm^2
	PR102	Positive	140 mJ/cm^2
	XP-2198 (Shipley)	Positive	30 mJ/cm^2
	KRF (from UCB-JSR)	Negative	20–30 mJ/cm^2
e-Beam	COP [Copolymer-(α-cyano ethyl acrylate-α-amido ethyl acrylate)]	Negative	0.5 $\mu C/cm^2$
	GeSe (germanium selenide)	Negative	80 $\mu C/cm^2$
	PBS [poly-(butene-1-sulfone)]	Positive	1 $\mu C/cm^2$
	PMMA	Positive	100 $\mu C/cm^2$
X-ray	COP	Negative	100 mJ/cm^2
	DCOPA	Negative	14 mJ/cm^2
	PBS	Positive	170 mJ/cm^2
	PMMA	Positive	6500 mJ/cm^2

Table 1.8 Development of Photoresists during the Past 38 Years

Year	Scale of Integration	Minimum Line Width	Photoresist
1970	1 Kb	10 μm	Rubber-based negative
1973	4 Kb	8 μm	Rubber-based negative
1976	16 Kb	5 μm	Rubber-based negative
1979	64 Kb	2 μm	Rubber-based negative
1982	256 Kb	2 μm	Novolak-type positive
1985	1 Mb	1.2 μm	High-resolution positive photoresist of DQ-novolak type
1988	4 Mb	0.8 μm	High-resolution positive photoresist and multilayer process
1992	16 Mb	0.5 μm	Deep UV resist, multilayer process
1995	256 Mb	0.25 μm	I-line (356 nm) resist
1999	1 Gb	0.18 μm	KrF (248 nm) resist
2002	4 Gb	0.13 μm	ArF (248/193 nm) resist
2005	16 Gb	0.1 μm	F2 (193/157 nm) resist
2008	64 Gb	0.07 μm	Extreme UV (13 nm) resist



Commercial products are supplied as soluble polyamic acid (PAA) intermediates, which undergo a thermal imidization with the evolution of water to form an insoluble polyimide (Figure 1.26). Polyimide is used as an interlayer dielectric because of its desirable characteristics such as a high thermal stability with a glass transition temperature, T_g > 300°C, a low dielectric constant ε, good chemical stability, and ease of processing. However, its tendency to absorb moisture causes the polyimide layers to swell and their dielectric constants to increase significantly. Various polyimide analogs have been developed to avoid the latter undesirable property.[31] A common approach to reduce the dielectric constant of polyimides is the inclusion of organofluorine components, in the form of pendant perfluoroalkyl groups. The polyamic acid precursor for fluorinated polyimides is commonly based on hexafluorodianhydrideoxydianiline (HFDA-ODA). The inclusion of fluorinated monomers in the polyimide backbone reduces moisture absorption and the dielectric constant. Unfortunately, these modified polyimides generally show an increased susceptibility to chemical attack, making their use in multilayer fabrication questionable. However, newer formulations have improved the chemical resistance of polyimides and have demonstrated a unique wet etch capability for making vias with aspect ratios approaching 1.2:1. Polyimide can be "wet etched" using a strong alkaline solution

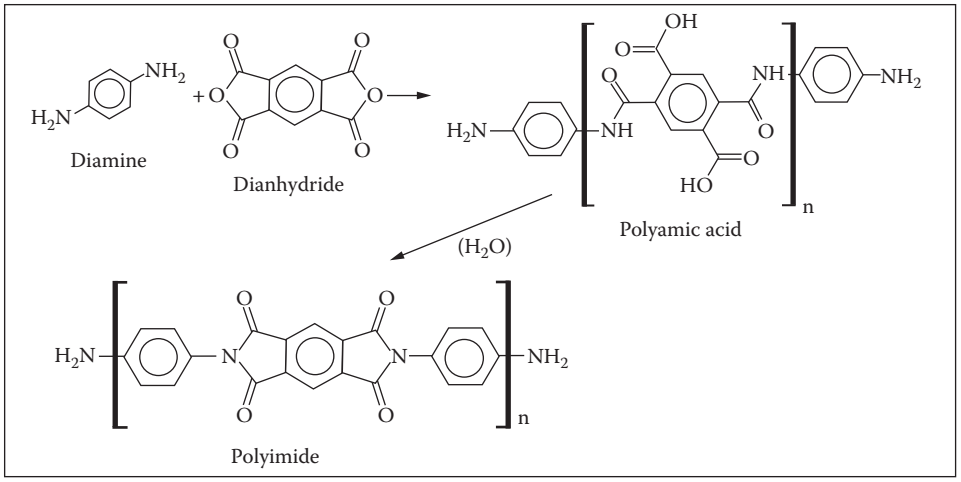


FIGURE 1.26 Typical imidization process used to form polyimides from polyamic acid.

such as TMAH. For dry etching of polyimide, one can use plasma-enhanced chemical vapor deposition (PECVD) silicon nitride as a mask with an O_2 plasma etch (possibly adding some CF_4). Tougher polyimide formulations are commercially available in polyamic acid form from Amoco under the trade name Ultradel. They have a slightly modified chemical structure based on hexafluorodianhydride-aminophenoxy-biphenyl (HFDA-APBP). The newest polyimides are extremely versatile materials and are used, for example, as stress-release layers in multichip modules, low dielectric insulation layers,[32] and even as optical waveguides based on fluorinated polyimides[33] (Figure 1.27; see also Chapter 3 on dry etching, Example 3.4). Ultradel 9000D is a soluble, preimidized, fluorinated polymer with properties optimized for integrated optical applications.

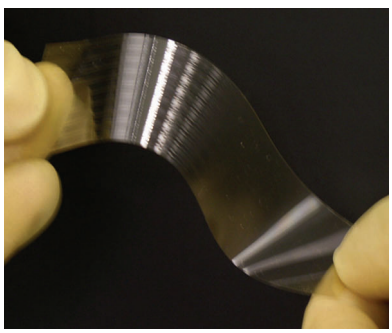

FIGURE 1.27 Flexible polyimide waveguide from Mitsui Chemicals. (Shioda, T. 2007. Next generation packaging technology which supports the ubiquitous devices. Application of the flexible optical waveguide to the consumer products. *Electr Parts Mater* 46:38–42.[35])

Typical absorption losses in the near-IR range from 0.2–0.4 dB/cm. In MEMS, polyimides have been used, for example, as flexible hinges in mechanical miniaturized structures (see Figure 7.86).[34]

Both nonphotosensitive polyimides and photosensitive polyimides (negative and positive) are available. Photosensitive polyimides have been processed in mass production lines using g-line (436 nm) and i-line (365 nm) exposure tools. Using photosensitive polyimides in manufacturing reduces the number of process steps dramatically compared with the use of nonphotosensitive polyimides. This is illustrated in Figure 1.28 for making polyimide vias in packaging. Positive tone polyimides, as used in Figure 1.28, are relatively new and were developed by HD Microsystems, a joint venture between Hitachi Chemical and Dupont (http://www.hdmicrosystems.com). The positive tone polyimides are more environmentally friendly than negative tone polyimides because of reduced organic solvents and associated volatile organic compounds. These positive tone resists also enable the process to use industry-standard TMAH developers. Polyimide films very strongly absorb UV light less than 350 nm. This absorbency is a result of the polymer's high aromaticity that is also responsible for the exceptional thermal properties of polyimides, which allows for processing at greater than 400°C. Polyimides in packaging and MEMS are further reviewed in Volume III, Chapter 4 on packaging.

Whereas in IC fabrication, sacrificial resist layers of 1 μm or less are common, in miniaturization

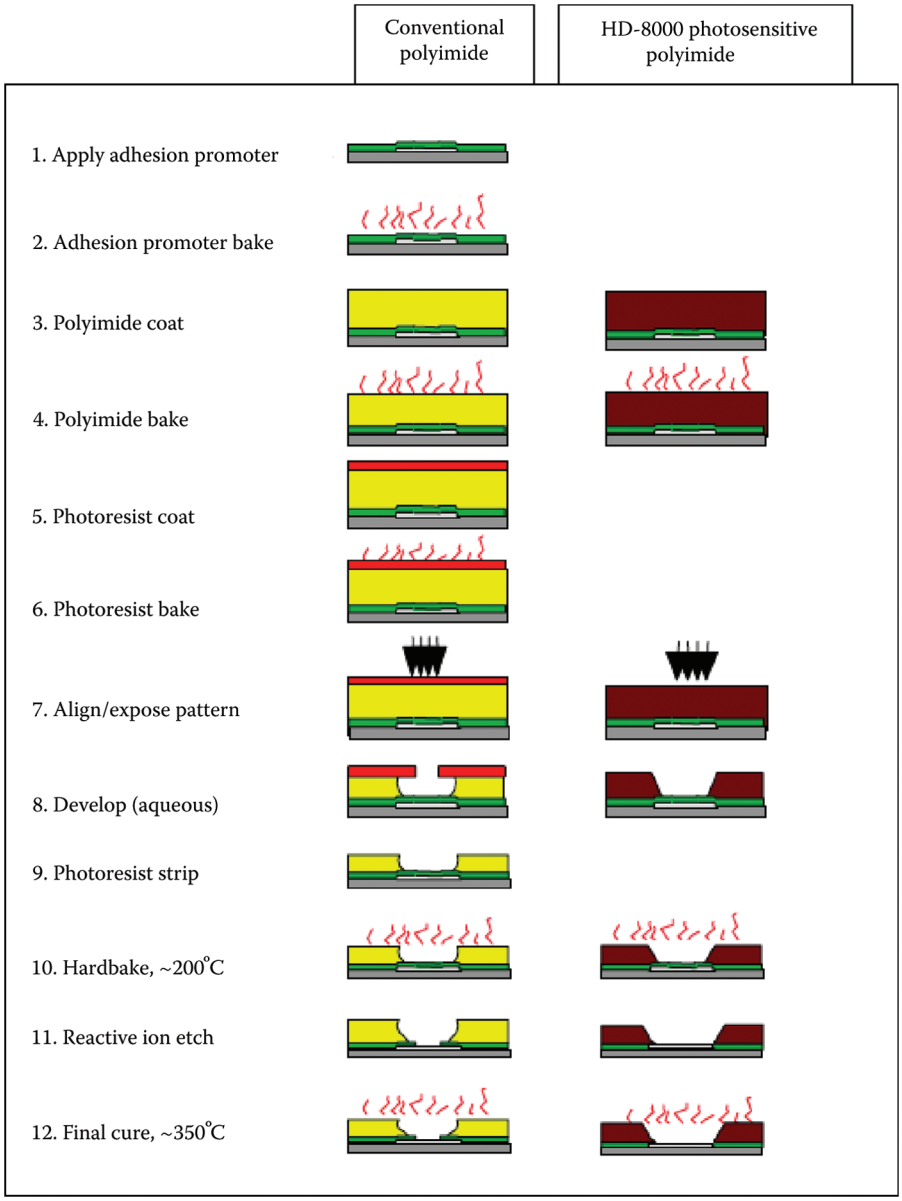

FIGURE 1.28 Comparison of conventional polyimide process and positive acting photosensitive polyimide process in packaging. The photosensitive polyimide process eliminates multiple steps and decreases cycle time. (Flack, W., S. Kulas, and C. Franklin. 2000. Process characterization of an aqueous developable photosensitive polyimide as a broadband stepper. SPIE. 3999–45.[36])

science, 3D structures frequently require thick permanent resist layers, capable of high resolution and high aspect ratios. Relatively new, chemically amplified deep UV resist systems, such as SU-8, can be applied in very thick layers (>100 μm) and have excellent sensitivity, high resolution, low optical absorption, high aspect ratio, and good thermal and chemical stability. These properties make SU-8 a good candidate for molds and other permanent MEMS structures. SU-8 is an acid-catalyzed negative photoresist, made by dissolving EPON®-SU-8 resin (registered trademark of Shell Chemical Company, http://www.shell.com) in an organic solvent such as cyclopentanone solvent or GBL (γ-butyrolactone) and adding a photoinitiator. The viscosity, and hence the range of thicknesses accessible, is determined by the ratio of solvent to resin. The EPON resist is a multifunctional, highly branched epoxy derivative that consists of bisphenol-A novolak glycidyl ether (Figure 1.29). On average, a single molecule contains eight epoxy groups, which explains the "8" in the name SU-8. The material has become a major

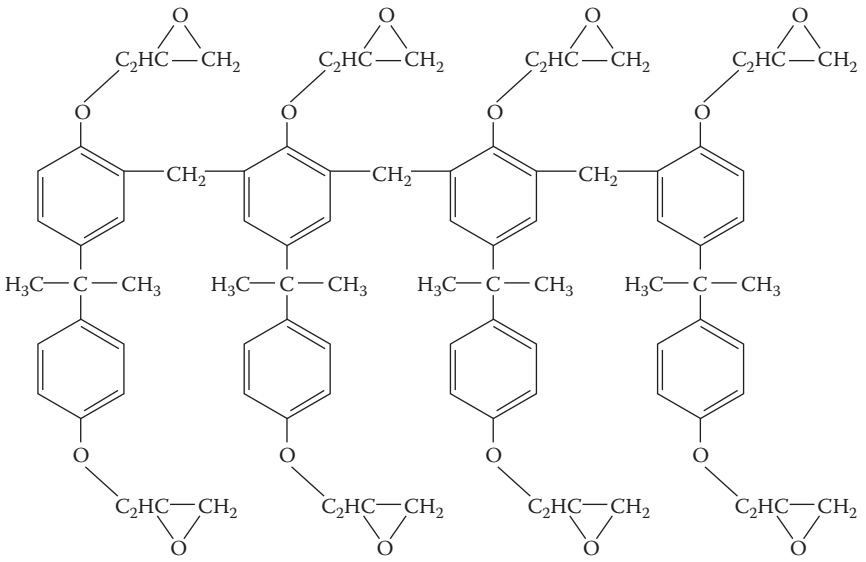

FIGURE 1.29 Glycidyl ether of bisphenol A: SU-8: cross-linking reaction of carboxy functional polymer with diepoxide.

workhorse in miniaturization science. In a chemically amplified resist like SU-8, one photon produces a photoproduct that in turn causes hundreds of reactions to change the solubility of the film. Because each photolytic reaction results in an "amplification" via catalysis, this concept is dubbed "chemical amplification".[37] We touch briefly on resist amplification here, in the context of SU-8 photoresist only, but will discuss the underlying principles in more detail in "Strategies for Improved Resolution through Improved Resist Performance" (this chapter).

Scientists at IBM discovered that certain photoinitiators, such as onium salts, polymerize low-cost epoxy resins such as EPON®-SU-8. An onium salt, on UV exposure, generates a strong Lewis acid and catalyzes the cationic polymerization of the resin. These salts are called photochemical acid generators (PAGs), and their action constitutes excellent dissolution inhibition of a phenolic resin. In contrast with conventional free-radical initiators, an onium salt cationic photoinitiator, for example, triphenylsulfonium hexafluoroantimonate, is oxygen insensitive and stable over a wide temperature range. On UV exposure of the resist, Lewis acids are released within the resist matrix, forming a latent image—a 3D distribution of the catalytic photoproduct—and image formation is realized after an activating postexposure baking (PEB), as shown in Figure 1.30. Not only UV light in the 365–436-nm range but also electrons and x-rays initiate a high level of cross-linking density, converting the SU-8 photoepoxy into a strong polymer with a T_g of more than 200°C (the T_g of the unexposed resist is 55°C).[38] During the PEB, the generated photoacid initiates the ring opening of the epoxy groups, and extensive cross-linking makes the SU-8 insoluble. An SU-8 soft bake is typically carried out at 95°C, and a hard bake at 200°C. Hot plating, on a level hot plate, is preferred over an oven heat treatment. For developing a 130-µm-thick SU-8 film, a 5-minute dip in undiluted propylene glycol methyl ether acetate, a rinse with isopropyl alcohol, and repeat of this procedure until all the unpolymerized material is dissolved works best.

SU-8 resist, patented by IBM in 1992, was originally developed for e-beam lithography[39] and became commercially available in 1996. Because of its aromatic functionality and highly cross-linked matrix, the SU-8 resist is thermally stable and chemically very inert. After a hard bake, it withstands nitric acid, acetone, and even NaOH at 90°C, and it is more resistant to prolonged plasma etching and better suited as a mold for electroplating than PMMA.* The low molecular weight [~7000 ± (1000)] and multifunctional nature of the epoxy gives it the high cross-linking propensity, which

* PMMA or poly(methyl 2-methylpropenoate) is the synthetic polymer of methyl methacrylate. This thermoplastic and transparent plastic is sold by the trade names Plexiglas, Limacryl, R-Cast, Perspex, Plazcryl, Acrylex, Acrylite, Acrylplast, Altuglas, Polycast, and Lucite and is commonly called acrylic glass or simply acrylic

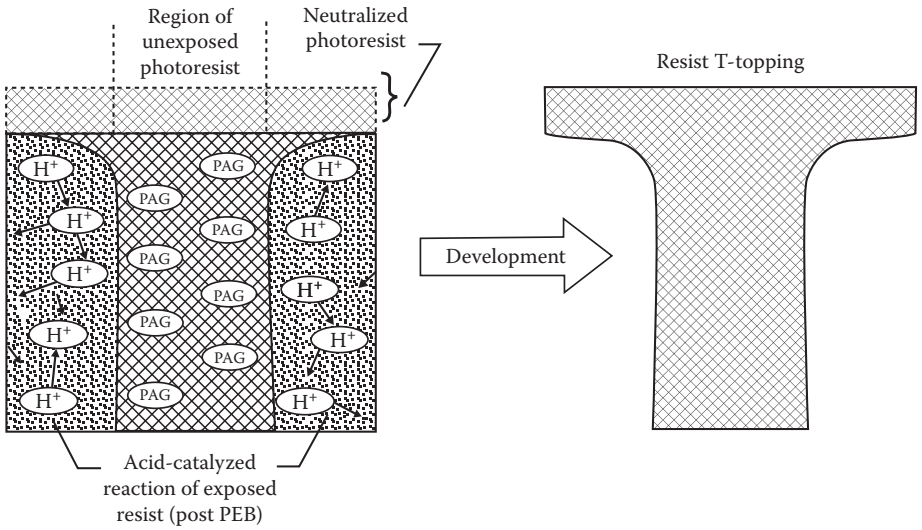

FIGURE 1.30 SU-8 is a negative-type amplified photoresist. Where light strikes the photochemical acid generators (PAGs), a Lewis acid is released within the resist matrix, forming a latent image—a 3D distribution of the catalytic photoproduct—and image formation is realized after an activating postexposure bake (PEB). After development a T-topped structure often results (see text).

also reduces the solvent-induced swelling typically associated with negative resists. As a result, very fine feature resolution, unprecedented for negative resists, has been obtained, and epoxy-based formulations are now used in high-resolution semiconductor devices, such as 0.35 μm CMOS logic (e.g., with CGR* chemically amplified negative resist). Low molecular weight characteristics also translate into high contrast and high solubility. Because of their high solubility (up to 85% solids by weight in solvents such as methyl-iso-butyl ketone), very concentrated resist casting formulations can be prepared. The increased concentration benefits thick film deposition (up to 500 μm in one coat) and planarization of extreme topographies. The high epoxy content promotes strong SU-8 adhesion to many types of substrates and makes the material highly sensitive to UV exposure. On the negative side, strong adhesion makes stripping of the exposed SU-8 material currently one of the most problematic aspects. Stripping of SU-8 may be carried out with hot 1-methyl-2-pyrrolidon, plasma, or laser ablation. There are other issues to be resolved with this resist; for example, thermal mismatch of SU-8 on a Si substrate (the thermal expansion coefficient α. for silicon is 2.361 ppm/K vs. 21–52 ppm/K for SU-8) produces stress and may cause film cracking. Moreover, the absorption spectrum of SU-8 shows much higher absorption coefficients at shorter wavelengths. As a result, lithography using a broadband light source tends to result in overexposure at the surface of the resist layer and underexposure at the bottom. The resulting developed photoresist tends to have a negative slope, which is not good for mold applications: the mold sidewall should have a positive or at least a vertical slope for easy release of the molded part from the mold. The exaggerated negative slope at the top of the resist structure surface is often called *T-topping* (see Figure 1.30). UV light shorter than 350 nm is strongly absorbed near the surface, creating locally more acid that diffuses sideways along the top surface. Selective filtration of the light source is often used to eliminate these undesirable shorter wavelengths (<350 nm) and thus obtain better lithography results. For example, Reznikova et al. used a 100-μm-thick SU-8 resist layer to filter exposure radiation at 334 nm,[40] and Lee et al.[41] reported using a Hoya UV-34 filter to eliminate the T-top (overexposed top part). Nearly vertical sidewalls can be achieved using a Hoya UV-34 filter. However, there might still be a beaked feature created at the very top of the resist features. This results from the diffraction at the interface between the

* CGR, chemically amplified resist based on poly(p-hydroxystyrene) or its copolymers with styrene or vinylcyclohexane with powderlink crosslinker and a photochemical acid generator.

mask and the photoresist, and it can be eliminated by filling this gap with index matching oil (see results by Wanjun Wan in Figure 1.31). Besides its sensitivity and relatively low cost (<$100/L), aspect ratios up to ~25 for lines and trenches have been demonstrated in SU-8-based contact lithography.[42] When patterned at 365 nm, the wavelength at which the photoresist is the most sensitive, total absorption of the incident light in SU-8 is reached at a depth of 2 mm. In principle, resist layers up to 2 mm thick can be structured.[43] Wan et al.[44] recently confirmed this astounding potential experimentally. Wan's group at Louisiana State University, using both wavelength optimization by patterning using a filtered i-line (365 nm) and air gap compensation (with glycerin or a Cargille refractive index matching fluid), demonstrated aspect ratios greater than 190 (for a feature with a 6-μm thickness and a height of 1150 μm) and structures as high as 2 mm. In the inset in the header of this chapter we reproduce one result of Wan et al., and more are displayed in Figure 1.31.

New resists like SU-8 have enabled miniaturization scientists to make LIGA (German acronym for *Lithographie*, *Galvano-formung*, *Abformung*)-like structures less expensively. LIGA is the ultimate lithography technique for making high-aspect-ratio features. In LIGA, a synchrotron x-ray source is used for exposure, and resist walls with the ultimate in wall straightness and wall smoothness are obtained (see Chapter 10). For many applications, photolithography with a much less expensive UV exposure system and a thick photoepoxy, such as SU-8, suffices. This alternative method to LIGA is sometimes referred to as *poor man's LIGA*. The example SU-8 application from Mimotec (http://www.mimotec.ch) shown in Figure 1.32 is a typical LIGA-like application, in

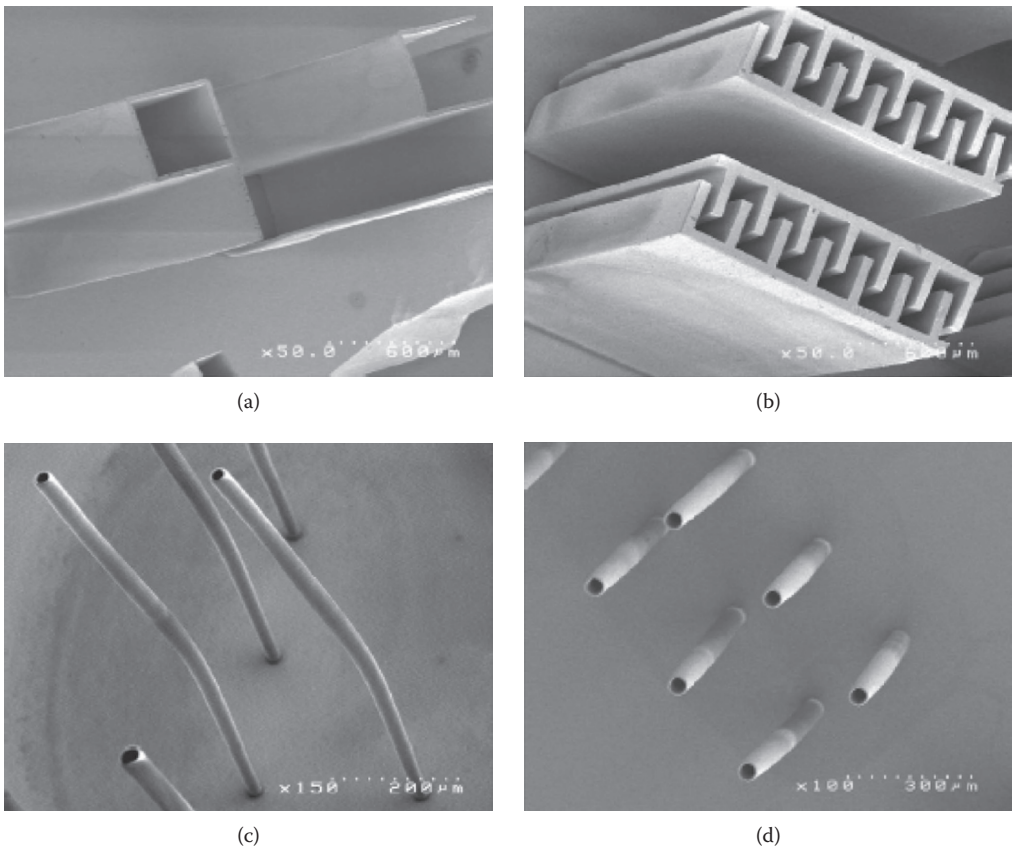

FIGURE 1.31 Ultrahigh-aspect-ratio structures obtained using a filtered light source (using a thick PMMA plate as filter) and with gap compensation (using an index matching solution). (a) Micro features with designed thickness of 7 μm and height of 2000 μm. (b) Micro comb structures with designed thickness of 40 μm and height of 2000 μm. (c) Micro cylinders 1150 μm tall and designed wall thickness of 6 μm and an internal diameter of 20 μm. As the thickness is reduced, the strength of the cylinders becomes too low to maintain their upright position. (d) Micro cylinders 1150 μm tall and designed wall thickness of 9 μm and internal diameter 27 μm.

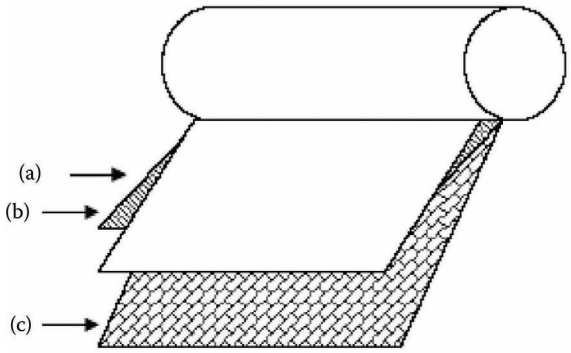
which a sacrificial cavity in SU-8 resist has been electroplated to make a metal positive replicate of the cavity. The advantages of the poor man's LIGA method are that it is inexpensive and can be quickly brought into play, all of which makes the process very competitive compared with LIGA.

To find the latest updates on SU-8 applications and processing tips, visit http://aveclafaux.freeservers.com/SU-8.html. This site also lists all the relevant physical properties of SU-8 accompanied with literature references. Another resource with plenty of SU-8 information is the MEMScyclopedia at http://memscyclopedia.org/su8.html.

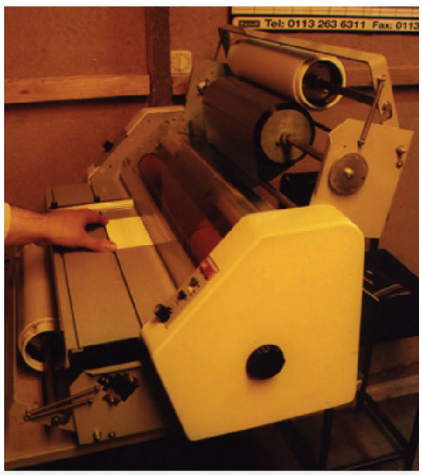
The first two companies that bought an SU-8 sales license from IBM were MicroChem Corporation[45] and Sotec Microsystems.[46] The latter company, now defunct, developed conductive and magnetic SU-8 and used dry SU-8 films to laminate over large cavities and channels[42]. MicroChem (previously named Microlithography Chemical Corp.) is the oldest manufacturer of the SU-8 photoresist, licensed by IBM. SU-8 Gerstel Engineering Solutions, Ltd. (http://www.gersteltec.ch) not only sells SU-8 under the name SU-8 GM-10## with different viscosities (e.g., GM-1040, GM-1060, and GM-1070) but also offers prototyping and mass production of SU-8 microsystems.

Dry Resist Most resists in IC and MEMS fabrication are deposited as liquids, whereas resists used in printed wiring board (PWB) manufacture are usually dry film resists that come in rolls (ranging from 2–60 in. wide and 125–1000 ft. long) and are laminated onto the substrate instead of being spin coated onto it (Figure 1.33). Dry film resist formulations are sandwiched between a polyolefin release sheet and a polyester base, rolled up on a support core (Figure 1.33A and B). These protective covers shield the film from environmental oxygen and facilitate handling. The dry film resist layer comes in thicknesses starting from 25 µm and goes up to 100 µm. Resist thicknesses of 1–1.5 mils are common for imaging purposes, and thicker resists (1.5–2.0 mils) are used as plating, rather than etch, resists. Dry film resists offer advantages such as excellent adhesion on most substrates, no liquid handling because there is no solvent, high process speed, excellent thickness uniformity over a whole substrate (even substrates with holes), simple handling, no formation of edge beads, low exposure energy, low cost, short processing time, and near vertical sidewalls. The photoresist film is applied by removing the polyolefin sheet before lamination of the resist onto the substrate. The polyester top cover sheet remains on top of the photo polymer until later in the process. This coversheet protects the resist from scratches, keeps contaminants from the surface, and prevents the exposure tool from touching and perhaps sticking to the resist. Conformation of the resist to the substrate is achieved by heating under pressure in a hot-roll or cut-sheet laminator (Figure 1.33C). The heat and pressure of the laminating rollers cause the dry film to soften and adapt to surface topologies. The resist is then exposed to a UV light source. Modern dry film resists are developed in a simple sodium carbonate solution (1–2%) after removal of the top cover layer. The biggest disadvantage of dry resist is its relatively low resolution compared with liquid resists as illustrated in Figure 1.34. Two major reasons for this poorer resolution are the many-times thicker resist coating and the fact that the mask is positioned on top of a thick protective Mylar cover

(A)



(B)



(C)

FIGURE 1.33 (A) Dry film resist roll. (B) Dry film photoresist composition; three-layer structure, (a) polyethylene separation sheet, (b) photoresist, and (c) polyester support. (C) Dry lamination equipment.

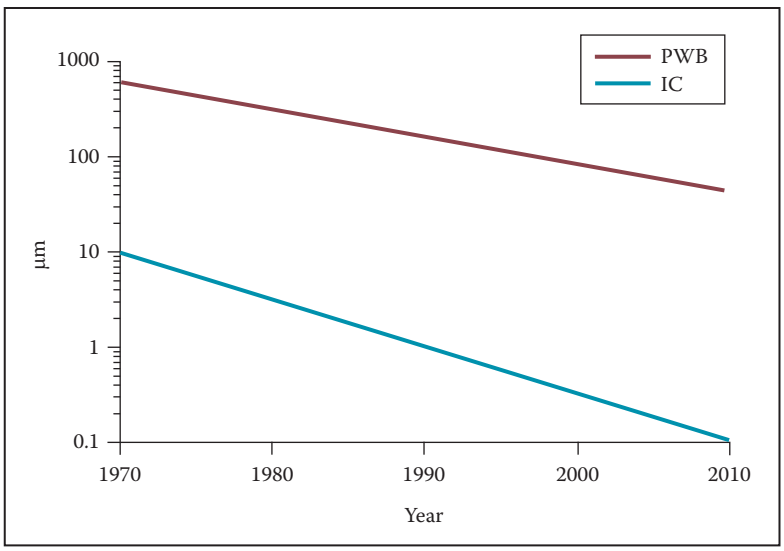


FIGURE 1.34 Comparison of resolution obtained with liquid resist compared with dry resists as a function of time. (Drawn by Mary Amasia from UC Irvine.)

film. Under highly controlled conditions, one can achieve an opening (space) of 25 µm with a 25-µm-thick dry film, but under production conditions, it is rather difficult to achieve such resolutions. By removing the top cover sheet from the photoresist before exposure, higher resolutions are possible. The removal of 25 µm of separation between the photoresist and the exposure tool decreases the chances of light diffusion. Also, foreign particles that collect on the coversheet are removed along with the coversheet.

There are a variety of dry film photoresists widely used and commercially available; examples include Riston®, Ordyl BF 410, Etertec® 5600, DF 4615, and DFR-15. All are used in the manufacture of circuit boards and can be made thick; additionally, all are candidates for broad use in MEMS as well.

Today it is difficult to obtain high-aspect-ratio devices with these resists because of their resolution limitation, high optical absorbency, and the difficulty in obtaining layers thicker than 50 µm in a single coat.[29] However, for many applications, the poorer resolution of dry resists (25–75 µm) is no obstacle for their usage in mesoscale devices (100s of micrometer to millimeter scale).

The potential benefits of using dry resist films as permanent components in the mass production of biosensors and microfluidics were recognized and described, for example, by Madou et al.[47] These authors suggest that continuous, web-based manufacturing may finally make ubiquitous, disposable miniaturized devices such as biosensors and microfluidics possible (see also Volume III, Chapter 1, Example 1.1). Dry resist film materials are less expensive than silicon and form a convenient substrate; they come in rolls so that large sheets can be processed. In the future, this author envisions a continuous lithographic process, including exposure and development, taking place between a dry resist supply roll and a pick-up reel. This would be especially attractive if higher resolution dry resist could be formulated. Dry film SU-8, as Louis Guerin suggested many years ago, holds the promise of continuous high-aspect-ratio, high-resolution lithography (http://www.geocities.com/guerinlj).

At MicroChem (http://www.microchem.com/about/index.htm), progress is being made making SU-8 dry resist films, and Dupont already offers the MX series dry film for MEMS applications. The new MX products feature an aspect ratio of 3:1. At a thickness of 50 µm, resolution is 16–17 µm, which is better than any other dry film product. Additionally, these films can be multilaminated to build up the thickness (http://tyvek.com.mx/APL/en_US/products/mx/index.html).

Nonspin liquid resist-coating methods such as roller coating or spraying (see above) also will play an important role in MEMS manufacturing of the future. Large substrate sheets can be accommodated; the throughput is higher than with dry resists; and the resolution is considerably better.

Glass Transition Temperature of a Resist (T_g)

Resists must meet several rigorous requirements: good adhesion, high sensitivity, high contrast, good etching resistance (wet or dry etching), good resolution, easy processing, high purity, long shelf life, minimal solvent use, low cost, and a high glass transition temperature, T_g. Most resists are amorphous polymers that exhibit viscous flow with considerable molecular motion of the polymer chain segments at temperatures above the glass transition. At temperatures below T_g, the motion of the segments is halted, and the polymer behaves as a glass rather than a rubber. If the T_g of a polymer is at or below room temperature, the polymer is considered a rubber; if it is above room temperature, it is considered to be a glass. Because above T_g the polymer flows easily, heating the resist film above its T_g for a reasonable amount of time enables the film to anneal into its most stable energetic state. In the rubber state, it is easy to remove the solvent from the polymer matrix; that is, soft bake the resist. Extreme attention needs to be given to the cleanliness of the working environment with the resist in this state. When softening the resist at or above T_g, it may be easier to remove solvent, but the resist tends to pick up impurities. The importance of resist reflow, as we will learn later, also lies in planarizing of undesirable topography. The glass transition temperature of a resist is influenced by baking and exposure; the T_g for SU-8, for example, is 55°C for the unexposed material but 200°C after exposure and hard baking. In the fabrication of carbon-MEMS structures from photoresist

by pyrolysis (Volume III, Chapter 5), we make sure that the temperature always stays below the T_g to avoid collapse of the resist features.

In general, polymers that crystallize are not useful as resists because the formation of crystalline segments prevents the formation of uniform high-resolution isotropic films.[19]

Wafer Priming

Resists, especially positive resists, do not adhere well to a Si wafer. The native silicon dioxide on a Si surface, typically 20–50 Å thick, forms long-range hydrogen bonds with water adsorbed from the air. When resist is spun onto such a surface, it adheres to the water molecules rather than to the surface, resulting in poor adhesion. This effect is more pronounced when the humidity is high or if the wafer has been previously immersed in water. Good humidity control (at ~40% relative humidity) and annealing are required to remove surface water and prepare a silicon wafer for resist coating. In the early 1960s, photoresist was spun directly onto the wafer surface. This worked for the large geometry circuits at the time, but when geometries reached the 20-μm range, further feature decrease became intimately linked to the quality of the resist adhesion. To faithfully reproduce the smallest features of a circuit design, a better photoresist/Si wafer contact had to be devised. To this end, surface priming with reactive silicone primers was introduced. A typical resist adhesion promoting primer is 1,1,1,3,3,3-hexamethyldisilazane (abbreviated HMDS) [formula: $(CH_3)_3SiNHSi(CH_3)_3$], developed and patented by IBM. Other primers include trichlorophenylsilane (TCPS) [formula: $C_6H_5SiCl_3$] and bistrimethylsilylacetamide (BSA) [formula: $(CH_3)_3SiNCH_3COSi(CH_3)_3$]. Reactive Si–NH–Si functional groups in HMDS react with the oxide surface in a process known as *silylation*, and a strong siloxane bond to the surface (Si-O-Si) is created (Figure 1.35). At room temperature, unhydrolyzed silane does not react with surface silanols [$Si(s)–OH + (CH_3)_3SiOCH_3 \rightarrow$ no reaction], but with some surface-adsorbed water present, a small amount of reaction occurs as a result of methoxysilane hydrolysis, followed by reaction with surface silanols [$Si(s)–OH$ + Surface $H_2O + (CH_3)_3SiOCH_3 \rightarrow (CH_3)_3SiOH + Si(s)–OH$ and $(CH_3)_3SiOH + Si(s)–OH \rightarrow Si(s)–O–Si(CH_3)_3 + H_2O$]. When silylation is carried out with HMDS, a strong catalytic effect is observed. The amine adsorbs onto the relatively acidic surface silanols, rendering the oxygen attached to the surface silicon atom highly

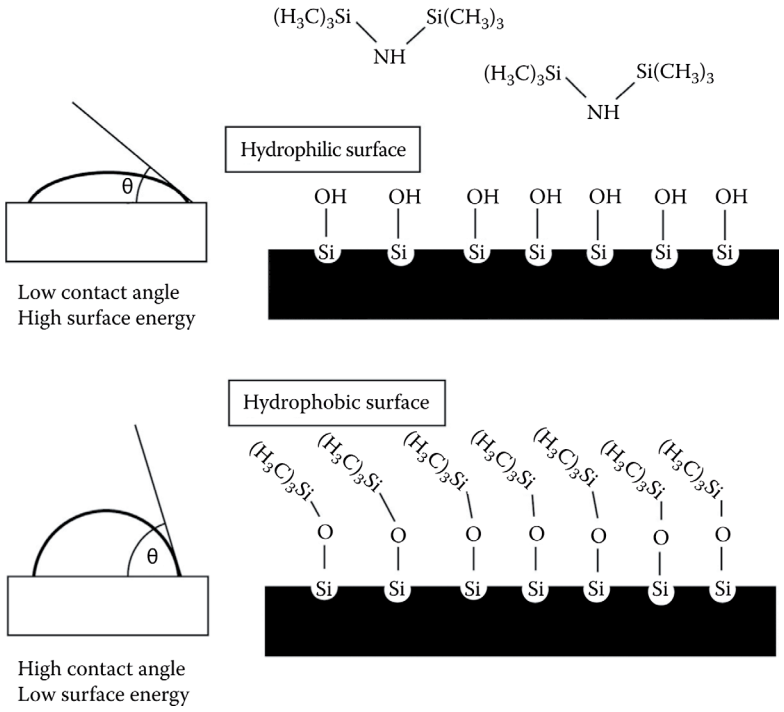

FIGURE 1.35 HMDS reaction mechanism monitored by the contact angle θ of a drop of water on the treated surface.

nucleophilic. This oxygen then attacks the relatively electrophilic silane silicon, resulting in surface silylation. The more hydrophobic the wafer surface, the better the resist adhesion, and the methyls, it is assumed, bond/adhere to the photoresist, enhancing the photoresist adhesion. The process works not only on silicon dioxide but also on other oxides (e.g., Al_2O_3). It should be noted that HMDS is extremely flammable and a suspected carcinogen; it should be handled with care. A dehydration bake of the SiO_2 surface at 200–250°C for 30 minutes (with optional vacuum) removes adsorbed water from the silanol groups at the silicon surface, which then can react with the amino groups of the HMDS vapor. The primer may then be applied by dipping the wafer in a 1–10% HMDS solution in xylene or by spin coating it onto the wafer. Baking the wafers to dehydrate and then removing them from the oven and transporting them to a dip solution or a spinner poses a serious problem, however, because on removal from the bake oven, the surface may rehydrolyze. Further shortcomings of this approach include a tendency to generate and deposit particles and HMDS wastage. Today priming of wafers is performed in a process that combines a bake and prime in the same vacuum. The wafer is exposed to HMDS vapor in a stream of dry nitrogen in a vacuum chamber while heating the wafer for approximately 40–60 seconds. This method provides the best adhesion and constitutes the best overall process as it remedies several problems: 1) no rehydrolyzation can occur because the unprimed wafers are not exposed again to the atmosphere before priming; 2) the same vacuum that is used during the bake cycle is used to draw monolayer amounts of HMDS; and 3) the interior of the chamber may be evacuated several times (with intermediary nitrogen backfills) before exposure to HMDS. Thus, at the time of HMDS exposure, the amount of oxygen present in the chamber (and hence the chance of a flammable mix forming) is very low. After treating a Si wafer with HMDS, a contact angle test with a drop of water reveals the surface to be much more hydrophobic (see Figure 1.35).

The chemical modification of oxide surfaces using organofunctional silanes is important not only in affecting better resist adhesion but also for the fabrication of water-repellent and antifouling coatings, DNA arrays, protein arrays, enzyme-based sensors, and so on.

Sputtering of the surface (Chapter 3), for some applications, presents an attractive alternative to vapor priming; the microroughness at the surface induced by sputtering provides for mechanical adhesion of the resist to the substrate. Primers for GaAs include monazoline C, trichlorobenzene, and xylene.

Resist Stripping

We now turn to the last step of the photolithographic process: photoresist stripping, as illustrated in Figure 1.1f.

Wet Stripping

Photoresist stripping, in slightly oversimplified terms, is organic polymer etching. The primary consideration is complete removal of the photoresist without damaging the device under construction. Turning back to Figure 1.1, once the exposed oxide has been etched away in (e), the remaining photoresist can be stripped off with a strong acid such as H_2SO_4 or an acid-oxidant combination such as H_2SO_4–Cr_2O_3 attacking the photoresist but not the oxide or the silicon (Figure 1.1f). Other liquid strippers include organic solvent strippers and alkaline strippers (with or without oxidants). Acetone can be used if the postbake is not too long or occurs at a low enough temperature. With a postbake of 20 minutes at 120°C, acetone is still fine. But with a postbake at 140°C, the resist develops a tough "skin" and has to be burned away in oxygen plasma. There are many commercial strippers available; some are specific for positive resists (e.g., ACT-690C from Ashland), others for negative resists, and still others are universal strippers (e.g., ACT-140 from Ashland). Other popular commercial strippers are Piranha and RCA clean. The RCA1 clean for organics was described above. To make up a Piranha solution, measure 5 parts of H_2SO_4 in a Pyrex beaker, and very slowly add 1 part of H_2O_2. Note that this mixture is exothermic. When cool, it may be refreshed by very slowly adding more H_2O_2.

The ozone-water method is a Piranha alternative. In this process, water of 25–95°C, depending on the application, is sprayed onto the substrate

as it is rotated. At the same time, dry ozone gas is injected into the reaction chamber. The ozone diffuses through the thin boundary layer of water to react with the organics on the substrate. Strip rates exceed 1.2 μm/min.[48]

The oxidized Si wafer with the etched windows in the oxide (Figure 1.1f) now awaits further processing. This might entail a wet anisotropic etch of the Si in the oxide windows with SiO_2 as the etch mask.

Dry Stripping

Dry stripping or oxygen plasma stripping, also known as ashing, has become more popular as it poses fewer disposal problems with toxic, flammable, and dangerous chemicals. Wet stripping solutions lose potency in use, causing stripping rates to change with time. Accumulated contamination in solutions can be a source of particles, and liquid phase surface tension and mass transport tend to make photoresist removal difficult and uneven. Dry stripping is more controllable than liquid stripping, less corrosive with respect to metal features on the wafer, and, more importantly, it leaves a cleaner surface under the right conditions. Finally, it does not cause the undercutting and broadening of photoresist features that can be caused by wet strippers.

In solid-gas resist stripping, a volatile product forms either through reactive plasma stripping (e.g., with oxygen), gaseous chemical reactants (e.g., ozone), and radiation (UV), or a combination thereof (e.g., UV/ozone-assisted). Plasma stripping uses a low-pressure electrical discharge to split molecular oxygen (O_2) into its more reactive atomic form (O). This atomic oxygen converts an organic photoresist into a gaseous product that may be pumped away. This type of plasma stripping belongs in the category of chemical dry stripping and is isotropic in nature (see Chapter 3). In ozone strippers, ozone, at atmospheric pressure, attacks the resist. In UV/ozone stripping, UV helps to break bonds in the resist, paving the way for a more efficient attack by the ozone. Ozone strippers have the advantage that no plasma damage can occur on the devices in the process. Reactive plasma stripping currently is the predominant commercial technology because of its high removal rate and throughput. Some different stripper configurations are barrel reactors, downstream strippers, and parallel plate systems. These prevalent stripping systems are reproduced in Figure 1.36.[49] More details will be provided in Chapter 3.

Posing new challenges to modern stripping processes are shrinking feature sizes, increasing aspect ratios, and stripping of resist over some of the newest dielectrics ($\sigma_r < 3$) and copper interconnects. Especially novel dielectric materials, such as fluorinated silicate glass, carbon-doped oxides, and fluorinated amorphous carbon, are easily attacked or degraded by stripping.[48] In practice, combinations of dry and wet etching often form the most successful strategy.

Dry stripping of resist has been so successful that it has accelerated the use of plasmas in other lithography steps such as development and deposition of resist. For example, it was the study of the attack of oxygen on polymers that led to the development of dry developed resists as used in the DESIRE process (see page 75). Such dry developed resists are vital for future submicrometer lithography where

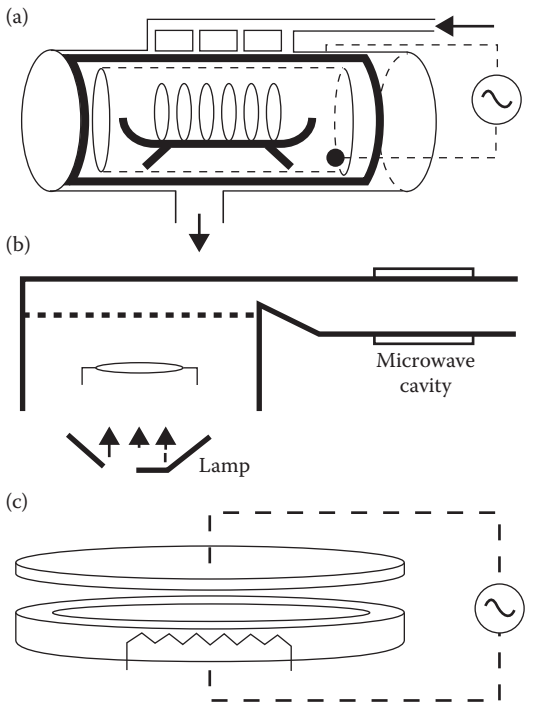

FIGURE 1.36 Various dry stripping reactors: barrel reactor (a), downstream etchers (b), parallel plate systems (c). (From Flamm, D.L. 1992. Dry plasma resist stripping. Part I: overview of equipment. *Solid State Technol* 35: 37–39. With permission.[49])

underetching and broadening of features are most critical. Although not detailed in the current short treatise, inspection and metrology techniques (see Volume III, Chapter 6) play a crucial role at various points in the lithography process.

Critical Dimension, Overall Resolution, Line Width Metrology

The absolute size of a minimum feature in an IC or a miniature device, whether it involves a line width, spacing, or contact dimension, is called the *critical dimension* (CD). The overall resolution of a process describes the consistent ability to print a minimum size image, a CD, under conditions of reasonable manufacturing variation.[50] Many aspects of the process, including hardware, materials, and processing considerations, can limit the resolution of lithography. Hardware limitations include diffraction of light or scattering of charged particles (in the case of charged-particle lithography or hard x-rays), lens aberrations, mechanical stability of the system, and so on. The resist material properties that impact resolution are contrast, swelling behavior, thermal flow, and chemical etch resistance. The most important process-related resist variables include swelling (during development) and stability (during etching and baking steps). Resolution frequently is measured by line-width measurements using either transmitted or reflected light or other metrology techniques. Optical techniques perform satisfactorily for features of 1 μm and larger, providing a precision of ±0.1 μm (at 2 σ, i.e., all data points within plus and minus two standard deviations). By 1998, devices with features as small as 0.25 μm were launched and necessitated equipment requirements for line-width measurement with a precision of at least ± 0.02 μm (at 3 σ). Scanning electron microscopes (SEMs) or atomic force microscopes have come forward as the methods to reach these goals. A line width, L, is defined as the horizontal distance between the two resist-air boundaries in a given cross-section of the line at a specified height above the resist/substrate interface. Because different measurements may measure the line width of the same line at different heights of the cross-section, the measuring technology used always needs to be identified. The successful performance of devices depends on the control of the size of critical structures across the entire wafer and from one wafer to another, referred to as line-width control. A rule of thumb is that the dimensions must be controlled to tolerances of at least ± 1/5 of the minimum feature size. Typically, a series of features with known sizes across a substrate is measured and then plotted as a function of position on the wafer. The standard deviation at the 1 or 2 σ level is adopted as the line-width control capability of the particular exposure/resist technology. Plotting these data as a function of time enables line managers to maintain optimum performance on a manufacturing line.[50]

In Volume III, Chapter 6, the metrology tools used in IC, MEMS, and NEMs are discussed: laser interferometers for accurate alignment of mask to wafer (with a 5-nm "resolution"), film thickness measurement with profilometers, SEM, scanning transmission electron microscope (STEM), scanning probe microscope (SPM) with vertical resolution of 1 Å, and lateral resolution depending on tip sharpness.

Lithographic Sensitivity and Intrinsic Resist Sensitivity (Photochemical Quantum Efficiency)

Lithographic Sensitivity

A distinction must be made between the intrinsic sensitivity of a resist (that is, the resist's response to radiation) and the lithographic sensitivity when defining the measurement of the efficiency that translates resist exposure into a sharp image. In the literature, the values given for the lithographic sensitivity of a resist show a tremendous spread as a result of the complex relationship between the intrinsic resist sensitivity and the dose required to successfully process that resist. This relationship involves the intrinsic resist sensitivity and the bandwidth of the optical exposure system, baking conditions, resist thickness, developer composition, and development conditions. To reproduce a reported lithographic sensitivity, all these parameters need to be duplicated exactly. The best way to determine lithographic sensitivity is experimentally, as we will explain next.

Intrinsic Sensitivity of a Resist (Photochemical Quantum Efficiency)

A first indication of the intrinsic sensitivity of a resist to a certain wavelength can be deduced from the spectral-response curve of the resist. If the resist absorbs strongly in ranges where the radiation source shows strong emission lines, relatively short exposure times can be expected. Practical limits confine resist sensitivity: too sensitive a resist might mean an unacceptably short shelf life, and yet clearly the resist should be insensitive to the yellow and green light of the clean room.

High intrinsic resist sensitivity is a sought-after characteristic. To increase resolution of photolithography, the shortest possible wavelengths must be used. At those wavelengths exposure sources become less bright and optics absorb more. Because the total energy incident on a resist is a function of light source intensity, time, and absorption efficiency of the exposure optics, a decrease in intensity and an increase in light absorption require compensation through longer exposure times. This results in a smaller throughput of wafers per hour; conversely, a more sensitive resist decreases the exposure time, resulting in a higher throughput.

The intrinsic sensitivity or photochemical quantum efficiency, Φ, of a resist is defined as the number of photoinduced events divided by the number of photons required to accomplish that number of events:

$$\Phi = \frac{\text{Number of photon-induced events}}{\text{Number of photons absorbed}} \qquad (1.4)$$

For polymer resins where the polymer undergoes scission or cross-linking without the need for light-absorbing sensitizers (one-component resists), a *G*-value is introduced. The *G*-value corresponds to the number of scissions or cross-links produced per 100 eV of absorbed energy. For scission reactions, the symbol $G(s)$ is used; for cross-linking, the symbol $G(x)$ is used. In contrast to lithographic sensitivity, the measurement of intrinsic radiation sensitivity as expressed through Φ, $G(s)$, or $G(x)$ is reliable, and values from different sources agree relatively well.

The experimental determination of the quantum efficiency of a one-component resist is a complex undertaking. Samples of the polymer must be exposed to a known dose of gamma radiation, and the molecular weight of the irradiated samples must be measured either by membrane osmometry or gel permeation chromatography. Quantitative analysis of the molecular weight versus dose in polymers that undergo scission or cross-linking leads to an important relationship for a better understanding of resist exposure. We will use such a relationship when exploring x-ray lithography for the creation of "high-rise" PMMA resist structures (»10 µm high; see Chapter 10 on LIGA). Let us consider a positive resist here. For a positive resist sample of weight w (in grams) containing N_0 molecules before exposure, the definition of average molecular weight M_n^0 is given by[28,51]:

$$M_n^0 = \frac{wN_A}{N_0} \qquad (1.5)$$

where N_A is Avogadro's number. Expressing the dose, D, in eV/g, the total number of scissions produced in the sample, N^*, is proportional to the absorbed dose, or:

$$N^* = KDw \qquad (1.6)$$

where K is a constant dependent on the polymer structure, generally expressed in terms of a *G*-value. $G(s)$ (for positive resists) and $G(x)$ (for negative resists), like Φ, are figures of merit used to compare one resist material with another. With K expressed in terms of $G(s)$, Equation 1.6 can be rewritten as:

$$N^* = \left[\frac{G(s)}{100}\right]Dw \qquad (1.7)$$

in which we divide by 100 to express the number of events per 100 eV. As scission occurs, the number of molecules increases, and the new average molecular weight after exposure to dose D is then given by:

$$M_n' = \frac{wN_A}{N_0 + N^*} \qquad (1.8)$$

where the total mass of the polymer is assumed to remain constant during exposure.

By substituting Equations 1.5 and 1.7 into Equation 1.8, we obtain:

$$M_n' = \frac{N_A}{\frac{N_A}{M_n^0} + \left[\frac{G(s)}{100}\right]D} \tag{1.9}$$

which is independent of the sample mass *w*. Rearranging Equation 1.9 we obtain:

$$\frac{1}{M_n'} = \frac{1}{M_n^0} + \left[\frac{G(s)}{100}\right]D \tag{1.10}$$

From Equation 1.10, we conclude that a linear relationship exists between the inverse of the average molecular weight and the exposure dose *D*. The intercept on the *y*-axis yields $1/M_n^0$, and the slope allows one to calculate $G(s)$. There is a very high correlation between $G(s)$ values for gamma radiation [the radiation commonly used to determine $G(s)$] and sensitivity for electrons, ions, and x-rays.

The $G(s)$ of polymers commonly used as one-component, positive resist systems ranges from 1.3 for some PMMAs to approximately 10 for certain poly(olefin sulfones). A PMMA with a $G(s)$ value of 1 has a corresponding photochemical quantum yield for scission, Φ (Equation 1.4), of 0.02.[28] For some polymers, both scissioning and cross-linking events occur simultaneously on exposure. It is possible, even in the latter case, to uniquely determine both scission efficiency $G(s)$ and cross-linking efficiency $G(x)$.[51]

For one-component negative resists the figure of merit for intrinsic sensitivity, $G(x)$, expressed as number of cross-links per 100 eV absorbed dose, ranges from 0.1 for poly(ethylene) to approximately 10 for polymers containing oxirane groups (epoxy groups) in their side chains.

For a two-component positive system such as DNQ, Φ in Equation 1.4 corresponds to the quantum efficiency, that is, the number of sensitizer molecules converted to photoproduct, divided by the number of absorbed photons required to accomplish that conversion. Quantum efficiency in this case can easily be measured by using a narrow-bandwidth radiation source and a UV-Vis spectrophotometer. The quantum efficiency, Φ, of typical DNQ sensitizers ranges from 0.2–0.3 (compared with 0.02 for PMMA). Because of the high opacity (i.e., high nonbleachable absorption) of novolak resins in the deep UV region (200–300 nm) region, other resists like PMMA are used for shorter wavelength exposures (e.g., for deep UV, e-beam, and x-ray lithographies). The quantum efficiency of the bis(aryl) azide sensitizers in negative resist systems ranges from 0.5–1, making negative resists more sensitive than positive resists.

Resist Profiles

Overview of Profile Types

Manipulation of resist profiles is one of the most important concerns of a lithography engineer. Depending on the final objective, one of the three resist profiles shown in Figure 1.37 is attempted. A re-entrant, undercut, or a reverse resist profile (resist sidewall >90°) is required for metal liftoff (see below for more details). Some authors confusingly call slopes >90° *overcut* [28]; most, including this author, refer to this type of resist profile as an *undercut* (Figure 1.37a). Shallow resist angles (<90°) enable continuous deposition of thin

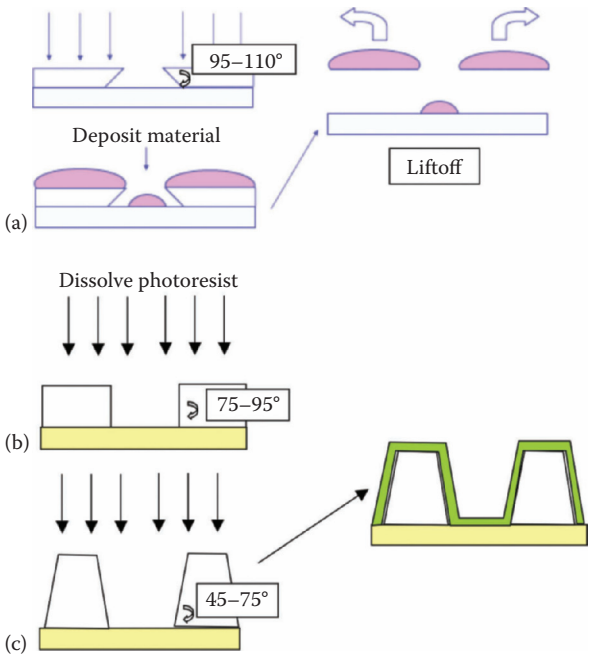

FIGURE 1.37 The three important resist profiles. (a) Re-entrant, undercut, or a reverse resist profile (resist sidewall >90°) is required for metal liftoff. (b) A vertical (75–90° resist sidewall angle) slope is desirable for a perfect fidelity transfer of the image on the mask to the resist. (c) Shallow resist angles (45–75° < 90°) enable continuous deposition of thin films over the resist sidewalls.

films over the resist sidewalls (Figure 1.37c). A vertical (90° resist sidewall angle) slope is desirable for a perfect fidelity transfer of the image on the mask to the resist (Figure 1.37b). If resist sidewalls are perpendicular, or if the resist layer is undercut, a deposited metal is likely to be noncontinuous: there is a separation between the desired and the undesired metal for a liftoff process. In the case of a shallow slope, the deposit is continuous.

In general, after development of negative and positive resists, three different photoresist wall profiles may be obtained as summarized in Figure 1.37 and tabulated in Table 1.9. In the table, R is the development rate of the exposed region, R_0 is the development rate of the unexposed region, and γ is the resist contrast. The resist contrast will be explained in greater detail later in this chapter. This table also lists typical applications for each resist profile. First, we will concentrate on the dependence of the resist profile of a positive resist on exposure dose and development mode. In a developer-dominated process, "force" developed with $R/R^0 < 5$, a shallow outward sloping resist profile results, and thinning of the entire resist layer occurs. For positive resists, the shallow angle is the most typical profile with a 45–75° resist wall angle. With a quenched developer, $R/R_0 = 5–10$, and a moderate dose, a straight resist wall profile results (~90°, e.g., 75–95°). In the vertical wall case, the removal of the laterally exposed region has been inhibited, and a perfect pattern transfer of the mask features onto the resist is obtained. An undercut profile is difficult to achieve in positive resists because the optical exposure dose (and hence the development rate of the system) is greater at the surface than at the resist/substrate interface, resulting in a normal profile with shallow resist angles. An undercut profile is desirable for liftoff processes in which deposited layers are lifted from the substrate

Table 1.9 Photoresist Profiles Overview

Profile	Dose	Developer Influence	R/R_0	γ	Uses
(A) Positive resists undercut (a) 	High (often with backscatter radiation)	Low	>10	>6	Ion implant; liftoff; not good for plasma etching; often only obtained through image reversal
Vertical (b) 	Normal dose	Moderate	5–10	<4	Liftoff; reactive ion etch; wet etch; ion beam etch; perfect fidelity
Normal or overcut (c) 	Low	Dominant	<5	<3	Typical for positive resists; wet etch; metallization; <20% resist loss
(B) Negative resists undercut 	Dominant	Little influence	<0.1	<3	Permanent resists; larger devices; MEMS

(A) Positive resist. (a) Desired resist profile for liftoff, that is, exposure-controlled profile also called *undercut*. (b) Perfect fidelity image transfer by applying a normal exposure dose and relying moderately on the developer. (c) Receding photoresist structure with thinning of the resist layer, that is, developer control also called *overcut*, the normal profile for positive resists. (B) Negative resist. Profile is mainly determined by the exposure. Development swells the resist slightly but otherwise has no influence on the wall profile for the older types of resists. The undercut profile is the normal profile for the newer types (aqueous developable) of negative photoresists.
Source: Based on Moreau, M.W. 1988. *Semiconductor lithography*. New York: Plenum Press. With permission.[28]

by dissolving the underlying resist structure (see next section). In the extreme case of overexposure and a fast developer, the result is a lip, retrograde or inward wall-angle undercut (>90, e.g., 95–110°). This profile might come about if there is a lot of light back scatter from shiny surfaces at the interface of the substrate and the bottom of the resist layer. A ratio of $R/R_0 > 10$ qualifies as a fast developer. However, liftoff profiles with positive resists are more readily formed with multilayer resist (MLR) systems or with a postexposure soaking procedure (see below). With negative resists, forming more insoluble products at the resist surface than at the resist/substrate interface, one more easily obtains an undercut profile; a single-layer resist (SLR) will do, and no complicated MLR systems are required in this case.

A more rigorous, mathematical treatment of resist profiles is presented under Mathematical Expression for Resist Profiles.

We now detail the more unusual profiles for positive and negative resists a bit further. Not all photons strike the resist/substrate interface at the same angle; especially with a high overdose, scattering at a reflective interface may cause broadening of the radiation profile at the substrate/resist interface. The scattered radiation profiles for overexposed positive and negative resists are shown in Figure 1.38.

Time-independent organic solvent development (with a strong developer) of overexposed negative resists from outside the scattered region reveals the scattered radiation zone because cross-linking and further swelling inhibit its removal. On the other hand, development of overexposed positive resists using aqueous alkaline is time dependent and rapidly removes the exposed region, edge-scattered radiation zones, and part of the photoresist top unless the developer is quenched. The time-dependent aspect of this process enables the operator to tailor positive resist profiles. With negative resists, the exposed regions remain, as they are rendered insoluble; with positive resists, the exposed region develops, and the unexposed regions usually remain soluble. Swelling in traditional negative resists is one of the reasons these resists used to be limited to the manufacture of devices with minimum feature size of about 3 μm. Scattered radiation and swelling result in a broadening of the remaining resist features. Positive resists do not exhibit this swelling because of a different dissolution mechanism. The oxygen effect, quenching the cross-linking of negative resists as discussed earlier, usually means a disadvantage for negative resists but can be turned into an advantage to improve resolution. We already know that oxygen can scavenge the photogenerated reactive nitrene species and that this reaction eliminates the precursors for cross-linking and insolubilization. Excluding oxygen from the top surface of the resist by flushing with an inert gas or blocking with a polymer topcoat causes the oxygen dissolved in the polymer film to move laterally from the unexposed dark areas into the light zone. The light zone

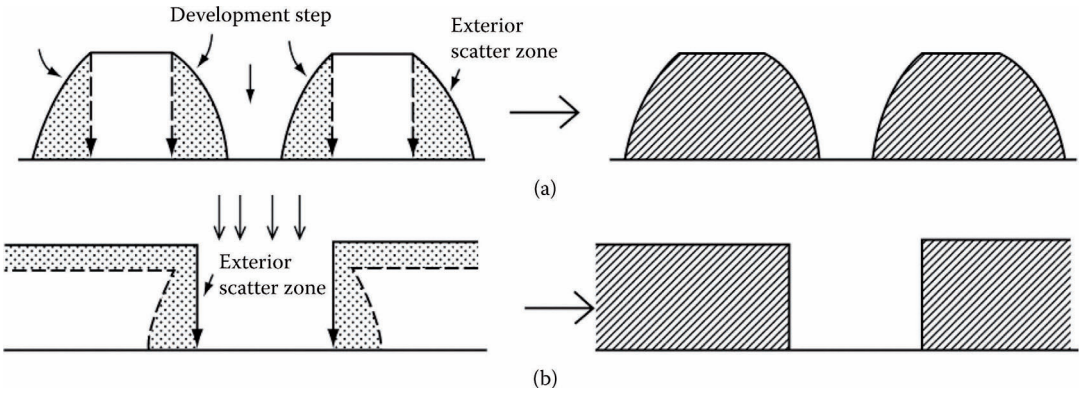

FIGURE 1.38 Edge-scattered radiation profile for negative and positive resists. (a) Negative resist image; time-independent development of cross-linked negative resist fails to remove light scatter zone. (b) Positive resist image; development of positive resist rapidly removes exposed region and can be quenched to inhibit removal of lateral scattered exposed resist region. (Based on Brodie, I., and J.J. Muray. 1982. *The physics of microfabrication*. New York: Plenum Press. With permission.[52])

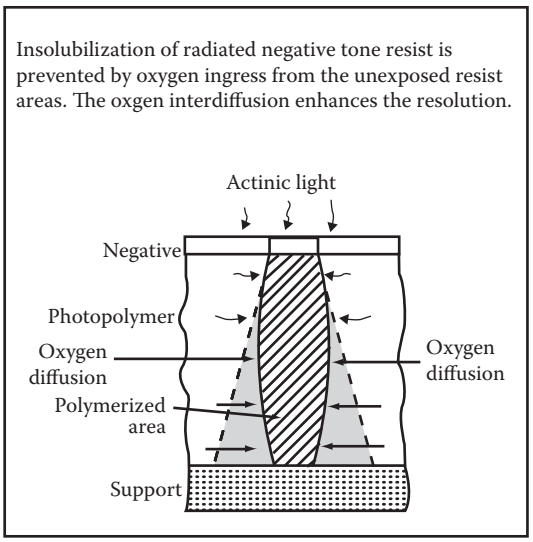

FIGURE 1.39 Lightly scattered zones do not insolubilize. (From Moreau, W.M. 1988. *Semiconductor lithography*. New York: Plenum Press. With permission.[28])

becomes an oxygen sink, and the lightly scattered zones (Figure 1.39) do not insolubilize, leading to better resolution.[28]

Liftoff Profile

The creation of a straight photoresist wall or, better yet, that of a lip or undercut can be taken advantage of in a so-called lift-off process. Lift-off is important, for example, for patterning catalytic metals such as Pt, frequently used in chemical sensors but not easily patterned directly. In the process sequence, shown in Figure 1.40, a solvent dissolves the positive photoresist underneath the deposited metal, starting at the edge of the unexposed photoresist, and lifts off the metal. It is important that there be a discontinuity or gap in the metal deposit so that solvent can get at the uncoated resist wall. This is accomplished by depositing the metal with a line-of-sight–type technique such as thermal evaporation, which is described in Chapter 7. In a line-of-sight deposition technique, a vertical or inward sloping wall will receive little or no metal deposit, leaving a gap for the resist solvent to dissolve the unexposed resist and lift off the metal on top of it. One disadvantage of this technique is the rounded profile, a result of shadowing, associated with deposited features and temperature limitations (see Figure 1.40). A more desirable profile for a conductor line has a rectangular cross-section minimizing electrical resistance. The latter is one reason why liftoff in IC fabrication, where contact resistance is of prime concern, is used with discretion. Also with liftoff,

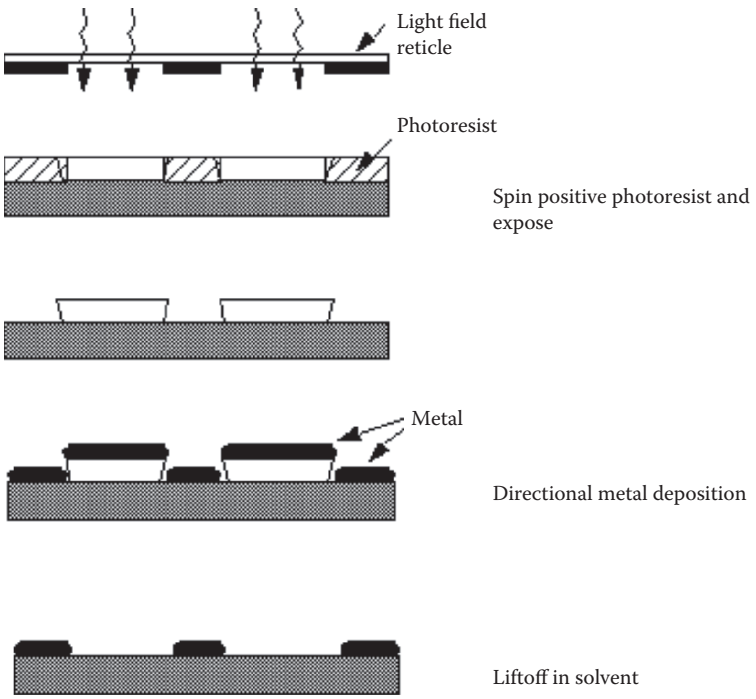

FIGURE 1.40 Example of liftoff sequence with positive resist for the construction of a Pt-based electrochemical sensor electrode. Rounding of deposited features through shadowing is observed (see text).

the metal deposition technique is limited to temperatures less than 200–300°C, where resist begins to degrade.[53]

In a liftoff process, one can either use a negative resist, such as the alkaline-developing ZPN1100, or modify a positive resist to exhibit the desired undercut. We know already that an undercut does not readily form with a positive resist: therefore, some "tricks" are in order. The first trick is to "presoak" the positive resist surface with an aromatic solvent (e.g., chlorobenzene) to convert a surface layer. This layer will develop at a much slower rate than the bulk of the resist film, thereby providing an undercut during development in alkaline solution. The second method, image reversal, follows further below.

A presoak process to develop an undercut on a positive resist (Shipley 1827) involves the following steps—with typical example materials, equipment, and process parameters:

1. Dehydration bake of Si wafer to remove all moisture. Typically this is done in a natural convection oven at 200°C for 30 minutes.
2. Wafer priming using HMDS.
3. Spin coat resist using a Solitec 5100 spinner. Spin to 1000 rpm for 5 seconds to spread the resist and then at 7000 rpm for 35 seconds to complete the spin cycle.
4. Soft bake at 90°C for 20 minutes in a natural convection oven.
5. Expose the wafer for 15 seconds in a Kasper Contact Mask Aligner.
6. A 5-minute chlorobenzene soak. Chlorobenzene diffuses into the photoresist top layer, causing it to swell. A gel is formed to the depth of the diffusion, which develops much slower than the bulk of the resist. This causes the developer to undercut the photoresist structures and produces the desired profile. After the soak, blow-dry the wafers with a nitrogen gun.
7. Develop the wafers using Microposit MF319 from Shipley. Development rates are increased with exposure time and decreased by soaking time. The exposed regions develop faster; the undercut of the structure is formed when the development front passes the gel layer, and fast lateral development of the unexposed regions begins. Use a development time of 5 minutes with mild agitation. Then place the wafers in DI water for approximately 2 minutes, and blow-dry with nitrogen.
8. Deposit desired material.
9. Liftoff. Dissolution of the photoresist is the final step in the liftoff process. Positive resist is very soluble in acetone, which has been used traditionally. Soak the wafers in acetone for 5 minutes with mild agitation.

There are many different techniques to make undercut resist profiles with a positive tone resist, including:

1. Chlorobenzene induced lip in single-layer photoresist (see above)
2. Multilayer resists (e.g., a bilayer) where top layer develops more slowly
3. Special undercoatings that develop faster than resist in developer
4. Trilayer methods
5. Image reversal resists (see next section)

Image Reversal

Because swelling does not take place during the development of positive photoresists, several process variations aim at reversing the tone of the image so that the resists can act as high-resolution negative resists. Examples of positive photoresists that may be used for this purpose are OCG 895i and Shipley 1800. One purpose of reversal processes is for the generation of an undercut profile for liftoff. As we have seen, positive resists more readily lead to overcut resist profiles as shown in Table 1.9Ac, whereas with a negative resist an undercut is more readily generated (Table 1.9B). A typical image-reversal process is demonstrated in Figure 1.41a. After a diazopositive resist has been patterned, an amine vapor (such as imidazole or triethanolamine, or, more generally, a base) is diffused into the exposed areas. The amine neutralizes the byproduct of the photodecomposition (a carboxylic acid in this case) and makes these exposed areas highly resistant to further change by exposure to light and highly insensitive to further development. The base inducing the

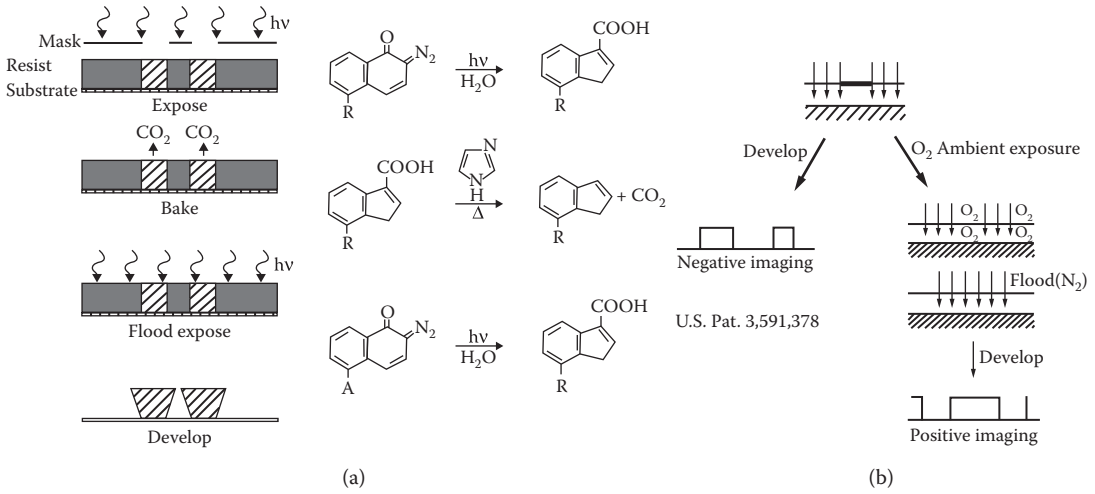

FIGURE 1.41 Image reversal process sequence. (a) Positive photoresist. (b) Negative photoresist. [(a) Based on Alling, E., and C. Stauffer. 1988. Image reversal photoresist. *Solid State Technol* 31:37–43;[54] (b) based on Moreau, W.M. 1988. *Semiconductor lithography.* New York: Plenum Press. With permission.[28]]

image reversal may also be added to the resist formulation before coating. A subsequent flood exposure makes the areas adjacent to the neutralized image soluble in conventional positive photoresist developers. The net result is a negative image of the mask with an undercut profile and improved resolution because the resist does not swell as negative resists do.

Image reversal with a negative resist, such as KTFR, is possible as well (see Figure 1.41b). We have already discussed that remaining oxygen in a resist can improve resolution by preventing insolubilization in light-scattered zones outside the exposed area (Figure 1.39). Image reversal is an extension of this insolubilization. By working at low intensity, oxygen flooding can scavenge all photogenerated azide polymerization precursors, making the exposed areas soluble in a developer as they are prevented from polymerizing. A subsequent flood exposure under a nitrogen blanket, at higher intensity, initiates the polymerization in the previously nonexposed areas.[28]

A dual-tone resist chemistry, based on a phenolic resin with diazonaphthoquinone as the acid generator and hydroxymethylmelamine as the hardening agent, was developed in 1986 by Feely and coworkers at Rohm and Haas (Figure 1.42).[10] The increase in molecular weight for the exposed dual-tone Rohm and Haas photoresist is the result of a condensation reaction between phenol formaldehyde resins and amino-based cross-linkers. Initially, the Rohm and Haas process drew a lot of attention because it promised to have many miniaturization science applications. Earlier, in Figure 1.8a, we illustrated the process flow options for this resist.[9]

Exposure produces the latent image, which results in the "normal" positive resist relief image when developed at this stage (right-hand path in Figure 1.8a). If, on the other hand, after exposure, the film is heated to induce the acid-catalyzed reaction of the melamine with the phenolic resin, the exposed areas become insoluble, and image reversal is initiated. The reversal is completed by a subsequent flood exposure, solubilizing the nonexposed areas and rendering a negative-tone image of the mask (left-hand path in Figure 1.8a). The cross-linked nature of the image imparts resistance to swelling and dissolution by aqueous and organic solvents, as well as dimensional and thermal stability to temperatures >300°C. By using three-tone masks that have opaque, transparent, and partial transmission (50%), stepped (positive-tone process) and cantilevered (negative-tone process) structures are produced (Figure 1.8b). By appropriate processing of image reversal systems, positive, negative, and vertical walls become possible as well. Figure 1.8c showcases an example of the types of microstructures that can be printed with the Rohm and Haas system. In principle, this resist could be the basis of a complete microstructural universe.

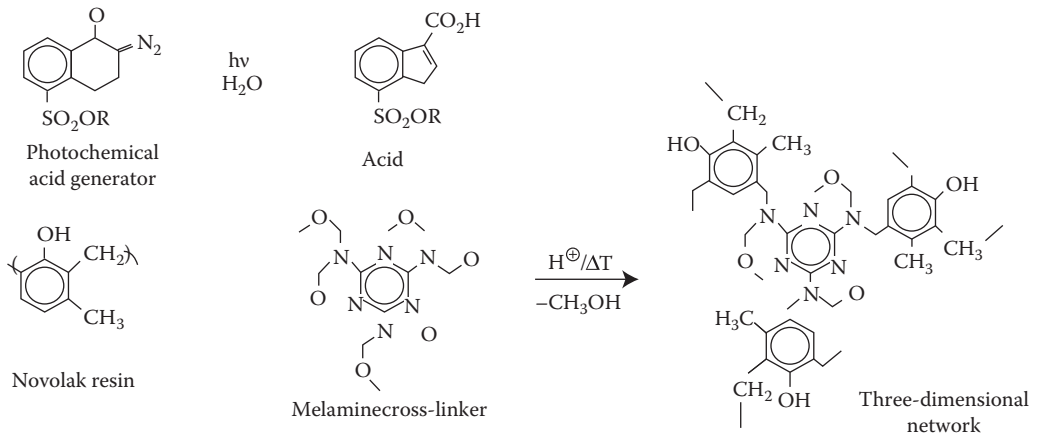

FIGURE 1.42 Cross-linking of a novolak resin through acid-catalyzed condensation with a melamine for negative aqueous-base development.

Contrast and Experimental Determination of Lithographic Sensitivity

The resolution capability of a resist, defined as the smallest line width to be consistently patterned, is directly related to resist contrast γ. For positive resists, the contrast is related to the rate of chain scission and the rate of change of solubility with molecular weight. The latter is very solvent dependent. After development, the thickness of the exposed resist layer decreases until, at a critical dose D_P, the film is completely removed. Lithographic sensitivity, D_P, and contrast can be obtained from the response curve—a plot of normalized film thickness versus log D (dose) (Figure 1.43a). To construct a curve as shown in Figure 1.43a, a series of positive resist pads of known area are subjected to varying doses and developed in a solvent that does not attack the unexposed film. The thickness of the remaining film in the exposed area is then measured and normalized to the original thickness and plotted as a function of cumulative dosage. Contrast γ_p is determined from the slope of this sensitivity or exposure response curve as:

$$\gamma_p = \frac{1}{(\log D_p - \log D_p^0)} = \left[\log \frac{D_p}{D_p^0}\right]^{-1} \qquad (1.11)$$

And the lithographic sensitivity D_p is the x-axis intersection. For a given developer, D_p corresponds

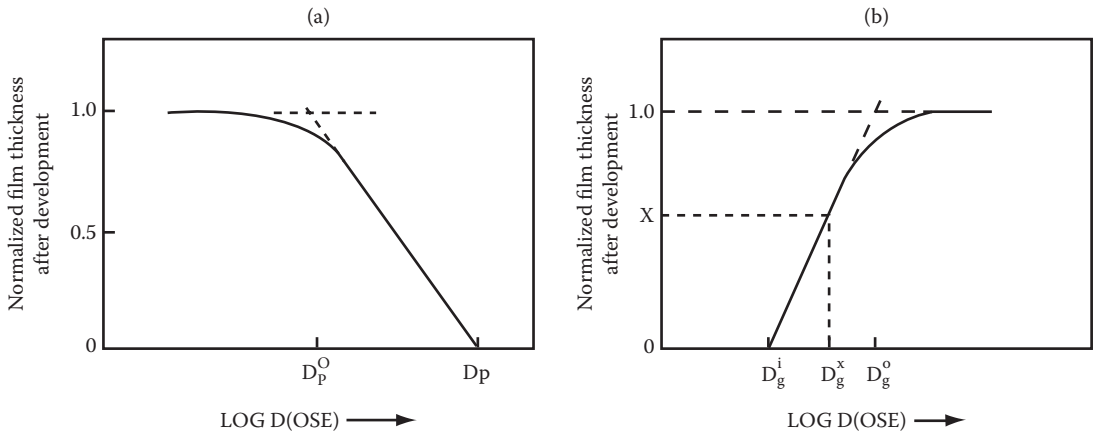

FIGURE 1.43 Typical response curves or sensitivity curves. (a) For a positive resist. Contrast γ_p is determined from the slope. The contrast for a positive resist is markedly solvent dependent. A typical contrast value for a positive optical resist is 2.2. (b) For a negative resist. The value of $D\gamma^x$ usually occurs at 0.5–0.7 normalized thickness as shown in Figure 1.44. The slope determines the contrast, γ_n. A typical value for the contrast of a negative optical resist is 1.5. (From Thompson, L.F., C.G. Willson, and M.J. Bowden, eds. 1994. *Introduction to microlithography.* Washington, DC: American Chemical Society. With permission.[55])

to the dose required to produce complete solubility in the exposed region while not affecting the unexposed resist. D_p^0 is the dose at which the developer first begins to attack the irradiated film. For a dose less than D_p but higher than D_p^0, another developer could "force develop" the resist. In force developing, the developer attacks or thins the original, unexposed resist (Table 1.9Ac). The above describes how the profile of a positive resist can be manipulated by the operator.

For a negative resist, contrast relates to the rate of cross-linked network formation at a constant input dose. This is simpler than in the case of a positive resist, where contrast is also very solvent dependent. Consequently, if one negative resist has a higher cross-linking rate compared with another, it also possesses the higher contrast of the two. With negative resists, the onset of cross-linking, as evidenced by gel formation, is not observed until a critical dose D_g^i (also called the *interface gel dose*) has been reached (see Figure 1.43b). In Figure 1.43b, we show the response or sensitivity curve: the normalized developed film thickness versus log dose. Below the interface gel dose, no image can form, as the film thickness is insufficient to serve as an etching mask. At higher doses, the image thickness increases until the thickness of the image equals that of the resist before exposure (in reality, it remains thinner as the film shrinks as a result of cross-linking). The latter dose is shown in Figure 1.43b as D_g^0, the dose required to reach 100% polymerization of initial film thickness (before exposure). Contrast, γ_n, is obtained from the slope of this curve as:

$$\gamma_n = \frac{1}{(\log D_g^0 - \log D_g^i)} = \left[\log \frac{D_g^0}{D_g^i}\right]^{-1} \qquad (1.12)$$

Lithography sensitivity (D_g^x) defines the dose cross-linking the film to the required thickness for optimal resolution. The required dose is sometimes defined as the dose resulting in dimensional equality of clear and opaque features (corresponding to nominally equal structures on the mask) imaged in the resist. The so-defined lithographic sensitivity can be determined separately from a plot of feature size versus dose for an opaque and a clear feature of equal size (Figure 1.44). This dose, D_g^x, corresponding to the lithographic sensitivity transposed on the x-axis of Figure 1.43b, fixes the required cross-linked film thickness after development on the γ-axis (usually 0.5–0.7 times the normalized thickness). The lithographic sensitivity also may be taken as the dose $D_{0.7}^x$, at which 70% of the original film is retained after development.[27]

Resists with higher contrast result in better resolution than those with lower contrast, and this can be explained as follows. In an exposure, energy is delivered in a diffused manner because of diffraction and scattering effects. Some areas outside the mask-defined pattern will receive an unintended dose higher than D_g^i but lower than D_g^x. The resulting resist profile will exhibit some slope after development. The higher the contrast of the resist, the more vertical the resist profile. Because line width is measured at a specified height above the resist/substrate surface, as the resist profile becomes less vertical, the resist line width represents the original mask dimension less accurately.

Values of D_p and D_g^x are figures of merit used only to compare different resists. For lithographic sensitivity numbers to have any value they must be accompanied by a detailed description of the conditions under which they were measured.

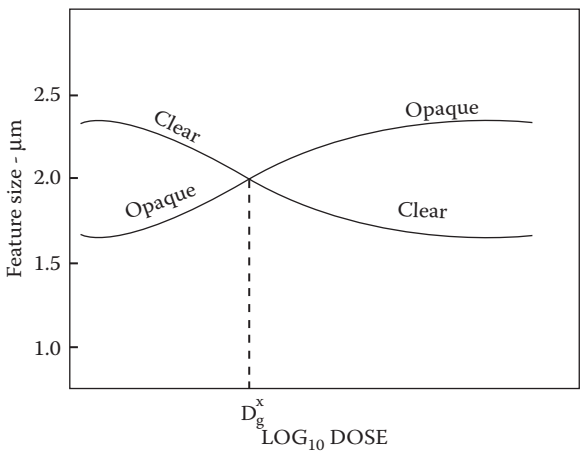

FIGURE 1.44 Size of a clear and opaque 2.0-µm feature (on the mask) as a function of the exposure dose for a negative resist. The dose (D_g^x) resulting in the correct feature size (same size as on the mask) is called the *lithographic sensitivity*. (From Thompson, L.F., C.G. Willson, and M.J. Bowden, eds. 1994. *Introduction to microlithography.* Washington, DC: American Chemical Society. With permission.[55])

Resolution in Photolithography

Introduction

A line-width measurement made with a SEM or another metrology tool from the many options reviewed in Volume III, Chapter 6 is used to determine the resolution of a lithographic system. Correct feature size must be maintained within a wafer and from wafer to wafer, as device performance depends on the absolute size of the patterned structures. The term *critical dimension* (CD) refers to a specific minimal feature size and is a measure of the resolution of a lithographic process. We first consider the theoretical resolution limits of different photolithography printing techniques; in the subsequent section, we review how one can go beyond those conventional limits by using resolution-enhancing techniques (RETs). With reference to Figure 1.6 where we compare contact, proximity, and projection printing, we now delve into a mathematical formulation of the expected resolution for each of these printing techniques.

Resolution in Shadow Printing and Self-Aligned Masks

Introduction

In the shadow printing mode, including contact and proximity arrangements of mask and wafer, optical lithography has a resolution with limits set by a variety of factors. These include diffraction of light at the edge of an opaque feature in the mask as the light passes through an adjacent clear area, alignment of wafer to mask, nonuniformities in wafer flatness, and debris between mask and wafer. Figure 1.45 illustrates a typical intensity distribution of light incident on a photoresist surface after passing through a mask containing a periodic grating consisting of opaque and transparent spaces of equal width, b.[51] Diffraction causes the image of a perfectly delineated edge to become blurred or diffused. The theoretical resolution, R, that is, the minimum resolved dimension in a grating mask (b_{min} for a line or a space) as illustrated in Figure 1.45 and using a conventional resist is given by:

$$R = b_{min} = k\sqrt{\lambda\left(s+\frac{z}{2}\right)} \qquad (1.13)$$

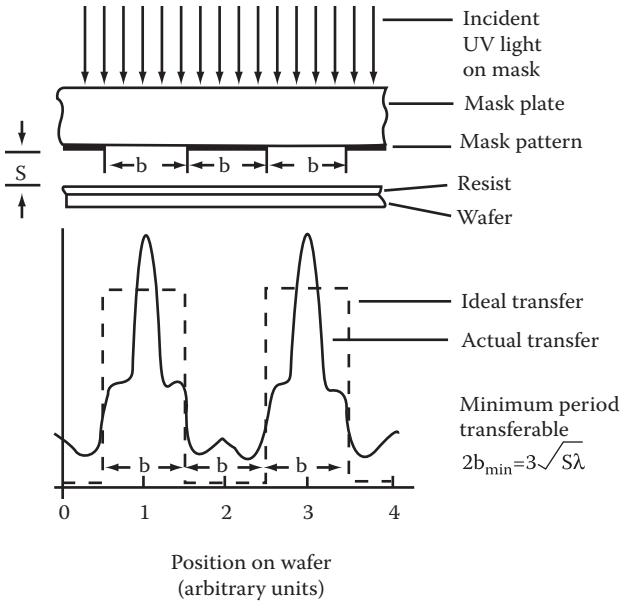

FIGURE 1.45 Light distribution profiles on a photoresist surface after light passes through a mask containing an equal line and space grating. (From Thompson, L.F., C.G. Willson, and M.J. Bowden, eds. 1994. *Introduction to microlithography*. Washington, DC: American Chemical Society. With permission.[55])

where

b_{min} = half the grating period and the minimum feature size transferable
s = the gap between the mask and the photoresist surface
λ = the wavelength of the exposing radiation
z = the photoresist thickness
k = a constant that theoretically is ~1.5

Depending on the relative magnitude of s and z, one distinguishes between contact and proximity printing. The square root relation in contact and proximity printing is a consequence of the near-field or Fresnel diffraction theory valid in the near-field region just below the mask openings; this contrasts with the far-field behavior (Fraunhofer diffraction) of projection lithography (see below). These three types of lithography are compared in Figure 1.46 (see also Volume I, Chapter 5 on far-field and near-field imaging).

Self-aligned printing can be regarded as an extreme form of contact printing where there is no gap between the mask and the substrate.

Contact Printing

In contact printing, a photomask is pressed against the resist-covered wafer with pressures in the range

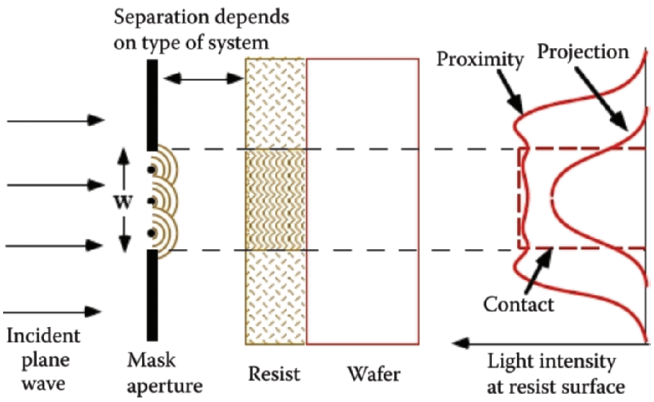

FIGURE 1.46 Proximity and contact printing are near-field, whereas projection is far-field or Fraunhofer diffraction (see Volume I, Chapter 5).

of 0.05–0.3 atm, and the s in Equation 1.13 is zero. In this case, Equation 1.13 reduces to:

$$R = b_{min} = k\sqrt{\lambda \frac{z}{2}} \qquad (1.14)$$

With $\lambda = 400$ nm and a 1-µm-thick resist, we conclude that a resolution higher than 1 µm is possible. For thinner resist layers, that is, z very small and with shorter wavelengths (e.g., 248 nm), the resolution capability of contact printing further improves. Equation 1.14 clarifies the need to use shorter wavelength and thinner resist layers to achieve higher resolution. However, the theoretical maximum resolution is seldom achieved because only diffraction effects were taken into account to derive Equation 1.13. The other factors mentioned above (e.g., wafer flatness, mask alignment) and shadowing effect (penumbral blur) usually conspire to make the resolution worse. Typical contact printers are the Kasper and the Cobilt 800. The required contact between mask and wafer also causes mask damage and contamination, rendering the method unsuitable for most modern microcircuit fabrication.

Proximity Printing

In proximity printing, spacing of the mask removed from the substrate (by at least 10 µm) minimizes defects that result from contact. On the other hand, diffraction of the transmitted light reduces the resolution. The degree of reduction in resolution and image distortion depends on the wafer-to-substrate distance, which may vary across the wafer. For proximity printing, Equation 1.13, with $s \gg z$, can be rewritten as:

$$R = b_{min} = k\sqrt{\lambda s} \qquad (1.15)$$

The technology parameter k theoretically is 1.5. Based on Equation 1.15, for a gap of 10 µm using 400-nm exposing radiation and a k value of 1.5, the resolution limit is about 3 µm.[56] More typical mask and wafer separations are in the range of 20–50 µm. The smallest features resolvable in a practical UV proximity exposure measure about 2–3 µm for most processes. A typical instrument used for proximity printing is the Canon PLA-600FA (the same setup can also be used for contact printing). Resolution is not as good as in contact printing (see above) or projection printing (see below), and for dimensions less than 2 µm optical projection methods are used.

The main disadvantage of proximity printing is a severe reduction in resolution as a result of diffraction spreading. Resolution can be enhanced by either decreasing the gap at the risk of contact and defect generation or by reducing the wavelength. Using wavelengths in the deep UV or even extreme UV range will not suffice for optical proximity printing to compete with projection printing. However, using x-rays with a wavelength of about 1 nm, feature sizes less than 0.2 µm can be produced with proximity methods. This makes 1× proximity x-ray a promising candidate for NGL.

Resolution with Self-Aligned Masks

The most desirable fabrication processes involve in situ deposited masks, also called *self-aligned* or *conformable* masks. These masks, forming molecular contact with the machine under construction, offer superior resolution as light has no chance to diffract between mask and substrate. They may be regarded as an extreme case of contact printing—that is, s is zero with the mask in atomic contact over the whole device under construction. Conformable masks comprise either permanent or sacrificial layers produced in intermediate process steps on the device itself rather than on separate quartz plates.

Figure 1.47 presents an important example of self-alignment with the so-called SALICIDE process, i.e., the **s**elf-**al**igned sili**cide** process, a process in which

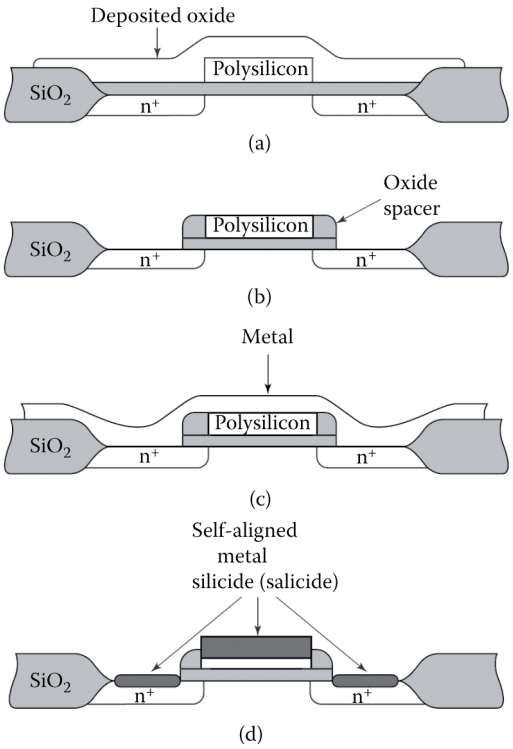

FIGURE 1.47 Example of a self-aligned silicide (SALICIDE) process in the formation of a MOS transistor. (a) An oxide is deposited over the polysilicon gate. (b) The deposited oxide is RIE patterned, leaving the sidewalls of the poly-Si covered with oxide (oxide spacer). (c) Metal is deposited over the structure and heated to form silicides where naked Si is exposed. (d) Unreacted metal is etched away, leaving silicide automatically aligned to gate, source, and drain region.

silicide contacts are formed only in those areas in which deposited metal is in direct contact with silicon. This self-aligning process is commonly implemented in MOS/CMOS processes in which ohmic contacts to the source, drain, and poly-Si gate are formed by the "salicide" process. The salicide process begins with deposition of a thin transition metal layer over fully formed and patterned semiconductor devices (e.g., transistors). The wafer is heated, allowing the transition metal to react with exposed silicon in the active regions of the semiconductor device (e.g., source, drain, gate) forming a low-resistance transition metal silicide. The transition metal does not react with the silicon oxide or nitride insulators present on the wafer. Following the reaction, any remaining unreacted transition metal is removed by chemical etching, leaving silicide contact metal automatically aligned to gate, source, and drain region.

We explained in Volume I, Chapter 4 that an important advantage of the SALICIDE process in new generation CMOS circuitry is that the entire junction area is used for contact formation, which translates into a lower overall contact resistance. The silicide contact materials on the transistors are then further contacted through chemical vapor deposition (CVD)-deposited plugs of pure W filling the contact vias (see Volume I, Chapter 4).

Projection Printing

Resolution

In projection printing, wafer contact is completely avoided; a high-resolution lens projects an image of the photomask onto the photoresist-covered wafer. Imaging in this case is far field or Fraunhofer diffraction dominated, as shown in Figure 1.46. A schematic of a projection lithography system is presented in Figure 1.48.

In Volume I, Chapter 5, we calculated (based on the Maxwell equations) the Rayleigh criterion for far-field resolution as:

$$R = 0.61\lambda/NA$$

with λ the wavelength of the light used for the pattern transfer, and NA the numerical aperture of the imaging lens system.

Diffraction in a small opening transforms normally incident light into an angular spread as

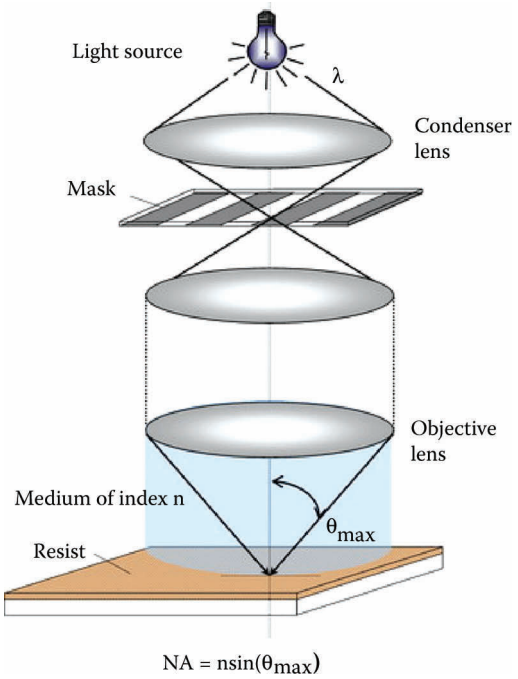

FIGURE 1.48 Optical projection printing. The basic components of a generic optical projection system.

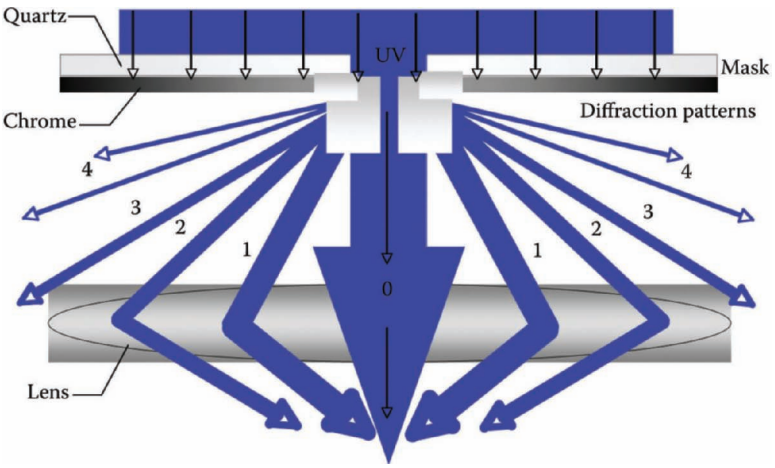

FIGURE 1.49 The numerical aperture (NA) of a lens tells us how much of this diffracted light the lens can capture and image (see Volume I, Equation 5.3: NA = nsinθ).

illustrated in Figure 1.49. The numerical aperture of a lens determines how much of this diffracted light the lens can capture and image (see Volume I, Chapter 5: NA = nsinθ). Because of this spreading effect, fewer diffracted orders are captured by the lens and form the image. This means that information about the smallest pattern is lost because the smaller the pattern the wider the spread. In Figure 1.50 we show the effect of including increasing numbers of diffracted orders on the image of a slit of width *w*. The more diffracted orders we can pick up, the higher the fidelity of the resulting image. As explained in Volume I, Chapter 5, for absolute image fidelity, we need an NA = 1. Pendry's near-field amplifying superlens (NFSL) offers that prospective. A near-field superlens illustrated in Volume I, Chapter 5 enables subdiffraction limit imaging so that even nanometer objects can be imaged with light of say 365-nm wavelength.

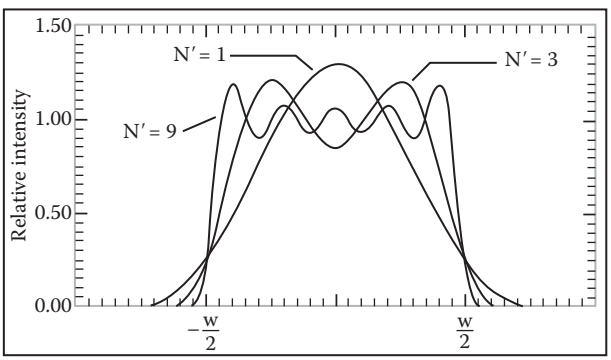

FIGURE 1.50 The higher the number of diffracted orders a lens can pick, i.e., the higher the NA of a lens, the better the resolution of the image.

The NA of lenses in projection aligners ranges from ~0.16–0.80 (see Figure 1.80). With a good lens, possessing an NA of 0.5, the Rayleigh expression suggests that the best resolution one can obtain roughly equals the size of the wavelength of the exposure system. Although the Rayleigh criterion is too simplistic—it only takes into account characteristics of the optical system—it correctly predicts that a larger NA or a shorter wavelength leads to better resolution.

The derivation of R = 0.61λ/NA (Volume I, Chapter 5) was based on the concept of a "point source" something that does not really exist. Here we want to introduce the practical resolution of a photolithography system starting from the grating equation. From the grating formula $d = \frac{N\lambda}{2n\sin\theta} = \frac{N\lambda}{2NA}$, we calculated that the resolution with incoherent illumination is better than with coherent light [R = 0.5 λ/NA for coherent light (Volume I, Chapter 5) vs. R = 0.25 λ/NA for incoherent light (Volume I, Chapter 5)]. We generalize these results using a dimensionless constant k_1 to define the practical limiting resolution *R* in projection printing as:

$$R = k_1 \frac{\lambda}{NA} \tag{1.16}$$

where k_1 is the experimentally determined dimensionless parameter that depends on resist parameters, process conditions, mask aligner optics, and so on.

To achieve higher resolutions, we want to work at shorter wavelengths λ, higher NA, and smaller k_1.

The k_1 parameter fluctuates between 0.3 for surface imaging resists to 0.5 for multilayer resists (MLRs), 0.75 for single layer resists (SLRs), and 1.1 for reflective surfaces like aluminum. Up until 1995, production engineers demanded that k_1 be about 0.7 for SLRs; today, its value is closer to 0.5 (see Figure 1.81). Technologies enabling lower k_1 values, besides surface imaging and MLRs, include phase-shift masking, antireflective coatings, and off-axis illumination. We will review these methods under resolution-enhancing technique (RET) and learn, for example, that with RET one can obtain a resolution about one-half of the exposure wavelength or even better. The better resolution afforded by a lower k_1 makes for a narrower process window and thus a more difficult process; it is expected that one cannot go much lower than a k_1 of 0.25 (see Figure 1.81).

Depth of Focus

To obtain good line-width control, the latent image must remain in focus throughout the depth of the resist layer. A certain amount of defocus tolerance is allowed. The defocus tolerance or depth of focus (DOF or δ) of an optical system is given by:

$$\text{DOF} = \pm\delta = \pm k_2 \frac{\lambda}{NA^2} \tag{1.17}$$

And by using Equation 1.16:

$$\text{DOF} = \pm\delta = \pm k_2 \frac{R^2}{k_1^2 \lambda} \tag{1.18}$$

In Equations 1.17 and 1.18, k_2 is a process-dependent constant hovering around 0.5. For a detailed mathematical derivation of the DOF equations we refer to Bowden.[56] From Equation 1.16, we know that to achieve better resolution we must reduce λ and increase NA. As deduced from the DOF equations, the penalty is a reduction in DOF, perhaps becoming so small that a focused image through the total depth of a typical 1.0–1.5-μm-thick photoresist cannot be achieved anymore. A good NA of a lens for a g-line (436 nm) lithography system is 0.54. With a k_1 factor of 0.8, this leads to a resolution of 0.65 μm (based on Equation 1.16). With i-line (365 nm) lithography, a resolution of 0.65 μm can be achieved with a 0.45-NA lens while exhibiting a superior DOF of 0.9 μm compared with 0.7 μm for the g-line. Wide-

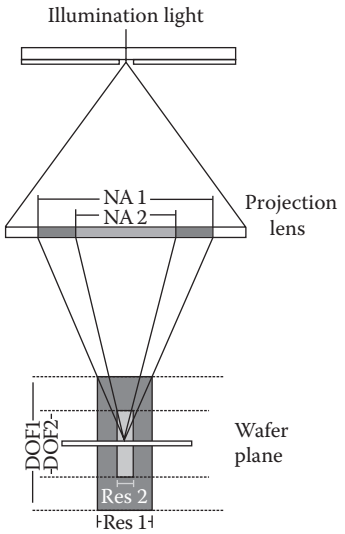

FIGURE 1.51 Variable numeric aperture stepper.

field i-line steppers with variable numeric apertures (Figure 1.51) are available with a 22 × 22-mm field, a 5× reduction ratio, and a resolution of better than 0.35 μm (e.g., the Nikon NSR-2205i14E, http://www.nikon.co.jp/main/eng/news/dec14e_97.htm). This type of equipment allows one to balance resolution, DOF, and wafer throughput for different applications. Because the patterns on wafers have their own topology and wafers may not be perfectly flat, a large DOF is needed to ensure that the image stays in focus over the entire field. If even a small part is out of focus, the final product will be ruined.

Photography enthusiasts easily relate to this discussion (see Figure 1.52): a high aperture setting on a camera leads to sharp images for objects that are close to the camera (see rose), whereas a small aperture keeps objects in focus all the way to infinity (see stones).

Microlithographic (or practical) DOF is defined as the total defocus allowable for a desired tolerance on a minimum feature size. It may be different from the values estimated from Equations 1.17 and 1.18. The practical DOF must encompass device topography, resist thickness, wafer flatness, and focus tilt errors. For sub-0.5-μm lithography, only a small amount of residual nonplanarity in device topography can be tolerated without negatively affecting critical dimension control. Small DOF values require expensive planarization processes to bring all IC features in focus within the DOF of the optical system. Some of these planarization processes will be reviewed

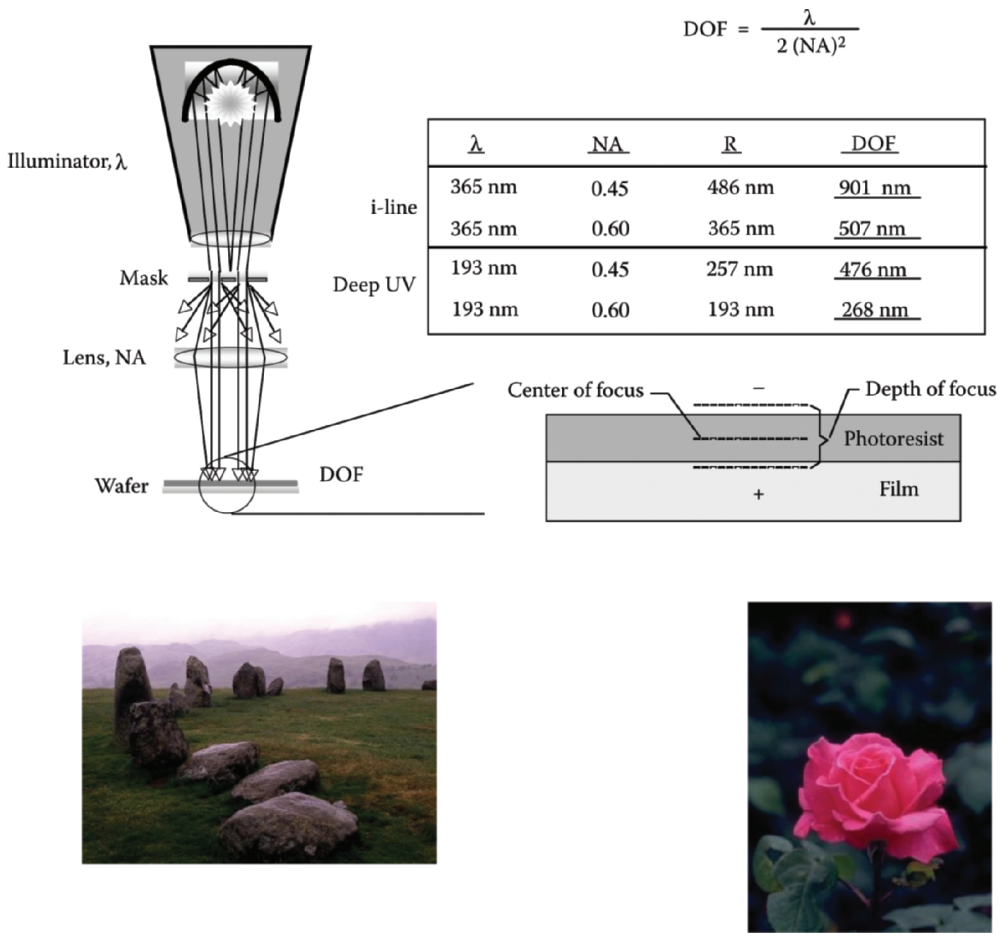

FIGURE 1.52 The concept of depth of focus (DOF) in lithography and photography.

further below. Thin film imaging (TFI) methods, reviewed below, also allow one to work around DOF problems by imaging in thin film resist layers and then transferring that image to underlying thicker resist layers. Miniaturized structures often possess more extreme topologies than ICs, making planarization an even bigger challenge. During the past 20 years, progress in expanding the DOF of semiconductor equipment has not kept pace with the decreasing CDs. For miniaturization science, the former is more important. We will learn how topographical masks and using x-ray and e-beam lithography have enabled the higher DOFs needed for high-aspect-ratio miniaturized 3D machines.

Types of Projection Methods

Since 1973, when Perkin-Elmer (http://instruments.perkinelmer.com) first introduced its scanning projection system for lithography, optical projection of mask patterns has become the standard lithography method. Some of the many projection systems in use include projection scanners (e.g., Perkin-Elmer's Micralign 700 series), 1:1 and reduction (e.g., 5:1 and 10:1 times, often denoted as 5× and 10×), step-and-repeat projection systems (e.g., 10× Electro-Mask), step and scan systems [e.g., ASML's (http://www.asml.com) PAS 5500/900], and double-sided mask aligners [e.g., the SUSS MicroTec MA/BA6 Mask Aligner (http://www.suss.com/products/mask-aligner/ma-ba6-gen2.html)].

A scanning projection system exposes the wafer in a single scan without the benefit of midscan realignment to local alignment marks. The wafer and the mask move simultaneously and continually on an air-bearing carriage through a light arc covering the whole mask and wafer at once. With a deep UV light source, resolution of 1 μm can be obtained, DOF of ±6 μm is possible, and an overlay accuracy of ±0.25 μm (1 σ) has been reached. In practice, these scanners are mainly used for alignment of patterns with CDs in the 3-μm range and for high throughput applications (e.g., 100 wafers/hour).

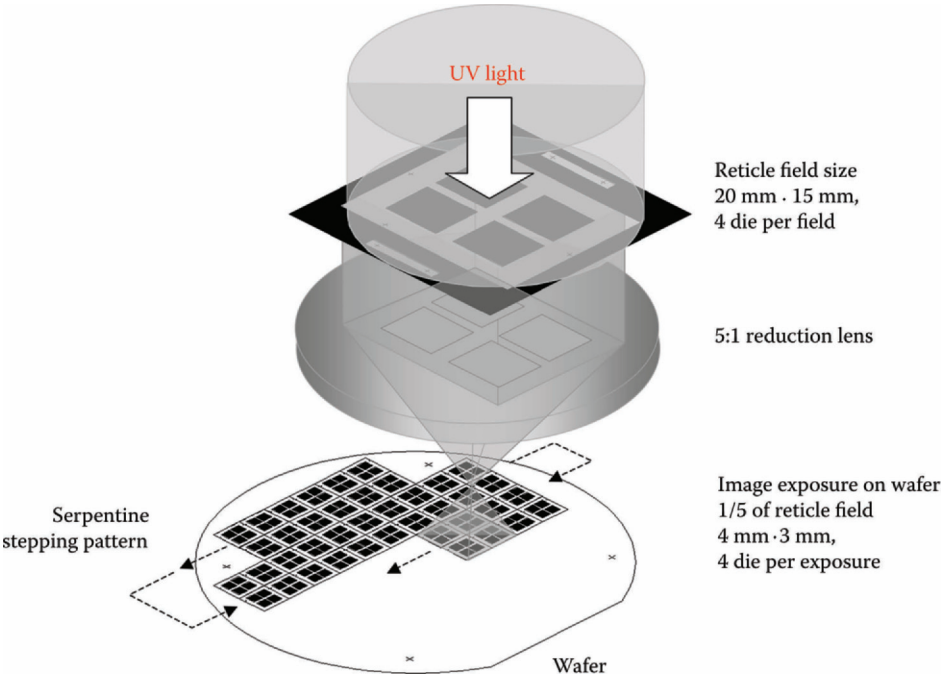

FIGURE 1.53 Stepper exposure field.

A stepper system, also step-and-repeat, exposes one small part of the wafer followed by a new exposure at the next position (Figure 1.53). By stepping and repeating, the entire wafer is covered with the reticle pattern. Steppers have the ability to align to each field and make adjustments to x, y, rotation and focus, and tilt. They offer higher alignment accuracies but are slower than scanners. Most steppers use reduction lenses (e.g., with a 10:1 or a 5:1 reduction) rather than one-to-one projection printing. The reduction printer exposes part of the wafer to a pattern from a mask 5–10 times larger than the projected image. The reduction process makes reticle inaccuracies less significant, consequently improving the resolution and resulting in easier mask making. The only drawback pertains to the size of the image field: the higher the reduction ratio, the smaller the image field. Because of lens imperfections and diffraction considerations, projection techniques have a lower resolution for pattern transfer than that provided by a contact or self-aligned mask; however, CDs of 65 nm have already been achieved today with projection lithography.

With steppers, the full exposure field (pretty much the whole lens) is illuminated, and the reticle image is projected in one flash at each location across the wafer. In newer step and scan systems (Figure 1.54), used in 193-nm lithography, only a narrow slit of the wafer is illuminated. In tools of this type, the wafer is stepped to a new field, which is then scanned; this sequence continues until all the fields have been scanned. This method projects a part of the image from the reticle onto the wafer and uses only a small fraction of the lens area. By synchronously moving the reticle stage (up to 1 m/s) and the wafer stage (up to 25 cm/s) in opposite directions, the whole reticle pattern is imaged onto the wafer. With step and scan systems, larger image fields can be exposed (see Figure 1.54), resulting in higher productivity; because a smaller area of the lens is used (only a slit over the center of the lens), each lens can be better optimized for higher resolution and lower distortion.

A mask aligner of particular interest to the non-IC miniaturization engineer is a double-sided mask aligner. With this equipment, features can be aligned on opposite sides of the wafer. An example is the SUSS MA-150 RH with a top-to-bottom precision alignment accuracy of 1 μm (1σ) in production. Another double-sided top and bottom aligner is the 600 series EV640 by Electronic Visions Co. (http://www.elvisions.com). Double-sided mask alignment is discussed in more detail under "Mask Alignment in Projection Printing," this chapter.

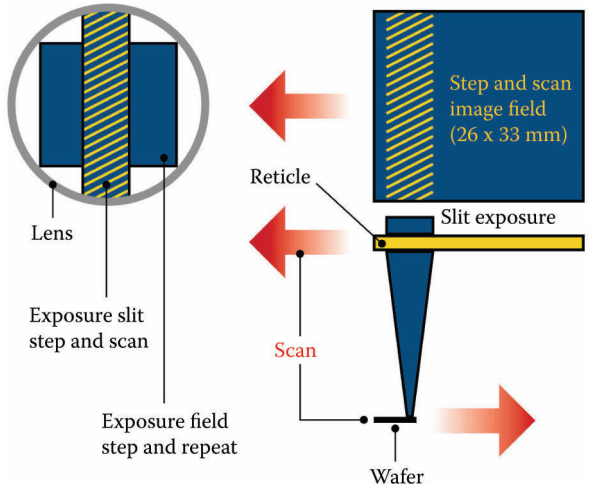

FIGURE 1.54 Step and scan systems. With wafer steppers, the full image is exposed in one flash, whereas with the step and scan systems, the wafer stage and reticle stage move simultaneously in opposite directions during the exposure to scan the image onto the wafer.

Modulation Transfer Function

In the projection printing of a grating, a series of light intensity maxima and minima are produced, as illustrated in Figure 1.55. Because of mutual interference, dark regions in the image never reach complete darkness, and the maximum brightness never corresponds to 100% transmission. The quality of the image transfer can be expressed by the modulation index (also simply modulation) M defined as:

$$M = \frac{I_{max} - I_{min}}{I_{max} + I_{min}} \qquad (1.19)$$

In this equation, I_{max} and I_{min} are the peak and trough intensities, respectively. M reveals the degree to which diffraction effects cause incident radiation to fall on the resist between the images of two slits in a mask. Ideal optics would give a modulation M equal to 1. In practice, exposure systems behave less ideally with an $M < 1$.

The optical imaging quality (that is, the capability of reproducing a mask feature on a wafer surface) for a given projection system can be characterized in terms of the modulation transfer function (MTF) curve. The MTF of an exposure system is defined as the ratio of the modulation in the image plane to that in the object or mask plane (that is, M_{im}/M_{mask}) as a function of spatial frequency (ν) or number of line pairs per millimeter on the mask. Because the intensity in the mask plane at the center of an opaque feature is essentially zero, we can equate $M_{mask} = 1$. Consequently, we can also equate MTF and M_{im} as shown in Figure 1.55 where the curve is normalized to 100%. An MTF curve is obtained by imaging a series of gratings with different spatial frequencies placed in the object plane, and the corresponding modulation $M_{im}(\nu)$ in the image plane is measured.[52]

The MTF of an exposure system depends on NA, λ, mask feature size, and the degree of spatial coherency of the illuminating system. Because NA and λ are fixed by the system hardware design, a plot of MTF versus feature size, parametrically changing the spatial coherency, often is used to compare a system's imaging capability. Coherence (σ) varies from $\sigma = 0$ for coherent radiation to $\sigma = \infty$ for fully incoherent illumination. Only point sources are completely coherent with all light waves impinging perpendicular on the mask. In reality, we deal with light sources of finite size as illustrated in Figure 1.56, resulting in partially coherent light. The degree of coherence of the light on the resist plane is dependent on that size, and the resulting light is usually only partially coherent. The definition of coherence is:

$$S = NA_c/NA_o \text{ or also } S = s/d \qquad (1.20)$$

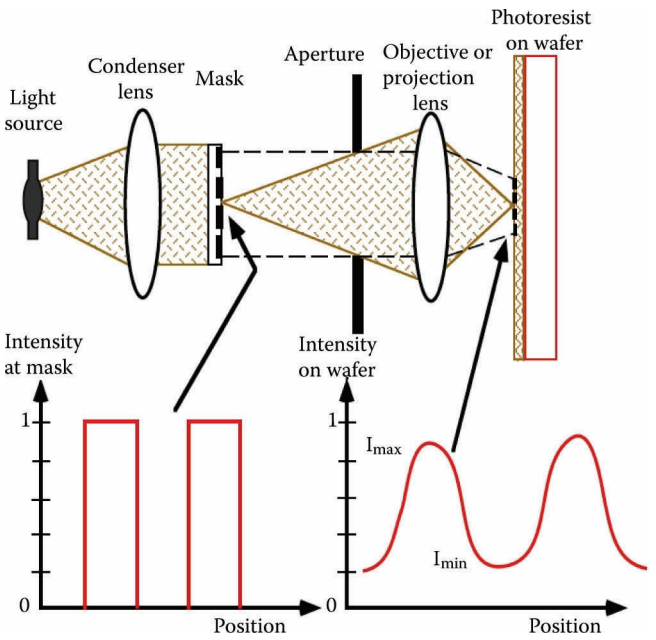

FIGURE 1.55 Modulation and modulation transfer function (MTF).

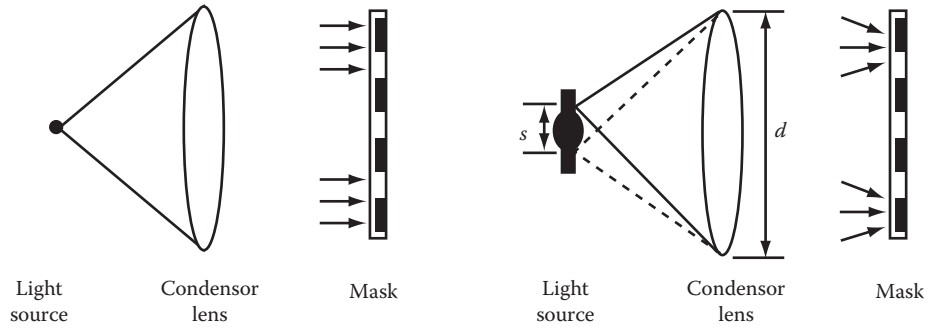

FIGURE 1.56 Coherent and incoherent light.

where NA_c and NA_o are the NA of condenser and objective lens, respectively, s is the size of the light source, and d is the diameter of the lens (see Figure 1.56).

MTF curves (also the modulation M_{im} in the image plane) for coherent, partially coherent, and incoherent illumination are shown in Figure 1.57. Contrary to the coherent case in which MTF remains constant up to the cutoff frequency $\nu_{max} = NA/\lambda$, the MTF curve for the incoherent case decreases monotonically as the frequency increases up to a maximum value ν_{max} of $2NA/\lambda$. Because $\nu_{max} = 1/2b_{min}$ and $R = b_{min}$, the maximum resolution for coherent light is predicted to be $0.5\lambda/NA$; for incoherent light it is $0.25\lambda/NA$ (see also the derivation of Equations 5.6 and 5.9 in Volume I). Completely incoherent light produces an MTF curve that has a greater resolution limit, but the MTF value only slowly increases as the feature size increases. For these reasons, partially coherent light often is preferred.[56] Based on various tradeoffs, a coherence value of ~0.7 typically is selected for a practical exposure. The cutoff frequency shown in Figure 1.57 defines the resolution limit of the exposure system. It is proportional to the NA of the lens and inversely proportional to the wavelength. Good sources for a more detailed treatise on the MTF are Bowden,[56] Sheaths,[57] and Wolf.[50]

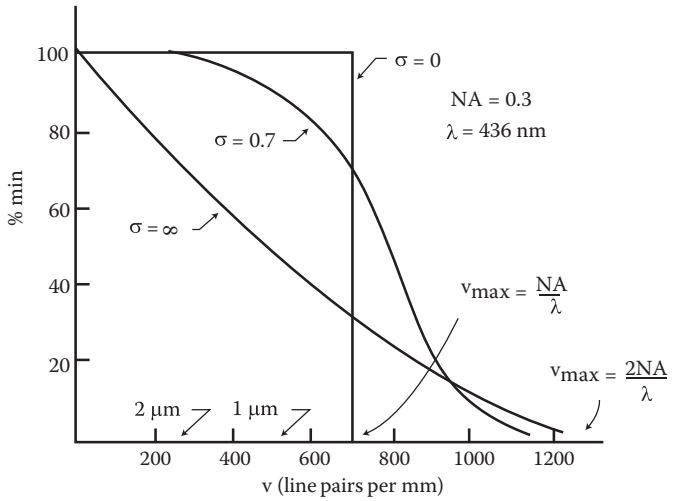

FIGURE 1.57 Percent modulation in the image plane, % M_{im}, modulation of an image as a function of spatial frequency ν for different coherency factors. σ = 0 (coherent), σ = 0.7 (partially coherent), and σ = infinite (incoherent). Critical MTF Values

For the practical resolution of a resist to approach the Rayleigh limit of the optical system, the resist should have an infinite contrast. Because a resist always has a finite contrast value, a greater degree of modulation is needed before an adequate image can be formed. Thus, the minimum MTF of an optical system to adequately define an image in a resist depends on the resist contrast value γ and is defined as the critical MTF, or $CMTF_{resist}$. The relationship between the resist contrast and CMTF is given by:

$$CMTF_{Resist} = \frac{10^{\frac{1}{\gamma}} - 1}{10^{\frac{1}{\gamma}} + 1} \qquad (1.21)$$

A resist material with $\gamma = 2$ results in a CMTF value of 0.52. For an exposure system to adequately print a given feature size, the MTF of the feature size must be larger than or equal to the $CMTF_{resist}$ of the resist used. If the MTF of an exposure system is known for various feature sizes, knowledge of the resist contrast and Equation 1.21 will allow prediction of

the smallest features printable when applying that system.

Mask Alignment in Projection Printing

Fiducial Marks Thus far we have not dwelled much on the alignment or registration of the wafer to the mask in so-called aligners or printers. In projection lithography, the mask, or reticle, is held in place above the projection lens by a reticle stage. The projection lens focuses the high-resolution images of the reticle patterns precisely onto a wafer that is positioned and held in place by the wafer stage. During this critical alignment process, the wafer stepper aligns the mask image to alignment or fiducial marks on the wafer. This ensures that the pattern pictured by each mask layer is precisely aligned and "overlays" the previous layer. In the process of manufacturing a miniaturized device, several thin films are stacked on top of one another; each is patterned differently; and each wafer goes through the wafer stepper 20–30 times. For a detailed description of mask alignment equipment, we refer the reader to the specialized literature.[58] We discuss the types of errors that can be expected from mask alignment below.

Mask alignment errors can have catastrophic effects on the performance of integrated circuits and miniature machines, often rendering them incapable of operating. For example, a device that has a minimum line width between 1 and 1.5 μm can only tolerate a variation of ±0.25 μm with respect to the alignment of masks without encountering greatly increased device failure rates. Product failure is caused mainly by poor alignment between the image being projected and the pre-existing patterns on the wafer. To align one layer with a previously fabricated layer when performing photolithography, appropriate fiducial marks are created on the mask. Different laboratories and foundries use different marks, and these may need to be placed in a specific position on the design. Additional requirements include a scribe lane around each chip to indicate where the wafer is to be cut when it is diced. The inclusion of a unique mask number and an indication of layer names on the mask make it possible to tell by looking how far through the fabrication process a wafer has progressed (http://www.dbanks.demon.co.uk/ueng). In Figure 1.58, we illustrate a

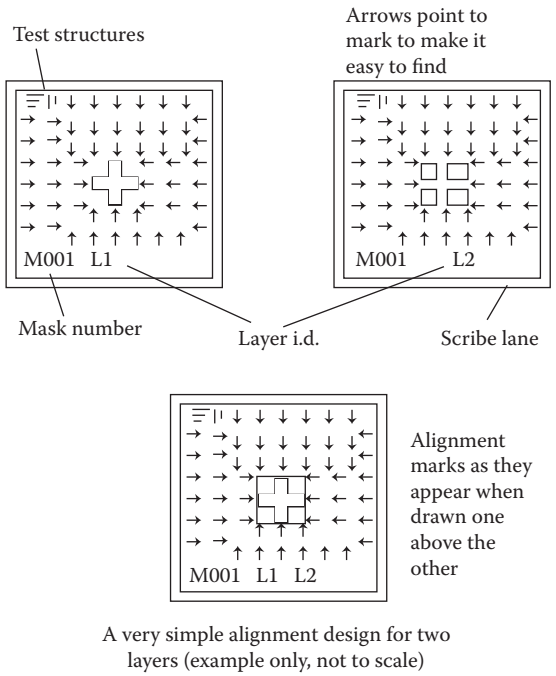

FIGURE 1.58 A simple set of fiducial marks and other important guiding features often found on masks. (Based on Banks at http://www.dbanks.demon.co.uk/ueng.)

mask set with many of the common features: fiducial marks, arrows to point to the marks, test structures, and mask and layer numbers. Optical vernier (Figure 1.59) patterns created on the different levels to be aligned are another common and useful feature. Vernier scales allow us to resolve alignment errors more accurately than the minimum feature size for a given process. To gain this fine resolution, vernier scales depend on accurately spaced lines. A pictorial tutorial on how to use vernier scales in lithography can be found on the Internet at http://www.schlenkent.com/vernier.htm.

Types of errors encountered in projection printing are illustrated in Figure 1.60. They range from misalignment to mask error, optical distortion, wafer or

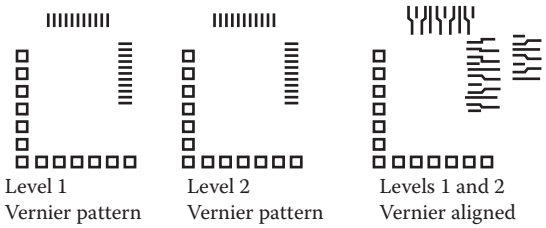

FIGURE 1.59 Standard optical vernier test pattern for overlay evaluation. (From Moreau, W.H. 1988. *Semiconductor lithography.* New York: Plenum Press. With permission.[28])

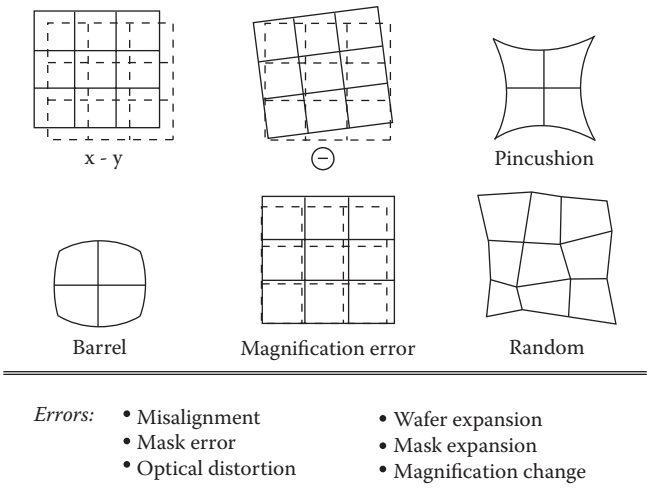

FIGURE 1.60 Sources of errors in projection printing.

mask expansion, and magnification change. Pattern registration capability is the degree to which the pattern being printed can "fit" mask alignment marks and previously printed patterns. With an optical stepper, the step-and-repeat operation is performed by laser interferometer-controlled stages to a positioning accuracy of <40 nm, thereby allowing the registration of successive layers of a semiconductor device with similar precision. Because interferometric schemes enable sensitivities at less than 10 nm, it appears feasible that aligners compatible with line widths of 0.1 µm or even 50 nm can be developed. For CDs of 0.25 µm and even down to 0.20 µm, conventional wafer steppers can be used. However, at design rules of 0.18 µm, step and scan technology becomes more important (see above under Types of Projection Methods).

Alignment in MEMS Alignment is more complex in 3D miniaturized machines than that in IC manufacture. Not only does one deal with high-aspect-ratio 3D features, which can cause problems for alignment systems with low DOF, but one also frequently needs to align 3D features on both sides of the wafer. The objective is to position alignment marks opposite each other on the two surfaces of the same wafer, allowing accurate positioning of all later feature-defining photolithographic patterns. There are several options for front-to-back alignment. One not too elegant or desirable way is by etching holes through the silicon wafer. Another better way is to use infrared to see through the silicon or, with visible light, to use a double-sided mask alignment system defining marks on opposite sides of the wafer with a set of mirrors, two light sources, and two masks. In the latter double-sided mask aligner, mask 2 is first aligned to mask 1; then the wafer is inserted and aligned, and UV exposure of both sides can begin. Wafers polished on both sides are used to minimize light scattering. Two popular commercial double-sided alignment and exposure systems are by SUSS, Germany, and Electronic Visions, Austria. The operation of the SUSS MA-150 is illustrated in Figure 1.61. Cross-hair marks on the mask are aligned to cross-hair marks on the back of the wafer. In the alignment process the alignment marks on the mask are first viewed by two microscope objectives, and the image is electronically stored. The wafer is then loaded with the back-side alignment marks facing the microscope objectives, and the wafer stage is moved and adjusted until the marks are aligned to

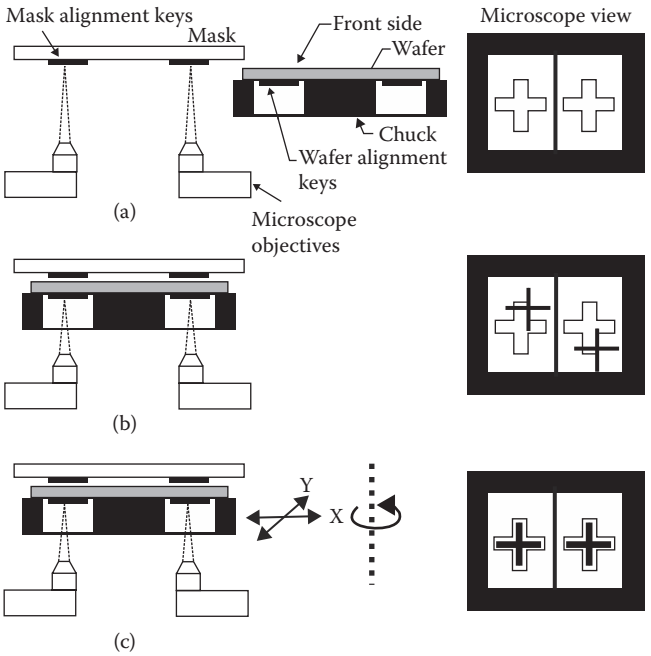

FIGURE 1.61 Double-sided alignment scheme for the SUSS MA-150 production mode system: the image of mask alignment marks is electronically stored (a); the alignment marks on the back side of the wafer are brought in focus (b); the position of the wafer is adjusted by translation and rotation to align the marks to the stored image (c). The right side illustrates the view on the computer screen as the targets are brought into alignment. [Adapted from product technical sheet (SUSS, Munich, Germany) and Maluf, N. 2000. *An introduction to microelectrochemical systems engineering*. Boston: Artech House.[59]]

the electronically stored image. With the alignment finished, exposure of the mask on the front side of the wafer is completed either in contact or proximity mode. On a SUSS MA-150 RH, with robotic bottom-side alignment (BSA), a standard deviation less than 0.33 µm on front-to-back alignment has been demonstrated; of course, the alignment accuracy depends on a multitude of process parameters, but in a typical production mode this mask aligner can achieve an accuracy of better than 1 µm (3σ).

Because two-sided mask aligners and infrared microscopes are costly, researchers have been looking into less expensive but still accurate alternatives. In the simplest, least-accurate approach, wafer flats can be used as reference for the double-sided alignment with, at best, 5-µm accuracy. In a slightly more sophisticated procedure, White and Wenzel[60] use a simple laboratory jig as shown in Figure 1.62. In this approach, mask 1, containing only alignment marks, is contact printed onto photoresist-coated mask 2 while both are positioned snugly against the three pins on the jig. After developing and etching the alignment marks on mask 2, the individual alignment patterns from the two masks are transferred onto the opposite faces of a semiconductor wafer coated on both sides with photoresist. This is accomplished by sandwiching the resist-coated Si wafer between the two alignment masks (again set snugly against the three pins of the jig), exposing each wafer surface (directly for one side and through the large hole in the jig for the other side). The alignment patterns then are etched into the wafer and used in a conventional one-sided mask aligner. The authors estimate the predictable alignment errors to be less than 1 µm across a 250-µm-thick, 2-in. wafer. Kim et al.[61] describe a different front-to-back alignment technique involving the visual alignment of stepper crossbars (alignment keys) to the center of a transparent thin diaphragm etched from the back of the wafer. These authors claim a <1-µm alignment error, but no experimental evidence is presented. Tatic-Lucic et al.[62] elaborated on the latter type of double-sided alignment method and demonstrated a <2-µm error across a 4-in. wafer. In this upgrade, only alignment marks on the front of the wafer formed in a low-stress insulating layer are required. This insulating layer with the alignment marks is later etched from the back so that a freestanding diaphragm with a cavity underneath it results. This cavity makes the front-side alignment marks visible from the back. This allows visual alignment from both sides of the wafer with a traditional GCA 4800 stepper. Yet another alternative to facilitate double-sided alignment is the pickup of capacitive signals between conductive metal fingers on the mask and ridges on a small area of the Si wafer. This technique, requiring close proximity between mask and wafer, is only applicable for 1:1 proximity lithography as used, for example, in LIGA (see Chapter 10).

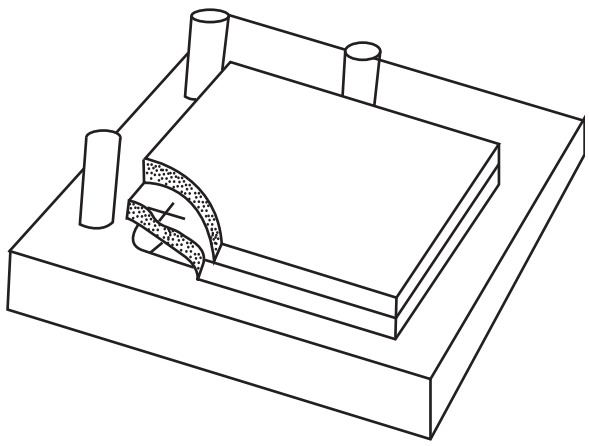

FIGURE 1.62 Sketch of two-sided alignment jig with the two alignment masks in place for contact printing marks onto mask 2 (top mask). The cross represents an alignment mark on mask 1. (Courtesy of Dr. Richard White, University of California, Berkeley.)

There are numerous problems associated with using classical exposure tools for fabricating highly nonplanar miniature machines. Therefore, maskless exposures to photons (in air) or electrons (in vacuum) with high-precision linear and rotary positioning stages and numerically controlled beam direction and stage position are gaining popularity with non-IC machinists. Nonplanar lithography methods are discussed in Chapter 2 on next generation lithographies.

Mathematical Expression for Resist Profiles

The slope of the resist edge (dz/dx) of an image of a mask feature of width W (see Figure 1.63), for a case where the dose D is low and the developer influence dominant, can be written as:

$$\frac{dz}{dx} = \left(\frac{dz}{dD}\right)\left(\frac{dD}{dx}\right) \qquad (1.22)$$

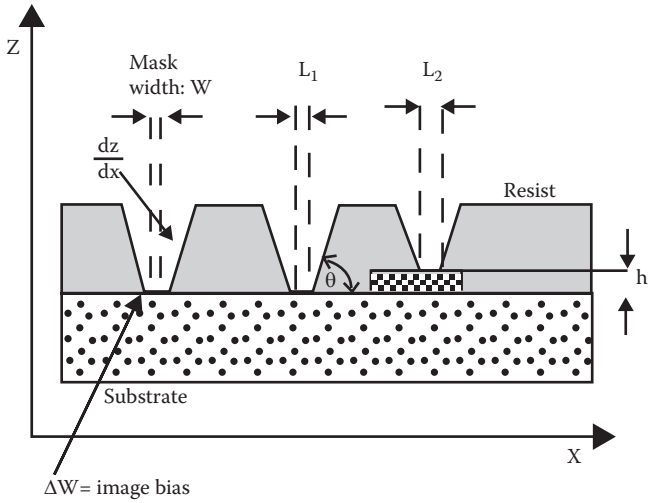

FIGURE 1.63 Edge slope of a positive resist, *dz/dx* primarily determines the image bias, Δ*W*. The change of line width of a feature developed in resist with a topographic feature of height *h* is given by $L_2 - L_1 = \Delta CD$.

where *z* is the thickness dimension and *x* is the lateral dimension in the resist.

The term *dz/dD* (developer elution term) is only resist- and resist-processing dependent. Additionally, the term *dD/dx*, the derivative of the energy or dose absorbed, also called the *intensity profile*, is a term dependent only on the exposure system and the object that is being imaged. The response of a positive resist to dose *D* is given by γ_p, the contrast of the resist, and the developer-process term in Equation 1.22 can be approximated by[63]:

$$\frac{dz}{dD} = -\frac{\gamma_p}{D_p} \tag{1.23}$$

where γ_p is the contrast of a positive resist as given by Equation 1.11, that is, the slope of the curve of thickness remaining versus log of exposure dose. In Equation 1.11, D_p^0 represents the exposure energy below which no resist removal by the solvent takes place, and D_p embodies the sensitivity of the resist or the exposure energy at which no resist remains after development. Exposure energy D_p^0 is independent of the thickness *t* of the resist. Resist sensitivity D_p, on the other hand, will vary strongly with the thickness, predominantly through the absorbance of the film:

$$D_p \approx D_T . 10^{\alpha t} \tag{1.24}$$

with α the resist absorbance per unit thickness and D_T a threshold exposure that depends on resist type and is equal to or smaller than D_p^0. With these further simplifications we can rewrite Equation 1.23 as:

$$\frac{dz}{dD} \approx \frac{1}{(a+\alpha t)D_p} \tag{1.25}$$

where *a* is a constant for the resist and α is the absorption coefficient. The *dD/dx* term in Equation 1.22, or the intensity profile, depends on the object and the imaging system. The intensity profile of the image is affected by the wavelength of exposure λ, the numerical aperture NA, the depth of focus of the exposure tool DOF, and the uniformity of illumination and can be written as:

$$\frac{dD}{dx} = \frac{2NA}{\lambda\left[1-k\left(\frac{DOF \times NA^2}{\lambda}\right)\right]^2} \tag{1.26}$$

where *k* is a parameter depending on the coherence of the light source. Based on Equations 1.25 and 1.26, we can rewrite Equation 1.22, describing the resist profile, in identifiable parameters, as:

$$\frac{dz}{dx} = \frac{2NA}{\lambda(a+\alpha t)\left[1-k\left(\frac{DOF \times NA^2}{\lambda}\right)\right]^2} \tag{1.27}$$

It follows that, for a steeper edge slope, *dz/dx*, the thickness and the absorption of the resist should be reduced, and the resist contrast γ_p should be as high as possible; finally the shorter the exposure wavelength λ and the higher the NA, the sharper the image profile. Because a higher NA means a lower DOF, which deteriorates image profiles at larger depths, there is an optimum NA for each exposure/resist system.

When imaging the grating of Figure 1.55 with a period p = 2b, the image intensity will be sinusoidal [$D \approx 1/2\ (1 + M \cos 2\pi x/p)$], where *x* is the lateral dimension, and *M* is the normalized modulation. The maximum image edge slope is then simply $dD/dx = \pi M/p$, and Equation 1.27 may then

be written with the maximum of the *dz*/*dx* term expressed as a function of the normalized modulation *M*, or:

$$\frac{dz}{dx} = \frac{\pi M}{2(a+\alpha t)D_p b} \qquad (1.28)$$

From this expression, we would want to work with the largest possible image modulation *M*.[63] Equation 1.27 also implies that a high-contrast resist with a low absorbency will have wider exposure latitude and can tolerate a larger intensity variation in exposure system output (D_p).

The image bias or error, ΔW, shown in Figure 1.63, is primarily a function of the resist edge slope and grows smaller as *dz*/*dx* becomes steeper. At a high radiation dose (>100 mJ/cm^2), the profile of a positive resist is dominated by the absorption of radiation, the reflected photons, and the quantum yield [Φ or $G(s)$] of the photochemical reaction (see Table 1.9Aa). The absorbed energy per depth *z* dominates the rate of dissolution. In a developer-dominated (also force-developed) resist profile (also overcut), the profile recedes, and thinning of the whole resist layer occurs (see Table 1.9Ac). This thinning does not occur in the case of insolubilized traditional negative resists, rendering those resists less susceptible to overdevelopment (see Table 1.9B). For traditional negative resists, γ_n is not influenced by the solvent, and apart from some uncontrollable swelling of negative resists during development, the resist profile cannot be manipulated in the development step. By using a normal exposure dose with moderate developer influence, a "perfect" image transfer can be accomplished with a positive resist as shown in Table 1.9 Ab. At those moderate doses, both the developer elution term and the energy absorption term contribute to the formation of the resist profile.

From Figure 1.63, we can see how the exposure gradient results in the developed positive resist profile having a larger opening on top, forming a so-called normal or overcut profile. This profile results in a difference of dimension in subsequent patterning steps over features with different topography. The change in CDs, ΔCD, relates to profile angle θ and topography height *h*, and can be expressed as:

$$\Delta CD = L_1 - L_2 = 2h\,(\tan\theta)^{-1} \qquad (1.29)$$

A lithography simulator such as PROLITH/2 (http://www.finle.com/index.asp) or Sample (http://cuervo.eecs.berkeley.edu/Volcano/docs/sample3D.html) may be used to perform resist profile simulations.[64] Experimentally determined parameters are fed into the simulated models to make the predicted resist profiles more accurate. An example is the measurement of deprotection reaction parameters of chemically amplified (CA) resists.[65] The concentration of the protection groups determines the solubility of the resist, and consequently the simulation parameters related to the deprotection reaction will have a significant influence on the accuracy of profile simulations of CA resists. The measurement is carried out by incorporating a PEB system inside a Fourier transform infrared (FTIR) spectrometer.

Planarization

Introduction

Microlithography process latitude can become severely limited by nonsmooth topography. Resist films crossing over steps have their local thickness altered; thinning occurs over high features, and pileup happens in low-lying regions. During exposure, the thin resist may get overexposed and the thick regions underexposed. Moreover, resist pileup regions may exhibit/standing wave effects (see below), leading to resolution losses. Reflective notching on buried topographical features could decrease resolution even further (see Figure 1.64). This rough topography creates problems for uniformity of subsequent layers, creating a need to planarize surfaces after each new layer. As seen above, practical DOF should encompass device topography, resist thickness, wafer flatness, focus, and tilt errors for the projected image to remain sharp over the whole wafer. Shallow DOF of high NA-optical-exposure tools, standing waves, and reflective notching can be solved by using very thin resist layers on planar substrates or by planarizing resist layers on nonplanar substrates. Chip makers stack metal lines four layers high, and five- and six-level devices are possible. These "high-rise" chips need rigorous interlevel planarization. The SEM image in Figure 1.65a is a cross-section of a modern IC device showing the various metallization lines (yellow) embedded

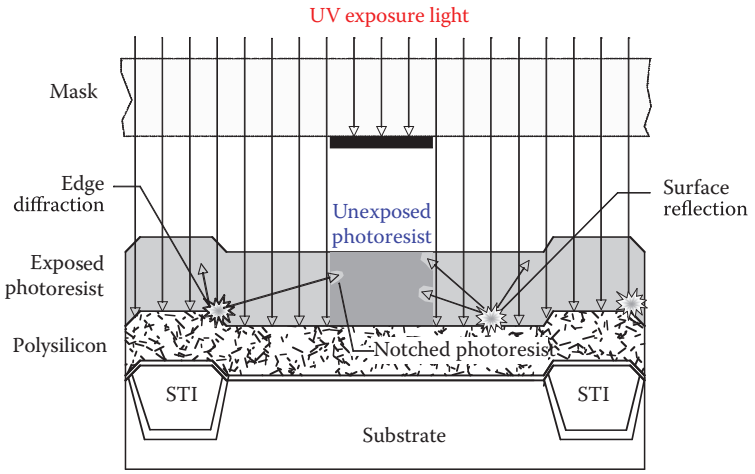

FIGURE 1.64 Reflective notching degrades resist profile. STI, shallow trench isolation.

in passivation material (e.g., silicon nitride). In Figure 1.65b we show an SEM section through 4-MB dynamic random access memory (DRAM) cells. The section was made by using a focused ion beam microscope a technique capable of performing corrective microsurgery on IC chips. The extremely high features often encountered in micromachining pose further challenging planarization problems. Strategies often rely on an interplay of deposition and removal of sacrificial layers (e.g., resist); some of the terminology used in this section will become better understood after reading Chapter 3 on dry etching and Chapter 7 that covers additive processes.

Planarization Strategies

Planarization provides a means of having very flat wafers even after previous patterning steps, and allows for very high-resolution (high R) lithography with limited depth of field (low DOF). Planarization methods provide degrees of smoothing rather

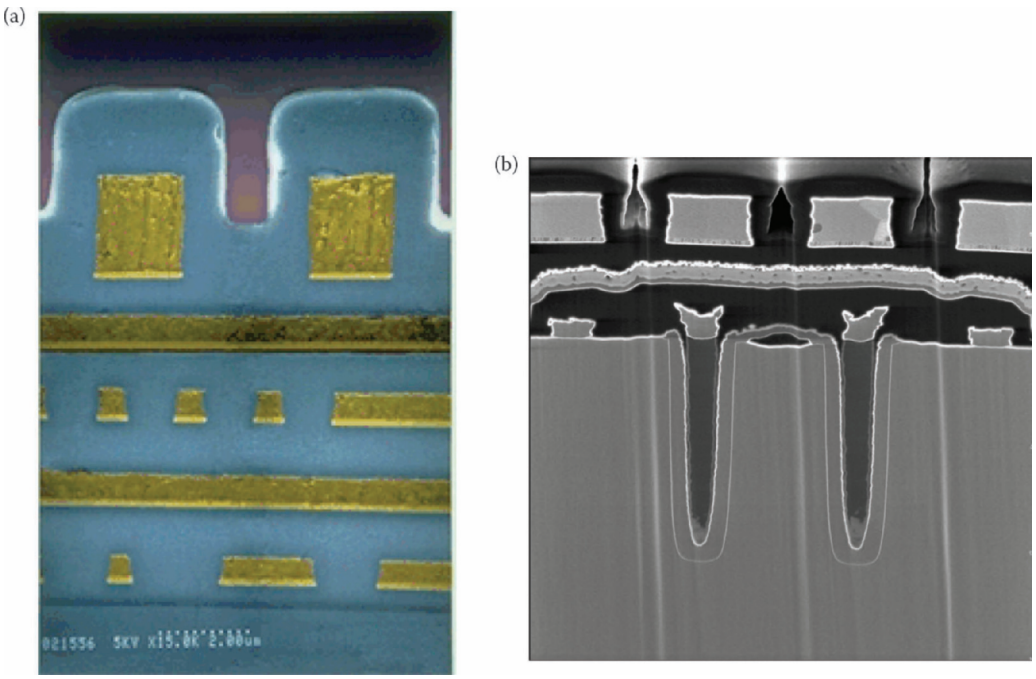

FIGURE 1.65 (a) SEM image of a cross-section of a modern IC device showing the various metallization lines (yellow) embedded in passivation material (silicon nitride, for example. (Courtesy of IBM.) (b) SEM section through 4-MB DRAM cells. The section was made using a focused ion beam microscope. (Courtesy of FIB International.)

than true absolute flatness. In IC fabrication, the chemical-mechanical polishing (CMP) process is used for interlevel dielectric layers (IDL), shallow trench isolation (STI—see Figure 1.64), and copper metallization (the "damascene" process).

A major cause for nonsmooth topography is chemical vapor deposition (CVD) of dielectric layers. CVD methods experience difficulty depositing thin layers conformably. More film tends to build on flat than vertical surfaces, and the pronounced tendency for narrow spaces to be covered (shallow trench isolation) before being completely filled in creates voids. Smoothing in this case should entail two components: filling in gaps and planarizing a film's top surface.

In the planarizing etch-back process, hilly contours left behind by, for example, a CVD oxide deposition technique, are planarized by spin-on glasses (SOGs) or resist sacrificial layers, after which both sacrificial layer and oxide are etched back simultaneously. As its name implies, a SOG dielectric is spun onto a wafer as a liquid and then cured at elevated temperatures. The etch-back process is adjusted, usually by adding oxygen to the etch gases to cause the sacrificial layer and the underlying film, principally oxide or other dielectrics such as PECVD silicon nitride, to etch at equal rates (see Chapter 3). In the etch-back planarization, photoresists are more popular than SOG because they tend to provide a more planar result.[66] SOG often is used in the dielectric sandwich approach for narrow gap filling. Using many thin dielectric layers piled on top of one another until the narrow spaces between metal lines are completely filled averts voids. In this sandwich, layers of CVD oxide alternate with coats of a SOG dielectric. Etching back with photoresist may then planarize the top surface of the film.

There are two types of SOGs: silicates (inorganic) and siloxanes (organic). The film properties of both resemble those of low-temperature CVD glasses. Silicate films tend to absorb water, resulting in a higher relative dielectric constant. In both cases, films tend to crack because of tensile strength as they are densified at 300–500°C. Film stress may be as high as 200 MPa in tension, but annealing lowers tension considerably. Silicate glasses are more prone to cracking, but doping with phosphorus makes them more crack resistant. Even phosphosilicate glasses can only be applied in layers of 1000 Å; thus, often two or three coats are required. It is easier to apply siloxane in a thicker film, for example, greater than 3000 Å. Hitachi Chemical Company America, Ltd. (http://www.hitachi.com) has developed an organosiloxane SOG able to deposit films thicker than 1 mm. As gaps in shallow trench isolation become increasingly narrow, the gap-filling to planarize a surface becomes more difficult. At gap spacings less than 0.3 μm, current SOGs fail to fill the gap completely and are prone to leave a small circular or teardrop-shaped void. Such voids appear with increasing frequency as the gap size decreases and as the gap aspect ratio increases. The effect is most pronounced with re-entrant angles.[67]

Replacing the oxides with a type of dielectric that fills and planarizes much the same as a liquid film may help to eliminate the severe topologies that CVD oxides create. Polyimides fit that dielectric by forming crack-free films that have virtually no pinholes, absorb stress, and generally exhibit a much lower dielectric constant than oxides. Currently, polyimides that will planarize a large pitch geometry to a 90% level with a single coat are available. Reluctance to expand the use of polyimide at this point is linked to its poor barrier properties toward moisture and ions. Also, the prevailing tendency is to trust inorganic CVD oxides more than organic polyimides.[66]

Because the electrical properties of SOGs are poor compared with CVD silicon oxides, an ideal solution would be if the CVD process itself filled the spaces between metal lines and planarized the top surface without breaking the vacuum within a single processing chamber. One example of this type of processing is electron cyclotron resonance CVD (ECRCVD) (see Figure 7.45 illustrating planarization using ECRCVD). ECRCVD uses ECR to generate high-density plasma that can deposit CVD SiO_2 at high rates while temperatures and pressures remain low. As deposition proceeds, the wafer is radio frequency-biased so that argon atoms from the plasma can simultaneously sputter-etch the substrate. The sputtering keeps submicrometer spaces open until they are filled. By carefully balancing the

two processes, one can deposit a film and sputter it back in such a way that high-aspect-ratio spaces are completely filled while the oxide surface planarizes. If planarization needs improvement, ECRCVD can be combined with an etch back.

CMP combines mechanical action with chemical etching; it typifies a planarization technique where a wafer with an uneven surface is polished in an abrasive suspended in an alkaline solution on a polishing pad (see Figure 1.66). Material removal rate is controlled by the slurry flow and pH, applied pressure on the polishing head, rotational speed, and operating temperature. Although slow (with removal rates less than 100 nm/min), CMP results in large surfaces with a roughness less than 1 nm.

The CMP process has been around for a long time but became popular only in the 1990s when it became one of the crucial steps in the manufacturing of IC chips. The reason CMP became crucial is because of its ability to achieve defect-free global planarization of surfaces. The chemicals in the slurry have a "softening" effect on the surface to be polished, thus reducing damage when the abrasives abrade the surface. Oxides, polysilicon, and metal topography can be planarized this way. For oxide or silicon polishing, an alkaline slurry of colloidal silica (SiO_2 particles in a KOH solution or NH_4OH) is continuously fed to the pad/wafer interface. CMP is also popular with micromachinists. For example, Sniegowski[68] is using CMP to enhance the manufacturability of polysilicon surface micromachinery.

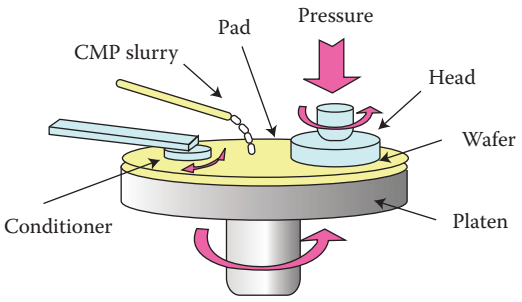

FIGURE 1.66 Schematic of chemomechanical-mechanical polishing (CMP). The CMP process involves pressing the face of the wafer to be polished against a compliant polymeric polishing pad and generating relative motion between the two surfaces. A slurry consisting of abrasives and chemicals is fed in between the interface between the wafer and the pad.

CMP planarization alleviates processing problems associated with the fabrication of multilevel structures, eliminates design constraints linked with nonplanar topography, and provides an avenue for integrating different process technologies. A typical CMP setup looks very similar to a lapping machine, but the precision is much higher.

The damascene process (named after an art form from the Damascus, Syria area) for inlaid metal objects (see Chapter 8, Figures 8.41 and 8.42) used for copper metallization is also dependent on CMP as one of its key steps.

A thin film of Au, Al, or Cu can effectively planarize when melted briefly with a laser. Planarization occurs rapidly because of the high surface tension and low viscosity of clean liquid metals.[69]

Photolithography Resolution Enhancement Technology

Introduction

Since the mid-1980s, the demise of optical lithography has been predicted as being only a few years away, but each time a new resolution limit approaches, some new method extends the useful life of the technology. The three main technologies involved in printing ICs and other miniaturized devices are resist technology, mask technology, and the exposure tool, all of which need to be addressed to optimize lithography resolution.

From the previous section, we learned that optimized production lithography uses projection printing operated close to the conventional Rayleigh diffraction limit with features about the size of the wavelength of the exposure source printed. In this section, we learn about resolution enhancement technology (RET) enabling subdiffraction printing through improvements in resist strategies, mask engineering, and exposure tools. However, the cost of RET is often prohibitive, and in the past, printing with shorter wavelengths has proven more economical.[25] But with CDs of 65 nm, one is forced to rely on RET. Miniaturization science is well suited to contribute to the development of new RET techniques, especially in the area of new mask engineering.

Strategies for Improved Resolution through Improved Resist Performance

Chemically Amplified Resists

Quantum yields for typical positive-tone resists are 0.2–0.3; for negative-tone resists they are 0.5–1 (see Table 1.6). As several photons are required for one useful scission (positive resist) or polymerization (negative) event, this places a fundamental limit on the photosensitivity of these resists. The situation is worse at shorter exposing wavelengths. Typical near-UV positive resists (e.g., DNQ-sensitized novolak resins) are not useful for deep UV lithography because of the strong unbleachable absorption at less than 300 nm (reminder: bleaching is the decrease in optical density during exposure enabling further penetration of the resist as the top layers are being cleared). The short wavelength absorption coefficients of the base resin and the added sensitizers are too high to allow uniform imaging through practical resist thicknesses (0.5–1 μm for ICs).

In the late 1970s, commercially available resists performed poorly at short wavelengths; those with a good plasma etching resistance, frequently based on novolak resins, had excessive unbleachable absorption, whereas those with an acceptable transparency, such as methacrylate-based resists, had insufficient etching resistance. This is of even greater concern in miniaturization science where often much thicker resist layers are used. Short wavelengths do not penetrate thick resist films completely, and very long exposure to dry or wet etchants, needed to create the desired features, degrades the resist. An additional problem, touched on before, is that deep UV optics absorb more light, thus making less light available at the resist plane.

To circumvent the intrinsic sensitivity limitation of low quantum yield resists, chemical amplification was proposed in 1980 and developed at IBM (http://www.ibm.com) in the early 1980s.[37,70–72] In this approach, a single photon initiates a cascade of chemical reactions of the sort that characterizes a silver halide photographic emulsion system. This amplification or gain is based on the photogeneration of a catalytic photoproduct, often an acidic species that catalyzes the scission of the base resin for a positive-tone resist or the cross-linking of the resin for a negative-tone resist. The overall quantum efficiency of the catalyzed reaction is higher than the efficiency for the initial acid generation.[73] Within a resist, which has been sensitized with an onium salt such as diphenyliodonium hexafluoroarsenate, a Lewis acid is released on photolysis. Compared with conventional free-radical initiators, the onium salts have excellent thermal stability and are not sensitive to oxygen.[29] In the case of a positive resist, the released acid, on baking at 100°C, may catalyze the cleavage or scission of the resist, making it more soluble. This type of imaging involves the usual formation of a latent image during exposure. However, the latent image, a 3D distribution of the catalytic photoproduct, does not immediately generate a concomitant change in dissolution rate, as do regular resists. Image formation only takes place after an activating thermal step—to diffuse the photogenerated acid (PGA) and complete the reaction—in a postexposure bake (PEB) at 100°C. A typical turnover rate for one acid catalyst molecule is in the range of 800–1200 cleavages. Resists amplified this way may attain a photosensitivity of 5 mJ/cm^2 or better. Tenfold sensitivity increases are common. Both the acid-catalyzed scission and cross-linking reactions are highly dependent on the PEB temperature, time, and method. The control of these parameters represents a significant difference with conventional resists. In Figure 1.67, a schematic representation of a generalized chemically amplified resist process is shown, as well as typical chemicals. Depending on the developer being polar or nonpolar, a positive or a negative image can be generated. Their dual-tone nature makes these resist systems more flexible. Chemical amplification resists are continually improving and today constitute an important foundation for the design of advanced resist systems for use in short-wavelength (<300 nm) lithographic IC technologies and miniaturization science applications. It was the advent of chemical amplification that made 248-nm lithography finally possible.

The pioneering chemical amplification work involved a catalytic deprotection scheme based on poly(tert-butoxycarbonyloxystyrene) and a triphenylsulfonium hexafluoroantimonate onium salt (Figure 1.68), in which a thermally stable, acid-labile

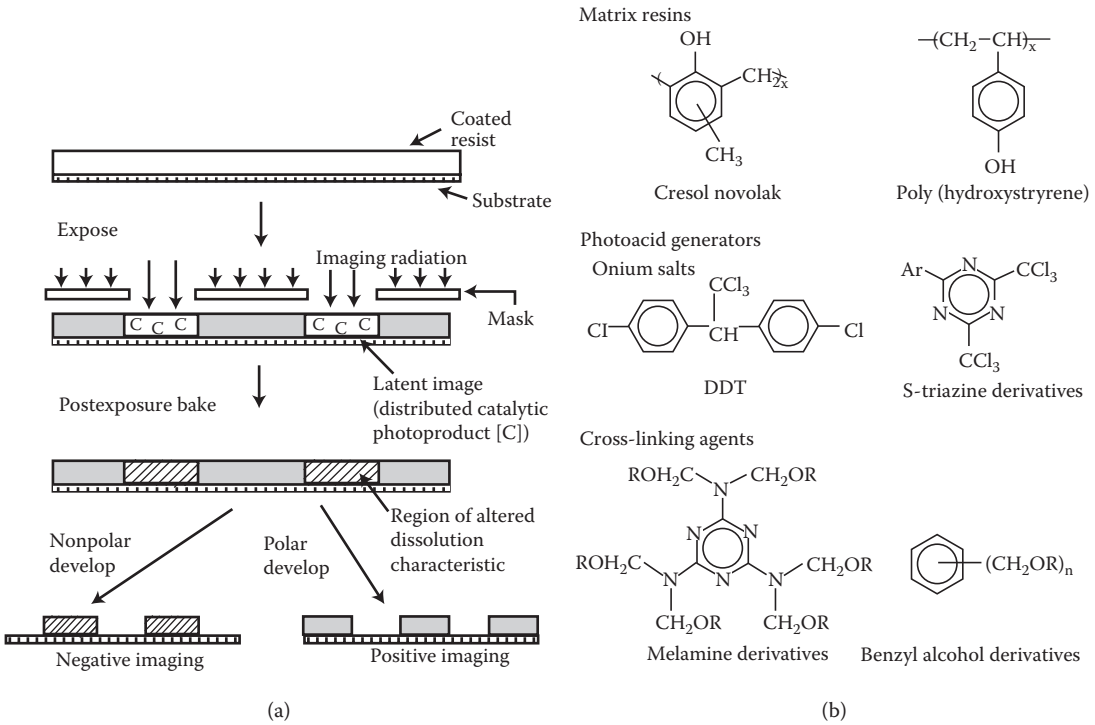

FIGURE 1.67 (a) Schematic representation of a generalized chemically amplified resist process. Depending on the developer being polar or nonpolar a positive or negative image can be created. tert-butoxycarbonyl group (tBOC) is used to mask the hydroxyl functionality of poly(vinylphenol).[24]

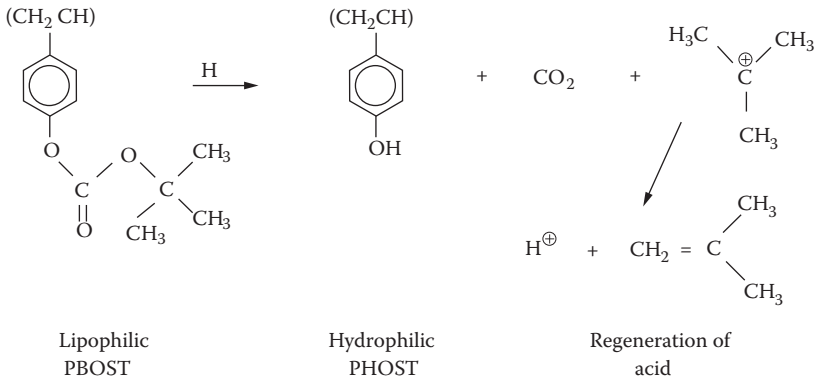
In this amplification scheme, development is based on polarity changes rather than molecular weight changes through scission and polymerization. On exposure to deep UV and subsequent baking to diffuse the photogenerated acid (PGA) and complete the reaction, the acid cleaves the labile tBOC protecting group to form a polar polyvinyl phenolic polymer. Deprotection (cleavage) of pendant groups



Acid-catalyzed deprotection for polarity change (tBOC resist); cleavage of a pendant group to convert a lipophilic polymer (PBOCST) to a hydrophilic polymer (PHOST)

FIGURE 1.68 Chemical amplification with a catalytic deprotection scheme based on poly(tert-butoxycarbonyloxystyrene) (PBOCST) and a triphenylsulfonium hexafluoroantimonate onium salt, in which a thermally stable, acid-labile tert-butoxycarbonyl group (tBOC) is used to mask the hydroxyl functionality of poly(vinylphenol). (Reichmanis, E., O. Nalamasu, F.M. Houlihan, and A.E. Novembre. 1999. Radiation chemistry of polymeric materials. *Polym Int* 48:1053–59.[24])

in tBOC induces a polarity change and allows for dual-tone (positive/negative) imaging. By using a nonpolar solvent, the unexposed resist is removed and a negative image formed. A polar solvent is used to remove the exposed area, resulting in a positive image. By the mid-1980s, tBOC was used in the production of millions of 1-MB DRAM devices at IBM.[37]

We encountered dual-tone resists earlier when reviewing the novolak/DNQ system by Rohm and Haas (see Figure 1.8).

The chemical amplification resist family today has become prolific and can be grouped into categories according to imaging mechanisms: deprotection (see tBOC), depolymerization, rearrangement, intramolecular dehydration, condensation, and cationic polymerization (SU-8). Cationically polymerizing monomers such as epoxies and vinyl compounds and condensation reactions between phenol formaldehyde resins and amino-based crosslinkers increase the molecular weight after exposure. Changes in polarity are achieved through the acid-catalyzed deprotection of a variety of esters.

Although chemically amplified resists provide reasonable throughput for e-beam and deep UV lithographies (short wavelengths), they often suffer from poor environmental stability and too high a sensitivity to processing conditions. Environmental effects (oxygen) cause surface inhibition by neutralization of photogenerated acid in the top resist layer. A resist topcoat can be used to minimize this effect. Unfortunately, such a multilayer resist further complicates the photoresist process.

Antireflection Coatings: Thin Film Interference Effects

When using single-layer resists, the deleterious effects of thin film interference effects need to be overcome for good CD control, especially of submicrometer features. The most important thin film interference effects are schematically illustrated in Figure 1.66. The effects manifest themselves as nonvertical resist profiles, line-width variations, reflective notching, scumming (underexposed resist leaving organics behind after development), and alignment inaccuracies. Solutions to thin film interference effects involve the use of antireflective coatings and the use of MLRs (see below). Antireflective coatings overcome interference effects caused by reflections from either the top or bottom of the resist (Figure 1.69a and b). Example antireflective coatings are the ARC coatings (trademark from Brewer; http://www.brewerscience.com), liquid resins that are cast into a film before coating the photosensitive resist layer. A key design element is for the cast film to absorb light very efficiently at specific wavelengths. In designing the light-absorbing properties of ARC coats, two strategies were pursued. One is the mixing of dyes with a polymer resin. The second is to design the polymer with molecular chains that intrinsically absorb light.

When a resist is exposed to monochromatic radiation, standing waves are formed in the resist as a consequence of coherent interference from reflecting substrates creating a periodic intensity distribution in the direction perpendicular to the surface (see Figures 1.69c and 1.70). The standing wave effect leads to light intensity variations, perpendicular to the resist film, of as much as a factor of three from one position to another. The standing wave effect is a strong function of resist thickness, and exposure variations resulting from variation in resist thickness in the vicinity of steps result in changes in

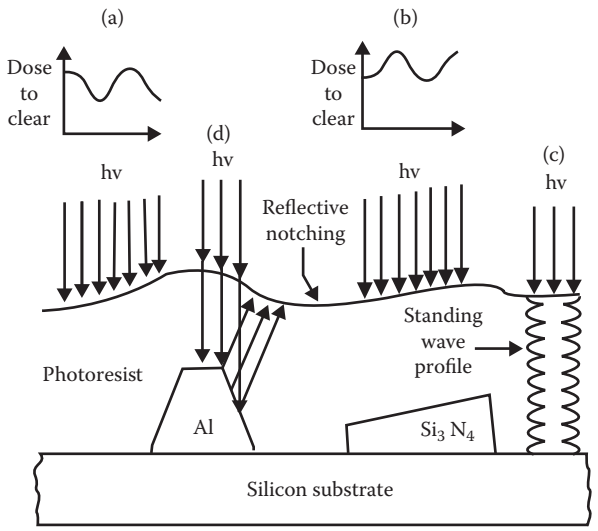


FIGURE 1.69 Thin film interference effects. Light reflected from resist/Si (a) or Si_3N_4/Si (b) interfaces through various resist or nitride thicknesses changes the dose necessary to clear the resist. Also, standing-wave profile (c) and reflective notching effects (d) are shown. (From Horn, M.W. 1991. Antireflection layers and planarization for microlithography. *Solid State Technol* 31:57–62. With permission.[76])

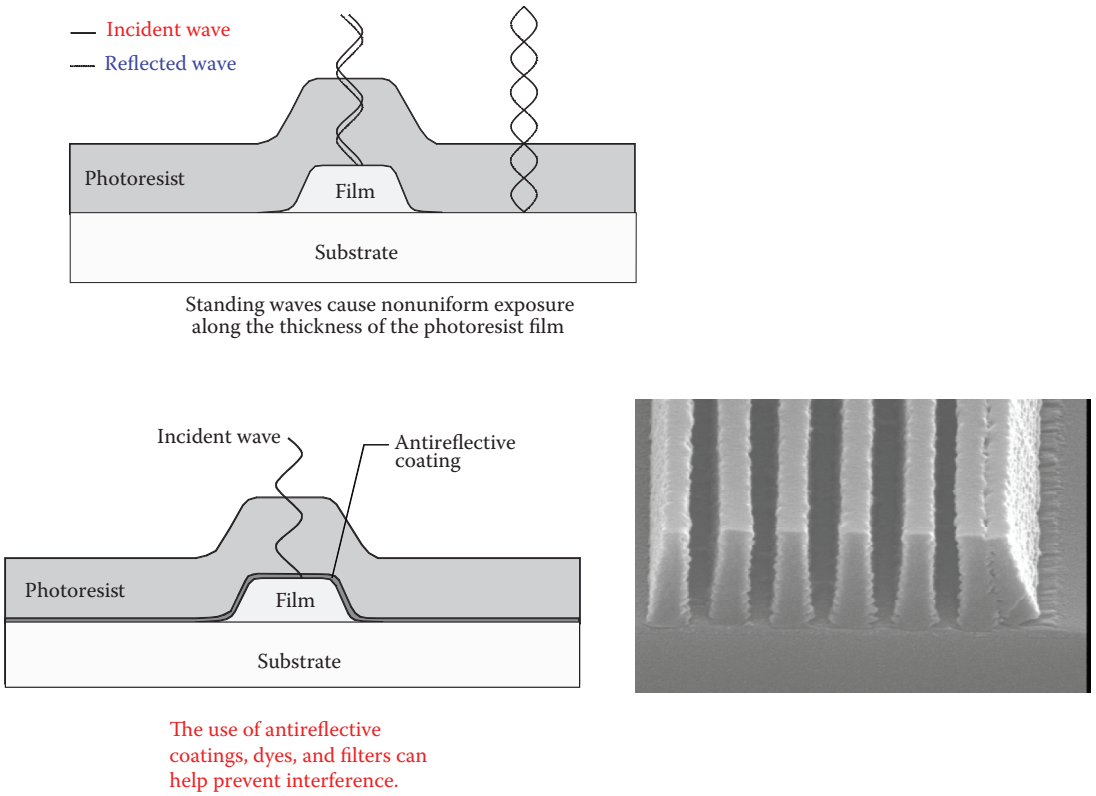

FIGURE 1.70 Standing waves and antireflective coatings.

line width. Because standing waves are the result of coherent interference of monochromatic light, using broadband illumination can decrease the effect. To minimize standing wave effects, one also can use thinner resists (<0.3 μm), but these cause a degradation in line-width control over varying topography. Reflective notching (Figures 1.69d and 1.70) comes about when light is reflected from the more reflective topological features buried in the resist.

Thin Film Imaging

Introduction Variations in resist thickness over steps lead to line-width control problems (see Figure 1.71). This lack of line-width control and the limitations of low source intensity and shallow DOF are overcome in thin film imaging (TFI). In TFI, the projected image is confined to a thin layer near the surface of the resist. Because the thin exposed layer is optically isolated from the substrate, the previously mentioned deleterious effects such as standing waves and scattering from underlying topography are avoided. There is often a need for a thick planarizing resist underneath because of topography and because a very thin film by itself usually does not have the required etch resistance. As a consequence, TFI usually involves a surface modified thick resist in the case of top surface imaging (TSI) or a multilevel resist stack (bilayer, trilayer, or multilayer). After the image has been transferred onto the thin top surface layer, it is transferred to the underlying resist layer(s). Pattern transfer often involves dry etching in oxygen plasma, that is, "dry development." We will discuss single-layer resist TSI first, and then discuss multilayer resist methods.

Thin Film Imaging in Single-Layer Resist—Top Surface Imaging Top surface imaging (TSI) is one approach to thin film imaging (TFI). In TSI, only the top surface of an SLR is modified under light exposure. A single layer of a thick, opaque resist is used, and exposure leads to differential diffusion/reaction rates of a silicon-containing compound into either exposed or unexposed areas (depending on the resist tone). It was Taylor et al.[77] who discovered that small amounts of Si (about 10%) drastically lower the etching rates of organic polymers. Areas containing Si convert to SiO_x in oxygen plasma and thus become plasma resistant.

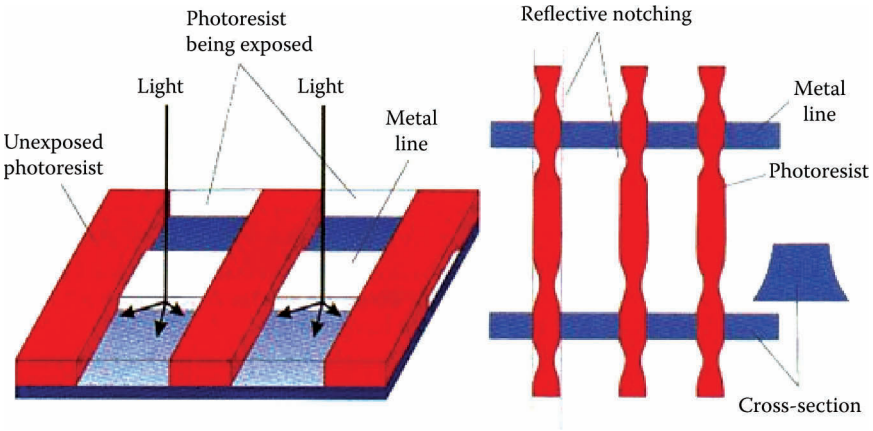

FIGURE 1.71 The dimensional variation of resist lines going over steps is a well-known phenomenon: reflection of light by the nonvertical sidewalls of the step causes increased incoupling of light into the resist adjacent to the step, leading to a reduction in line width. Similar effects may be observed on reflective materials with a particularly coarse-grained structure.

The DESIRE (dry etching of silylated image resist) process by UCB (Belgium, http://www.ucb.be), illustrated in Figure 1.72, exemplifies a single-layer resist TSI scheme. In this case, a short exposure of a thick layer of planarizing positive DQN-novolak resist produces latent images of indenecarboxylic acid. In a postexposure bake, in a vacuum, the layer is converted into a film enabling selective silylating. In the silylating process, Si atoms only diffuse/react on/into the surface of the exposed resist, locally forming a thin Si-containing resist layer. The polymer film is typically exposed and silylated to a depth of at least 1000 Å to provide sufficient differential plasma etch resistance for pattern transfer. An oxygen plasma etch subsequently removes the unexposed, unreacted resist, and the silylated mask remains because of the formation of a protecting silicon oxide layer; a negative-tone image of the mask results. The DESIRE process in Figure 1.72 illustrates not only dry resist development but also image reversal.

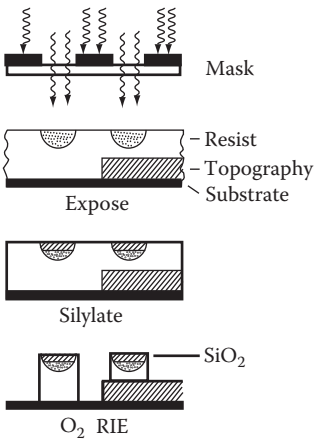

FIGURE 1.72 The DESIRE (dry etching of silylated image resist) process developed by UCB Chemical Company. Exposure and silylation are confined to the upper layers of the resist coating.

A major advantage of TFI techniques is that only the surface of the resist requires exposure, which, coupled with the anisotropic nature of plasma etching, allows for the use of thick resist layers that planarize the underlying topography to a higher degree than resists with more typical thicknesses could. The lithography process also remains unaffected by substrate reflection, and resist thickness variation as light does not have to penetrate the thickness of the resist. Image quality with DESIRE is excellent. An advantage of TSI over bilayer or multilayer TFI techniques is that only one single layer is spun on before silylation. DESIRE made it from research and development into manufacturing in the late 1980s at TI (http://www.ti.com).[78] It was used for the top metal level patterning in DRAM manufacture. This level had the most reflectivity and most topography. The resist that TI applied, using a standard coater, was the Plasmask® 200-g from Japan Synthetic Rubber (JSR, http://necsv01.keidanren.or.jp/A2J/data/06025.html). Two additional machines, a silylation tool and a dry develop etcher, were developed for the TSI process. Both liquid and vapor silylation are feasible and have been compared at IBM.[78] The use of a dry etch in development leads occasionally to

so-called *grass residue* in open areas (see Chapter 3, Figure 3.23). The grass is assumed to stem from sputtered silicon from silylated areas. With higher plasma density systems, less grass forms. This can be explained by the lower energy of the ions attacking the resist surface.

Pure poly(hydroxystyrene) (PHOST) (sensitivity 22 mJ/cm^2) has been studied extensively as a model TSI resist for use with 193-nm optical projection lithography.[79]

Multilayer Resist Thin Film Imaging In the bilayer TFI approach shown in Figure 1.73, the resist stack consists of a thick, planarizing bottom layer and a thin, top imaging overlayer. These layers function synergistically to achieve higher resolution otherwise impossible to obtain with thick, planarizing single-layer resists. After exposure and development of the thin imaging overlayer, the pattern is transferred to the planarizing underlayer. An intermediate isolation layer sometimes separates the planarizing and imaging layers, preventing their mixing. Depending on the exposure dose and development condition (wet etching) of the planarizing resist layer, an undercut or overcut may be generated. Alternatively, if good fidelity of the mask pattern is desired, dry directional etching (RIE) may be used (see Figure 1.73).

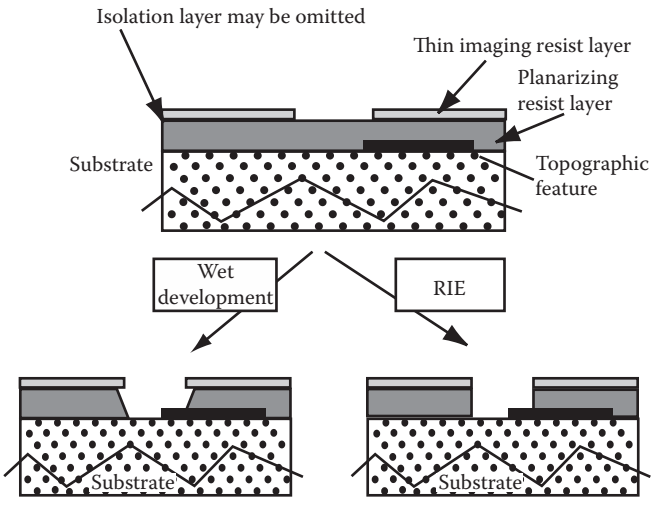

FIGURE 1.73 Multilayer resist scheme. Thick planarizing underlayer for planarizing of wafer topography, optional intermediate isolation layer, and thin imaging overlayer for optimum resolution. Wet etching (development) and dry etching (RIE) produce different resist profiles.

In a trilayer system, a thin imaging layer is spun onto a thin oxygen dry etch-resistant hard mask coated on top of a thick planarizing layer. The hard mask may be a plasma-deposited or spin-on silicon oxide.

With the advent of 193-nm lithography, TFI will become increasingly popular as radiation is readily absorbed by most photoresists at this short wavelength. Once extreme UV is used as the exposure radiation of choice (see below), widespread use of TFI might be unavoidable.[78]

Strategies for Improved Resolution through Improved Mask Technology

Background

Besides improved resists, mask engineering also provides important contributions to RET. Interestingly, Richard Feynman in the second of his now famous lectures on micromachining imagined a micromachined mask with miniature levers and valves that could be used over and over to generate different patterns.[80] The mask techniques described above are timid attempts to use micromachining technology for mask engineering. In one scenario, by controlling the phase and the amplitude of the light at the image plane in a phase-shifting mask, resolution and depth of focus are greatly improved.

In miniaturization science, where we often print high-aspect-ratio features, masks with an expanded DOF are favored—but masks with increased resolution remain of greater importance in IC manufacture.

Phase-Shifting Masks

One method that allows further improvement of photolithography resolution and DOF at a given wavelength (λ) and NA is to carefully control light diffraction using constructive and destructive interference to help create a circuit pattern. The idea of selectively altering the phase of the light passing through certain areas of a photomask to take advantage of destructive interference to improve resolution and DOF in optical lithography was first proposed in 1982.[81] The method is based on building PSMs. Using such a mask one can control both the amplitude and the phase of the light

and, in particular, arrange the mask so that light with the opposite phase emerges from adjoining mask features. Destructive interference can be used to cancel some of the image-spreading effects of diffraction.

In Figure 1.74, we illustrate the effect for three nearby mask apertures; a classical transmission mask is added for comparison.[82] The amplitude profile at the plane of the classical transmission mask consists of three square-cornered features with positive amplitude. The amplitude at the wafer level is broadened and rounded but does not change sign. With a PSM, a shifter layer results in a reversal of the phase of the light at the mask. As the photoresist only shows sensitivity toward the intensity of the light and not to the sign, the three bright features develop identically, and the areas where the light of opposite phases causes destructive interference form very dark contrast lines.

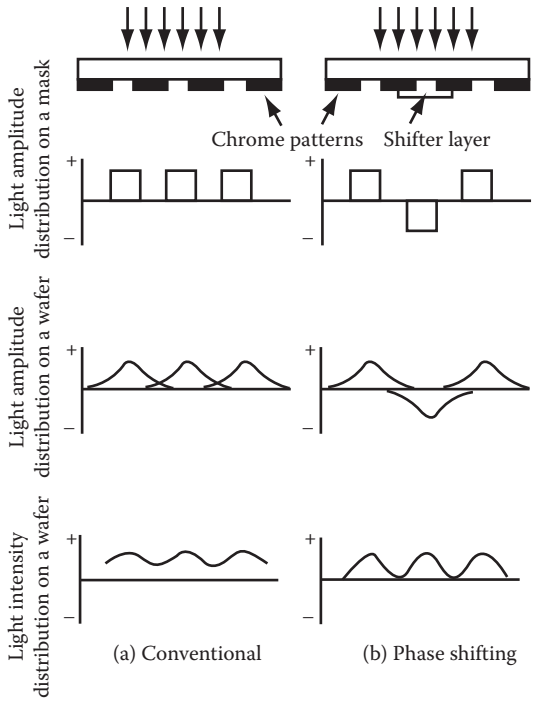

FIGURE 1.74 Comparison of a conventional transmission mask (a) and a "Levenson-type" phase-shifting mask (b). Both contain opaque chrome (Cr) regions, but the light passing through some of the apertures of the phase-shifting mask also passes through the transparent material of the phase shifter. This reverses the phase of the light at the mask, giving rise to destructive interference at the photoresist plane. (From Levenson, M.D. 1992. Phase-shifting mask strategies: isolated dark lines. *Microlithogr World* 6:6–12. With permission.[82])

One type of PSM is an alternating aperture PSM (AAPSM), also called a *hard* shifter. Going beyond the traditional chrome-on-quartz approach, AAPSMs accomplish the task of shifting the phase of the light by etching regions of the quartz substrate to the precise depth (which depends on the wavelength of the light to be used to expose the wafer) where shifting is desired and have become known as Levenson-type PSMs. The etched areas cause the light to become 180° out of phase with the light passing through the unetched regions (Figure 1.75).

An important alternative PSM is the embedded attenuated PSM (EAPSM). EAPSMs, or *soft* shifter masks, are similar to ordinary (binary) masks in that a quartz substrate is coated with a material in which the design is etched. The most common material used today is molybdenum silicide. Unlike chrome, molybdenum silicide allows a small percentage of the light to pass through; however, the amount passing through is "soft" and does not expose the resist on the wafer. Where it does pass through, the light is 180° out of phase compared with light passing through the quartz alone. Where the coating and quartz meet, light interferes in such a way as to sharpen the edges of the design. The most difficult task in the case of EAPSMs is to create a thin film structure with the desired transmission (4–8%) and phase (180°) at a specific wavelength (i-line or deep UV) that can be patterned, inspected, and repaired using currently available tools.[83] It has been

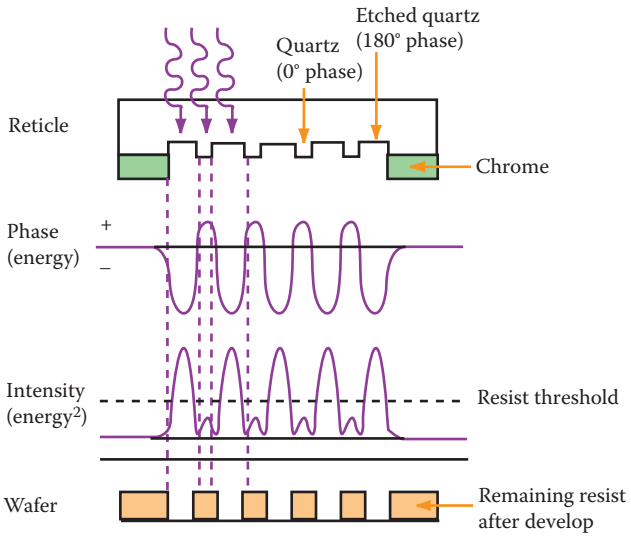

FIGURE 1.75 A hard shifter alternating aperture PSM or AAPSM.

estimated that a PSM mask for 100-nm work could cost up to $50,000. This makes RET often synonymous for Really Expensive Technology!

How narrow a feature can one make using PSMs? Oki Electric Industries (http://www.oki.de) sells a metal semiconductor field effect transistor (MESFET) device with a 0.18-µm gate patterned by i-line lithography, ordinarily considered capable of only 0.5 µm resolution![82] Thus, PSMs can easily improve resolution by 50–100%. Using 248-nm deep UV lithography researchers at MIT's Lincoln Laboratory have reported sub-100-nm features using phase-shifting masks. Because the same method is applicable to 193-nm radiation, the approach appears promising for further extending photolithography.[84]

The use of TSI and PSM techniques can reduce k_1 in Equation 1.16 to 0.4, well below the 0.61 expected from Rayleigh's criterion.

Optical Proximity Correction

Optical proximity correction (OPC) printing was first developed in the early 1970s as a means of addressing lithography distortions in IC manufacturing. The goal is to produce smaller features in an IC using current lithography equipment by enhancing the "printability" of a given wafer pattern. OPC applies systematic changes to photomask geometries to compensate for nonlinear image distortions. These distortions include line-width variations (nonuniform CDs), line-end shortening, and rounding of sharp corners. Sharp features, in general, are lost because higher spatial frequencies are lost as a result of diffraction. Causes of these distortions include reticle pattern fidelity, optical proximity effects, and diffusion and loading effects during resist and etch processing. Thus, a mask incorporating OPC is a system that negates undesirable distortion effects during pattern transfer. In OPC, the traditional (WYSIWYG—what you see is what you get) relationship between layout, mask, and silicon is no longer valid. OPC works by making small changes to the IC layout that anticipate these distortions. To compensate for line-end shortening, for example, the line is extended using a hammerhead shape that results in a line in the resist that is much closer to the original intended layout. To compensate for corner rounding, serif shapes are added to (or subtracted from) corners to produce corners on the silicon that are closer to the ideal layout (see Figure 1.76). Determining the optimal type, size, and symmetry (or lack thereof) is very complex and depends on neighboring geometries and process parameters. A sophisticated computer program is necessary to properly implement OPC. OPC improves the resolution by decreasing k_1.

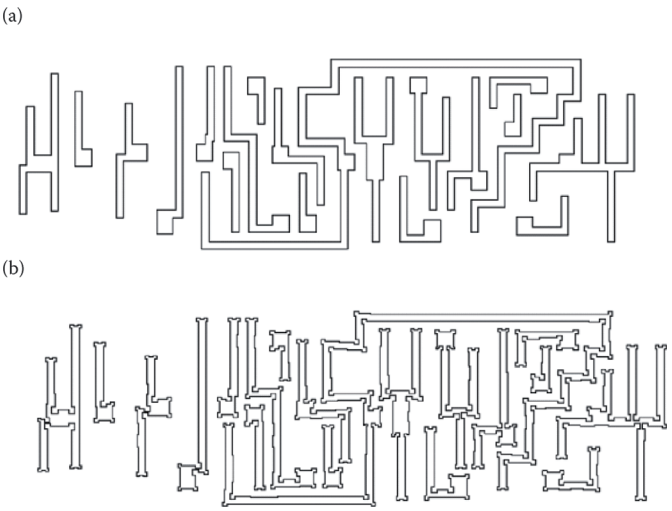

FIGURE 1.76 Optical proximity correction (OPC). (a) Mask of a standard cell before OPC. (b) Mask after OPC.

Strategies for Improved Resolution through Improved Exposure Technology

Background

Under "Improved Exposure Equipment," we describe progress in decreasing k_1 and NA in Equation 1.16 to further enhance resolution R by modifying the exposure equipment. Off-axis illumination (OAI) is one of the three major resolution enhancement technologies that have enabled optical lithography to push practical resolution limits far beyond what was once thought possible (the others being phase-shifting masks and optical proximity corrections; see above). We will briefly review OAI and Köhler illumination and finish this chapter by introducing immersion lithography.

Off-Axis Illumination and Köhler Illumination

With OAI, diffraction information is distributed selectively over the lens pupil, influencing the impact

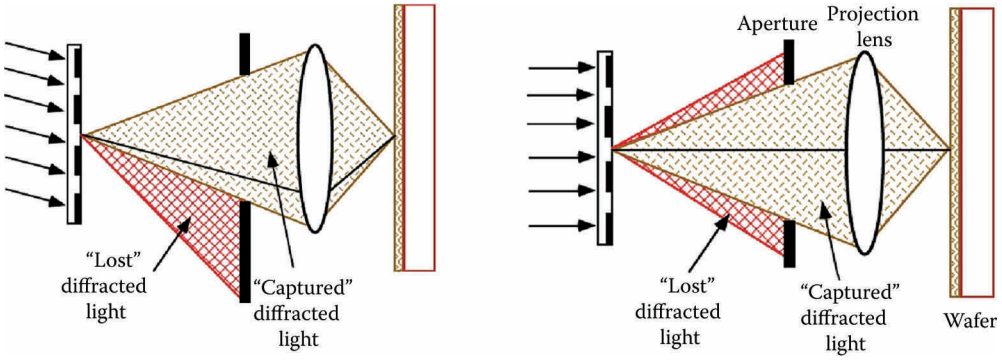

FIGURE 1.77 Off-axis-illumination (OAI).

of aberrations on imaging. Off-axis illumination allows some of the higher order diffracted light to be captured and hence can improve resolution (by decreasing k_1). OAI refers to any illumination shape that significantly reduces or eliminates the "on-axis" component of the illumination, that is, the light striking the mask at near-normal incidence. By tilting the illumination away from normal incidence, the diffraction pattern of the mask is shifted within the objective lens. This enables higher diffracted orders to be included in the lens aperture, which increases the resolution (see Figure 1.77). The increased focal depth for OAI can be understood in terms of the path difference, which is now shorter for all the waves arriving at the resist surface. OAI can improve imaging resolution by 20% and DOF by 40%.

Köhler illumination, named after August Köhler, the man who invented it in 1983, is also known as double diaphragm illumination because it uses both a field and an aperture iris diaphragm to set up the illumination in microscopy. If the light path is set up properly, one has the advantages of an evenly illuminated field, essential to avoid shadows, glare, and incorrect contrast. Köhler illumination in lithography achieves the same goals by using a collector lens in front of the light source (see Figure 1.78). This "captures" diffracted light equally well from all positions on the mask. This improves the resolution by bringing k_1 down.

Immersion Lithography

From the discussion up until this point, the resolution limit for 193-nm exposure systems may be calculated using the Rayleigh equation with $\lambda = 193$ nm, NA = 0.93, and $k_1 = 0.25$ (see Equation 1.16) as:

$$R = 0.25 \times 193/0.93 = 52 \text{ nm} \qquad (1.30)$$

From this calculation, a highly optimized ArF exposure system has an absolute optimal

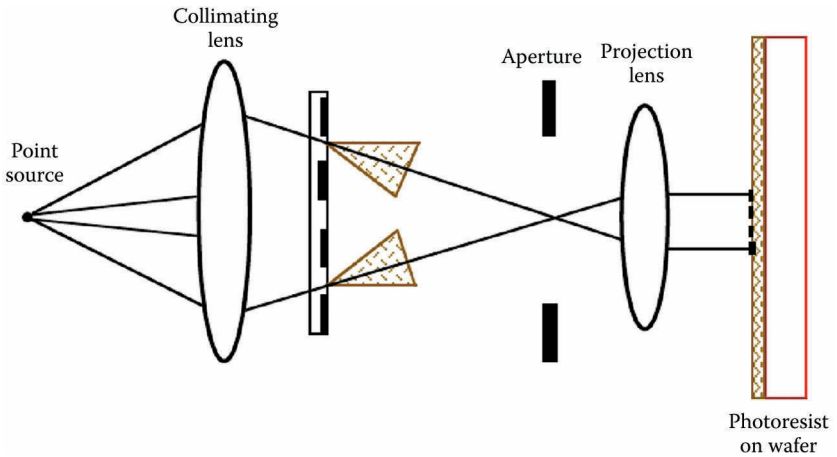

FIGURE 1.78 Köhler illumination in lithography.

resolution of 52 nm, sufficient for the 65-nm line widths introduced in 2005 but not capable of meeting the 45-nm line widths forecast in 2007. The technical challenges with 157-nm and shorter wavelength exposure systems make any technique that can improve the resolution of the 193-nm exposure systems and delay the need to move to shorter wavelengths an important development.

The NA is determined by the acceptance angle of the lens and the index of refraction of the medium surrounding the lens: NA = nsinθ (Volume I, Equation 5.3), where n is the index of refraction and θ is the acceptance angle of the lens. Because the sine of any angle is always <1 and n = 1 for air, the physical limit for an air-based system is clear, but what if a medium with a higher index of refraction is substituted for air? Microscopy has for years used oil as the medium surrounding the lens and the sample for resolution enhancement, and it is somewhat surprising that the semiconductor industry has taken this long to seriously consider the merits of replacing air with an alternative.

The medium between the lens and the wafer being exposed needs to have an index of refraction >1, have low optical absorption at 193 nm, be compatible with photoresist and the lens material, and be uniform and noncontaminating. Surprisingly, ultrapure water may meet all these requirements. Water has an index of refraction n = 1.47, absorption of <5% at working distances of up to 6 mm, is compatible with photoresist and lens, and in its ultrapure form is noncontaminating. Plugging n = 1.47 into Equation 5.3 (Volume I) and assuming sinθ can reach 0.93, then the resolution limits for 193-nm immersion lithography are:

$$R = 0.25 \times 193/1.470.93 = 35 \text{ nm} \qquad (1.31)$$

A 35-nm theoretical resolution carries 193-nm exposure beyond 2007. Similar techniques applied to 157-nm exposure could carry optical lithography even further, although it should be noted that water is not a usable medium at 157 nm and suitable mediums are still being researched (a high index fluid such as polyfluoropolyether is a candidate medium in this case). The resolution enhancement from immersion lithography is about 30–40% (depending on materials used), or about one technology node. The depth of focus is also 40–70% better (proportional to the refractive index of the imaging medium considered) than a corresponding "dry" tool at the same resolution.[85]

In Figure 1.79 we illustrate a schematic of an immersion lithography setup. It is estimated that such a setup may cost $30 million.

There are a large number of practical issues yet to resolve to implement immersion lithography. The stage on a 193-nm exposure tool steps from location to location across the wafer scanning the reticle image for each field. To achieve high throughput, the stage must accelerate rapidly, move accurately to the next field location, settle, scan the image, and then step to the next location all in a short period. Maintaining a consistent bubble-free liquid between the lens and the wafer is very difficult. One other issue that is likely to be significant for immersion lithography is temperature control. Variations in temperature cause variations in n and therefore image distortion. Maintaining temperature uniformity with a rapidly moving stage and a pulsed laser passing through the fluid will likely be a significant challenge. A more complete listing of issues includes:

- Very big lenses (hence expensive)
- Field size reduction
- Mechanical issues and hydrodynamics
- Stage vibrations transferred to lens
- Heating of immersion liquid on exposure
- New defect mechanisms at wafer level
- Interaction of photoresist with immersion liquid
- Fluid contamination
- Polarization effects degrading contrast

Summary Projection Lithography

As minimum line widths have shrunk, the exposing wavelength has also periodically shrunk. Table 1.10 lists the year, minimum line-width generation, and exposure wavelength for state-of-the-art ICs since the mid-1980s. At 1.2-μm and larger line widths, the g-line output of mercury lamps (λ = 436 nm) was used; at the 0.8-μm (800 nm) generation, the

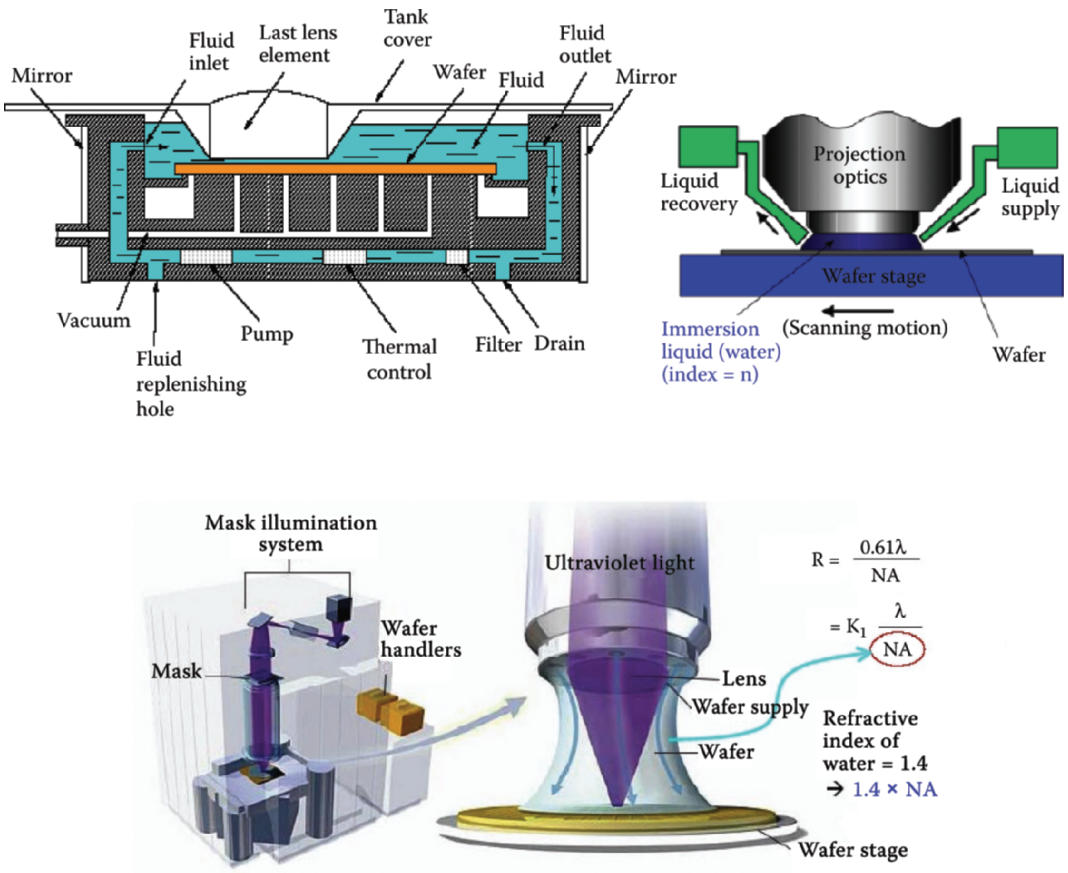

FIGURE 1.79 Schematics of an immersion lithography setup.

i-line output of mercury lamps (λ = 365 nm) was introduced for critical layers, and i-line use continued to the 350-nm line width, where early adopters began to use KrF excimer lasers (λ = 248 nm) as the exposure source. KrF use has surprised many observers by persisting through the 130-nm linewidth generation. With 90-nm line widths now entering production, KrF is finally running out of stream, and ArF excimer lasers are being introduced (λ = 193 nm). Beyond ArF, there are fluorine excimer lasers (F_2) with λ = 157 nm, but there are a number of technical challenges to overcome. At less than the 157-nm wavelength, the optical exposure systems must change to all reflecting optics because of high levels of absorption in refractive lens at shorter wavelengths. The introduction of an all-reflective lens exposure system introduces a number of technical challenges.

TABLE 1.10 Minimum Line Width and Exposure Wavelength versus Year

Year	Line Width (nm)	Wavelength (nm)
1986	1200	436
1988	800	436/365
1991	500	365
1994	350	365/248
1997	250	248
1999	180	248
2001	130	248
2003	90	248/193
2005 (fcst)	65	193
2007 (fcst)	45	193

At the same time that exposure wavelengths have been reduced, improvements in lens design have led to improvements in the NA of the exposure systems lens, as shown in Figure 1.80. In the mid-1980s an NA value of approximately 0.4 was typical; today 248-nm exposure systems are available with an NA greater than 0.8. The physical limit to NA for exposure systems using air as a medium between the lens and the wafer is 1; the practical limit is somewhere around 0.9, with recent reports suggesting that an NA as high as 0.93 may be possible for ArF systems in the future.

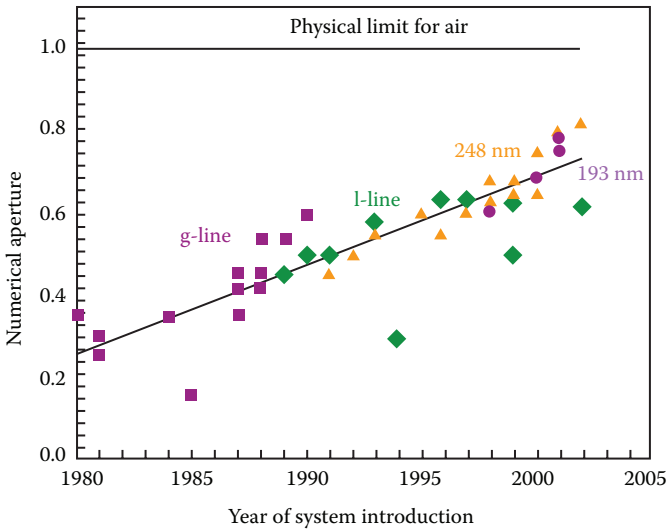

FIGURE 1.80 The evolution of the numerical aperture in lithography systems as a function of time.

The third element in the Rayleigh equation is k_1, a complex factor of several variables in the photolithography process such as the quality of the photoresist and the use of resolution enhancement techniques such as phase shift masks, OAI, and OPC. While exposure wavelengths have been decreasing and NA has been increasing, k_1 has been decreasing as well (see Figure 1.81). The practical lower limit for k_1 is thought to be about 0.25. In Figure 1.81, we plot the evolution of k_1 during the past 18 years.

From this chapter it is clear that photolithography remains the only viable IC, MEMS, and NEMS production technology. As we realize now it is very urgent that we look beyond photolithography for the next generations of ICs and NEMS. This is the problem we tackle in Chapter 2 on NGLs and lithography research.

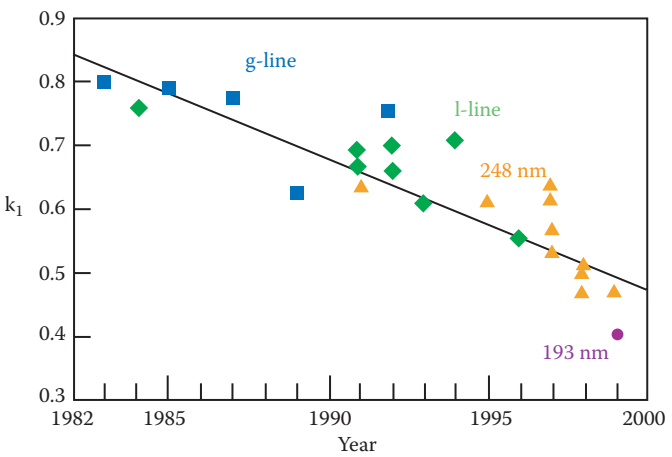

FIGURE 1.81 The evolution of k_1 versus time.

Appendix 1A: Spin Coating Process Troubleshooting

Film Too Thin

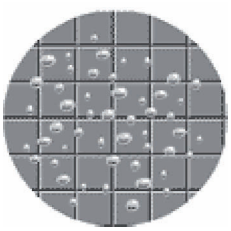
Spin speed too high: select lower speed. Spin time too long: decrease time during high-speed step. Inappropriate choice of resin.

Film Too Thick

Spin speed too low: select higher speed. Spin time too short: increase time during high-speed step. Exhaust volume too high: adjust exhaust. Inappropriate choice of resin.

Air Bubbles on Wafer Surface

Air bubbles in dispensed fluid. Dispense tip is cut unevenly or has burrs or other defects.

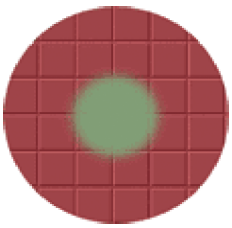


Swirl Patter

Spin bowl exhaust rate is too high. Fluid strikes substrate surface off center. Spin speed and acceleration setting is too high. Spin time is too short.

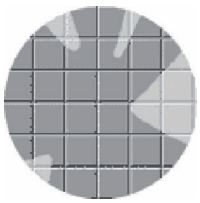
Center Circle

If the circle is the same size as the spin chuck: proper chuck selection should be based on substrate size and rigidity. The proper chuck diameter is 1/4–1-in. smaller than the substrate diameter.



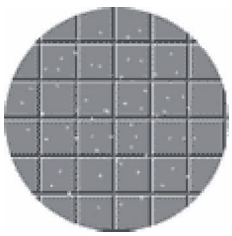
Uncoated Areas

Insufficient dispense volume.



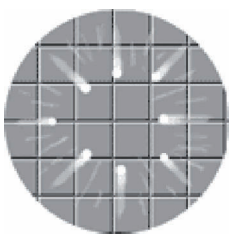
Pinholes

Air bubbles. Particles in fluid. Particles exist on substrate surface before dispense.



Comets, Streaks, or Flares

Fluid velocity (dispense rate) is too high. Spin bowl exhaust rate is too high. Resist sits on wafer too long before spin. Spin speed and acceleration setting are too high. Particles exist on substrate surface before dispense. Fluid is not dispensed at the center of the substrate surface.



Poor Reproducibility

Variable exhaust or ambient conditions: adjust exhaust lid to fully closed. Substrate not centered properly: center substrate before operation. Insufficient dispense volume: increase dispense volume. Inappropriate resin material. Unstable balance in speed/time parameters: increase speed/decrease time or vice versa.

Poor Film Quality

Exhaust volume too high: adjust exhaust lid or house exhaust damper. Acceleration too high: select lower acceleration. Unstable balance in speed/time parameters: increase speed/decrease time or visa versa. Insufficient dispense volume: increase dispense volume. Inappropriate resin material: contact resin manufacturer.

Questions

1.1: Analyze each of the expressions for photolithography resolution and explain how to improve resolution in each case. What are the advantages and disadvantages of using e-beam lithography compared to typical photolithography using UV radiation? What is the most likely next-generation lithography?

1.2: An exposure is performed with coherent light using a step and repeat projection printing system. The light source has a wavelength of 365 nm (i-line of a Hg arc lamp).
The pattern is a grating with a line-to-line spacing of 1 μm.
(a) Calculate the minimum value of the numerical aperture (NA) that will provide contrast at the image plane (the plane of the resist).
(b) What is the maximum value of the numerical aperture, above which there will be no improvement in image quality?
(c) Calculate the depth of field of the image for cases (a) and (b).

1.3: Lift-off refers to the process of exposing a pattern into a photoresist, depositing a thin film such as a metal or dielectric over the entire area, and then washing away the photoresist

to leave behind the film only in the patterned area. Why is it easier to obtain a lift-off profile with a negative resist than with a positive resist?

1.4: Which of the following statements are NOT correct?

(a) Short exposure wavelengths can create standing waves in a layer of photoresist.

(b) Regions of constructive interference create increased exposure.

(c) Standing waves can impair the structure of the resist, but they can be eliminated by use of multiple wavelength sources or postbaking.

(d) Standing waves effects are most noticeable at the center of the resist.

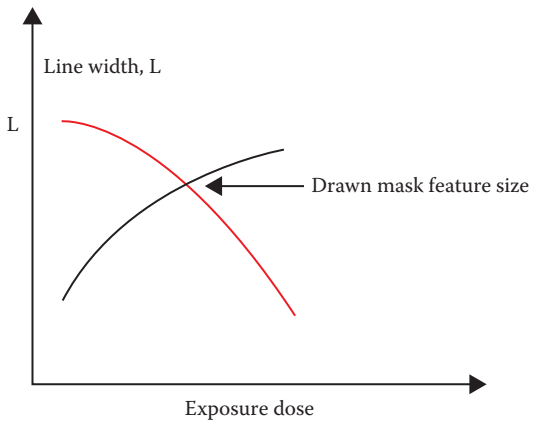
(e) The primary components of a positive photoresist are

1. Nonphotosensitive base phenolic resin
2. Photosensitive dissolution inhibitor
3. Coating solvent

(f) Projection lithography resolution is limited by exposure wavelength, resist thickness, and diffraction and dispersion of light.

(g) Proximity lithography resolution is limited only by exposure wavelength and resist thickness.

1.5: Indicate which line in this graph corresponds to **negative** photoresist and which corresponds to **positive** photoresist.



1.6: Why is it easier to find good data from the literature on resist sensitivity than on lithographic sensitivity?

1.7: Sketch the lithography steps involved in generating a staircase resist pattern that is oriented in the same direction on both sides of a Si wafer. The steps of the staircase need to be aligned within 2 μm and your laboratory cannot afford a >$250,000 double-sided mask aligner.

1.8: Present a comparison of negative and positive photo resists. Also explain what a permanent resist is. Describe what happens chemically to positive and negative resists when exposed to UV radiation.

1.9: A polyimide photoresist requires 100 mJ/cm^2 per micron of thickness to be developed properly. If a lamp provides 1000 W/m^2, how long does it take to expose a 20-μm-thick film?

1.10: List four major factors in which IC technology differs from MEMS or miniaturization science.

1.11: Why does one prefer a high T_g in a resist and why are there no crystalline materials used in lithography?

1.12: Provide a simple rule of thumb for dimensional tolerances in lithography. Why is the resolution with incoherent light larger than that for coherent illumination? How is the depth of focus (DOF) of an imaging system influenced by the numerical aperture NA of the imaging lens, the resolution of the system, and the wavelength of the exposing light?

1.13: Demonstrate with some simple sketches how you would pattern a small Pt electrode for an electrochemical sensor using wet etching. The substrate is an oxidized Si wafer. (Remember that Pt is very difficult to wet etch.)

1.14: Mark the INCORRECT statement(s).

(a) If we want to do the lift-off process, we do not need a postbake.

(b) Before we spin dry a wafer, we need to make sure the vacuum is off.

(c) To increase the pump-down speed for the metal evaporation process, we need to turn on the roughing and foreline pump at the same time.

(d) Ultrasonic vibration can help the lift-off process.

(e) Four-point resistivity measurements can be used to determine the doping concentration of the water.
(f) O_2 plasma etching can be used to remove the photoresist.
(g) After the fabrication is completed, we can deposit a thin layer of Si_3N_4 to protect the Al wires.

1.15: How is the diffraction limit expression derived? Hint: Use the mathematical expression for the intensity variation of the Fraunhofer diffraction pattern of a circular aperture (Airy disk) with radius a.

1.16: How does immersion lithography influence the value of the DOF?

1.17: What are the pros and cons of proximity, contact, and projection lithography?

1.18: Explain what happens chemically to positive and negative photoresist when exposed to UV radiation.

1.19: List the most important methods that can be employed to improve resolution in photolithography.

Resolution of photolithography system.

Introduction

In the integrated circuit (IC) industry, continuous improvements to deep UV (DUV) photolithography have postponed the industrial adoption of alternative next-generation lithographies (NGLs) because of the huge financial investment in existing photolithography equipment. DUV photolithography is expected to continue until the 45-nm node through resolution-enhancing techniques (RET) such as off-axis illumination (OAI), phase shift masks (PSM), and optical

proximity correction (OPC) as reviewed in Chapter 1. The 32-nm node is viewed as beyond the scope of DUV lithography. There are no clear lithography solutions listed in the International Technology Roadmap for Semiconductors (ITRS roadmap) for 2010 and beyond (Volume I, Appendix 1A).

In this chapter we introduce as possible NGLs: extreme ultraviolet lithography (EUVL), x-ray lithography, charged-particle beam lithography based on electrons and ions (such as electron and ion projection techniques), and imprint lithography [nanoimprint lithography (NIL) and step-and-flash imprint lithography (SFIL)]. These techniques are those that are regarded today as important technologies for the beyond the DUV lithography era, either for mask making or for IC production. We also review lithography approaches in the research and development stage, including lithography based on very thin resist layers and block copolymers, zone plate array lithography (ZPAL), quantum lithography (two-photon lithography), and proximal probe-based techniques such as atomic force microscopy (AFM), scanning tunneling microscopy (STM), dip-pen lithography (DPL), near-field scanning optical microscopy (NSOM), and apertureless near-field scanning optical microscopy (ANSOM). Also considered are holographic lithography and plasmonic lithography. Lithography with superlenses ("Pendry's dream") was reviewed in Volume I, Chapter 5 and will not be repeated here. As an example of a lithography method that is capable of patterning resist on nonplanar substrates (e.g., patterning a resist on the surface of a cylinder) we detail soft lithography.

It is possible that some of the alternative lithography tools we treat in the research and development category will emerge as serious NGLs in the coming years.

IC and miniaturization science are taking increasingly separate paths in adopting preferred lithography strategies. For ICs, throughput and finer geometries are needed, and batch processing is a prerequisite. In miniaturization science, modularity, good depth of focus (DOF), extension of the z-direction, that is, the height of features (skyscraper-type structures), incorporating nontraditional materials (e.g., gas-sensitive ceramic layers, polymers), and replication methods catch the spotlight, and batch fabrication is not always a prerequisite. While reading the current chapter, these important differences in characteristics of IC manufacture and miniaturization science should be kept in mind.

Moore's Law

Introduction

The dramatic increase in performance and cost reduction in the electronics industry derives from progress in IC fabrication and packaging. Speed and performance improvement of IC chips and their associated packages, and hence higher-level hardware such as computers, all are based on the minimum printable feature size [critical dimension (CD)].

Moore's Law states that the number of transistors per square centimeter roughly doubles every 18–24 months without increase in cost. Recent trends show that feature size decreases about 30% every 2 years, and one needs more and more upfront investment money to fabricate. Moore's Law—an observation, really—might hit an even bigger snag with CDs in the 32-nm mode, where DUV lithography runs out of steam and quantum effects start wreaking havoc.

After introducing Moore's Law, we analyze Ray Kurzweil's optimistic speculations about the future of Moore's Law.

Moore's Law Detailed

Control of the thickness (z) of films deposited on a substrate and control of the depth of a cavity etched in a substrate can be achieved with remarkable precision, down to 20 Å. The width and length (x, y) dimensions of a deposit or etch are more difficult to control and depend on the type of lithography used. The minimum x, y feature is determined primarily by the precise focus of the energy source that allows discrimination between areas of exposed resist and nonexposed resist. Other key factors are the tolerances on the mask, the ability to align the mask to the wafer and align subsequent layers of masks to create the proper vertical geometry, and the ability to control the rate and direction of etching and deposition.

Gordon Moore, inventor of the IC and former chairman of Intel, first described the rate of progress in reducing feature sizes for ICs when, in 1965, he observed that the surface area of a single transistor reduced by approximately 50% every 12 months. In 1975, he revised this to every 2 years, not every

Table 2.1 CDs, DRAM Bits, MPU Transistor Density, and Die (Chip) Sizes Based on the SIA Road Map*

	1997	1999	2002	2005	2008	2011
Minimum feature size: CD in nm	250	180	130	100	70	50
DRAM (bits)	256M	1G	4G	16G	64G	256G
MPU transistors/cm^2	3.7M	6.2M	18M	39M	84M	180M
DRAM chip size (mm^2)	280	400	560	790	1120	1580
MPU chip size (mm^2)	300	340	430	520	620	750

*See Figure 2.1 and Volume I, Chapter 4.

18 months as is often quoted.[1] Although only an engineer's rule of thumb, this is now widely known as Moore's law. In Table 2.1, based on the Semiconductor Industry Association (SIA) road map[2] (see also Volume I, Appendix 1A), we summarize the minimum feature size (CD), dynamic random access memory (DRAM)* bits, microprocessor transistors per square centimeter, and DRAM and microprocessor die sizes as a function of the year of their introduction.[3] With decreasing CDs comes more rigid CD control: a 180-nm line width requires ±14-nm CD control, and a 50-nm line width requires ±4-nm CD control.

Historically, DRAMs have driven the progress of microlithography more than microprocessors, which exhibit more relaxed design rules (see Table 2.1). The state of the art in ICs today is a 2-GB DRAM with 60-nm features (Samsung). Intel (Integrated Electronics) introduced the Core 2 Quad "Kentsfield" chip in January 2007, a chip featuring a 65-nm technology mode.

In Figure 2.1, we illustrate Moore's law by plotting DRAM bit capacity and minimum feature size on a logarithmic y-axis with time on the x-axis (see also Volume I, Chapter 4).

Looking ahead, IC developers relying on Si complementary metal oxide semiconductor (CMOS) architecture today will switch more to alternative CMOS materials and architectures. At least five fundamental technical roadblocks need to be addressed to scale down CMOS transistors further (beyond 45 nm):

1. Carrier mobility limitations/clustering of dopant atoms: As CMOS transistors shrink, mobility of carriers decreases, and to compensate, smaller devices need a higher amount of dopant atoms; however, above a certain limit the dopant atoms clump together, forming clusters that are not electrically active. The concentration cannot be increased further, and today's chips are close to the maximum.
2. Tunneling through the gate dielectric: The transistor gates that control the flow of electrons have become so small that they are prey to undesirable quantum effects such as tunneling through extremely small barriers (e.g., a gate oxide of 1.2 nm). High-k dielectrics are used to minimize this tunneling current.
3. Doping nonuniformity: Doping nonuniformity over a wafer surface is becoming statistically significant and appears in transistors, showing a varying degree of doping (see also point 1).
4. Interconnects: Interconnects are becoming the dominant portion of circuit speed and process complexity. By volume ICs have become all wires.
5. Power dissipation: The latest Pentium chips dissipate more heat than a stove-top cooking surface (100 W/cm^2).

A few comments and additional details on the above technical challenges follow; for yet more details, consult Volume I, Chapter 4.

Transistors with feature sizes between 0.5 and 0.25 μm are operated at low supply voltages to attain adequate gain and low leakage currents. A small supply voltage keeps the dissipated power within reasonable limits, makes for faster transistor switching, and allows the implementation of smaller transistors. The latter is an example of favorable downscaling because, as transistors get smaller, the insulation

* Dynamic random access memory. A type of memory component used to store information in a computer system. "Dynamic" means the DRAMs need a constant "refresh" (pulse of current through all of the memory cells) to keep the stored information.

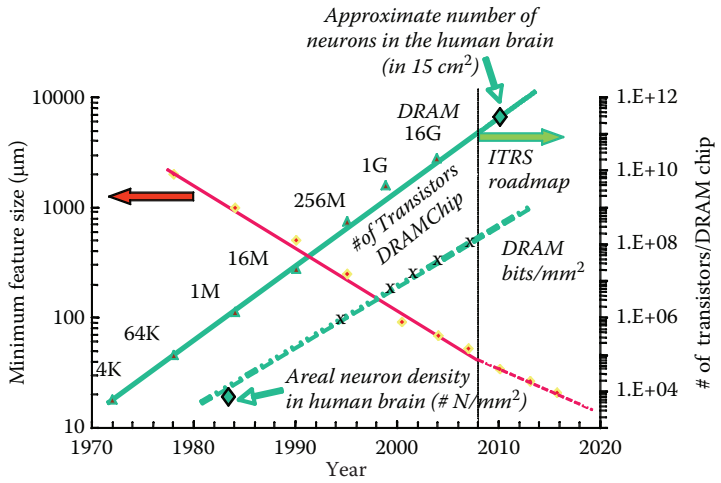

FIGURE 2.1 Semilog plot of DRAM bits and minimum feature size as a function of time. (Courtesy of Dr. Rashid Bashir, Purdue University.) See also Volume I, Chapter 4.

layer between the gate and the source/drain becomes thinner. With too high a supply voltage, electrons would "leak" through the thin insulation and compromise system stability. Eventually, the thin insulation layer will be only a couple of molecules thick, at which point transistor scaling will reach an abrupt end. In 1.8-V logic, threshold voltage is only 0.45 V. As this threshold becomes lower and lower, it will be easier for a minimal flow of electrons to be mistaken as a logical 1 instead of 0, thus causing operational problems.

Below 0.25 µm, cooling becomes necessary to maintain the same adequate transistor characteristics. Cooling of chips might be implemented using methods derived from miniaturization science, such as the use of miniature thermoelectric coolers or Joule-Thomson refrigerators (see Volume III, Chapter 8 on actuators). In the 30–50-nm range, quantum effects begin playing an important role. Quantum effects, as we saw in Volume I, Chapter 3 on quantum mechanics, can be exploited, and major efforts are underway to manufacture quantum boxes, lines, and dots for the next generation of ICs (gigascale integration or 1 billion devices per chip).

Interconnections pose another major challenge for further miniaturization of ICs. Like transistors, metal connection lines are scaled down with every new chip generation, but unlike transistors, their performance decreases as they become thinner because of increased resistance and capacitance. In this case, downscaling is disadvantageous. Connection lines were once aluminum, but copper is now replacing aluminum (e.g., in the Coppermine Pentium III) as interconnect material in building devices that not only run faster—because of copper's higher conductivity—but are also resistant to electromigration. Copper also reduces the number of steps required in manufacture. A more drastic advancement would be the use of superconducting materials for implementing interconnections, but currently no superconductor demonstrates the desired behavior under the temperature and current density conditions that exist in modern ICs. Optical interconnects are another possibility, although these have size limitations (they cannot be thinner than the wavelength of light they transmit), and the conversion of light pulses to electrical ones and vice versa could seriously compromise their performance. If optical interconnections were implemented, a switch from Si to GaAs would also be in order because GaAs offers far superior light source-making capabilities than Si. In Volume I, Chapter 5, we saw how the use of photonic crystals and metal plasmonics can circumvent size limitations of traditional optical waveguides. Photonic crystals and plasmonics offer perhaps the first real possibility for the integration of electronics and optics on the same chip.

One further comment is in order here. Ultimately, all the technological barriers listed above might be overcome, but the real question is, at what cost? Moore's second law states that capital costs increase faster than revenue and that the rate of technological

progress is controlled by financial realities. Specifically, Moore gloomily predicted that the cost of building a chip manufacturing plant doubles with every other chip generation, or roughly every 36 months. This is often referred to as Moore's "second law." The projected cost of an IC lab in 2015 is ~$100 billion.

Kurzweil: A View from an Optimist

To explore what the future of Moore's law holds, we consider Ray Kurzweil's optimistic predictions.[4] Kurzweil (Figure 2.2) and others observed that computing power had been growing exponentially long before the invention of the transistor. From Kurzweil we learn that from 1900 onward the speed of computation has doubled every three years, and that by 2020, computers will equal the human brain in terms of memory capacity and computing speed (see Figure 2.3).

Kurzweil believes that Moore's law is an illustration of a broader underlying law, *The Law of Accelerating Returns*, which is based on *The Law of Time and Chaos*. The latter, as quoted from Kurzweil, reads: "In a process, the time interval between salient events (that is, events that change the nature of the process, or significantly affect the future of the process) expands or contracts along with the amount of chaos." As a consequence, the *Law of Accelerating Returns* (a sublaw of the *Law of Time and Chaos*) states that as order exponentially increases, time exponentially speeds up, or the interval between salient events grows shorter as time passes.* It is assumed that another technology will take over when Moore's law, based on photolithography, is no longer valid. New technology may involve quantum devices, three-dimensional (3D) chips, superconductors, photonic crystals, plasmonic devices, and metamaterials. All that is needed for this evolution to take place is the growing order of the evolving technology itself and enough surrounding chaos—that is, diversity of options or alternatives—from which to draw new ideas. This is similar to natural evolution,

FIGURE 2.2 Ray Kurzweil is on the left, but does Bill believe him?

which needed the many options provided by a rich and varied environment to develop sophisticated and intelligent life forms. It follows that Moore's law, describing the speeding up of technology developments in the IC world, and Taniguchi's laws (see Chapter 6), describing the speeding up of technology developments in mechanical machining (tool development), are both examples of the *Law of Accelerating Returns*. Similarly, in data recording, the rate of progress has exponentially increased. It started slowly, perhaps with crude cave drawings, then pictorial script followed by symbolic script, then pen and paper followed by a colossal milestone, which speeded up things considerably, i.e., the Gutenberg printing press. Then magnetic recording in computers started with recording using a copper-wound coil; when this became too crude, the invention of the thin film read/write head by IBM's L. Romankiw in 1973 took over.[5] In magnetic data storage with thin film read/write, the ultimate limit at room temperature is projected to be 40 Gb/in.^{2}[2,6] A next leap forward in recording density is expected when proximal probes prove their mettle as read/write heads; 45 Gb/in.^{2} (Terris et al.[7]) and 400 Gb/in.^{2} (Kraus and Chou[8]) have been demonstrated already. Using a 32 × 32 (1024) array of AFM cantilevers, King et al.[6] thermomechanically wrote data bits 40 nm in diameter and pitch (this corresponds to a data density of 0.4 Tb/in.^{2}), and they read those bits thermally at a speed of 480 Mb/s. Figure 2.4 shows a picture of a thin film read/write head (a) and an STM-based read/write head (b) (IBM's millipede).

Yet another example of the *Law of Accelerating Returns* is exemplified in the Human Genome Project started in the mid-1980s (see Volume III,

* The other sublaw of the *Law of Time and Chaos* is the *Law of Increasing Chaos*. With chaos exponentially increasing, time exponentially slows down. The events developing after the Big Bang are an illustration of this law; most salient events occurred immediately after the Big Bang and became less frequent thereafter.

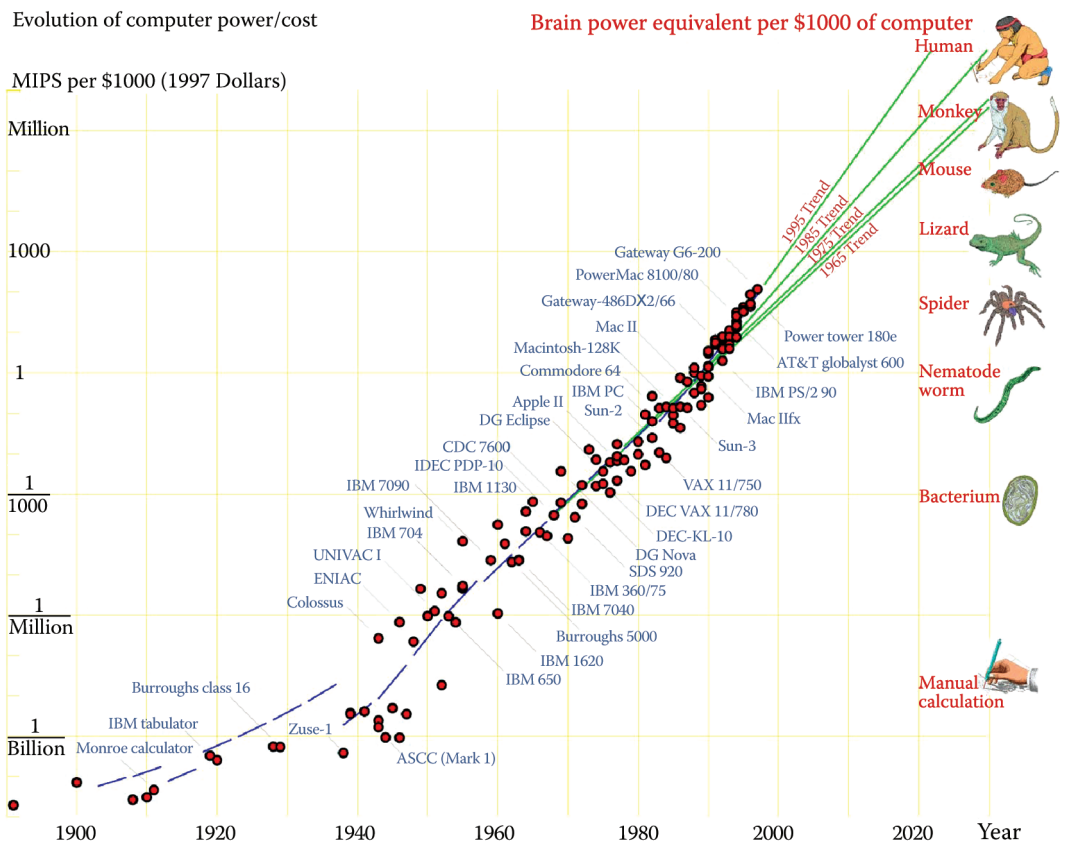

FIGURE 2.3 What $1000 of computing buys. The number of million instructions per second (MIPS) is a general measure of computing performance. (Based on Ray Kurzweil.)

Chapter 2). The speed of the process of writing down all 3.5 billion bits of the human genetic code exponentially increased since the start of the project, causing the project to finish ahead of schedule. For some additional reading from Kurzweil's work, see *The Singularity Is Near: When Humans Transcend Biology.*[9]

Next-Generation Lithographies

Introduction

Having set a rather optimistic forecast for the future of miniaturization sciences, we now introduce a set of possible next-generation lithographies

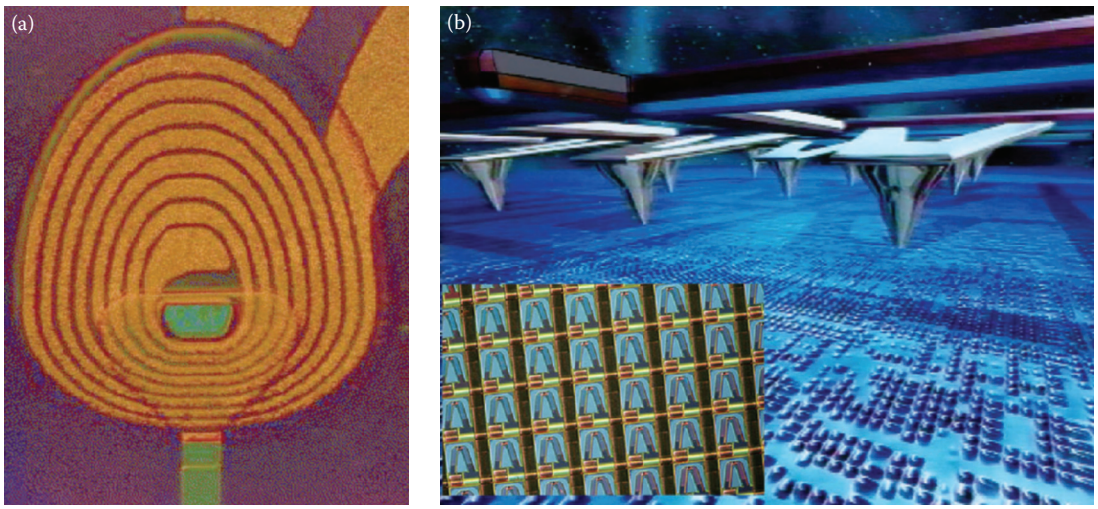

FIGURE 2.4 (a) Thin film read/write head. (b) STM-based read/write head (IBM's millipede).

(NGLs). This includes extreme ultraviolet lithography (EUVL), x-ray lithography, charged-particle-beam lithography, including scattering with angular limitation projection electron-beam lithography (SCALPEL) and ion projection lithography (IPL), as well as imprint lithography [nanoimprint lithography (NIL) and step-and-flash imprint lithography (SFIL)]. In the context of electron-beam lithography (EBL), we also look at progress made with micro-electromechanical system (MEMS)-based arrays of field emitters.

Extreme Ultraviolet Lithography

As mentioned before, the 32-nm node is viewed as beyond the scope of DUV lithography [even when applying all the resolution-enhancing technologies (RETs) or taking advantage of immersion lithography, which we learned about in Chapter 1]. EUVL is one of the most likely NGLs to achieve the 32-nm node.

Extreme ultraviolet lithography (EUVL), using wavelengths in the 10–14-nm range to carry out projection imaging, is the most natural extension of optical projection lithography as, in principle, it only differs in terms of the wavelength. This type of radiation is also referred to as *soft x-ray radiation* and *vacuum UV*. Sources for this type of radiation are laser-produced plasmas and synchrotrons.

To appreciate the merits of EUVL, we take as a starting point the expressions for resolution (R):

$$R = k_1 \frac{\lambda}{NA} \tag{1.16}$$

and depth of focus (DOF):

$$DOF = \pm\delta = \pm k_2 \frac{\lambda}{NA^2} \tag{1.17}$$

In Chapter 1 we learned that in practice, both resolution R and DOF are experimentally determined and are influenced by both resist and exposure systems. In large-scale IC manufacture with g- and i-line light, k_1 values used to be around 0.6 (see Figure 1.81) and DOFs were larger than 0.5 μm. At that time, these parameters led to the desired CD control within a tolerable process window. The push for higher resolution with 248-nm and 193-nm radiation made it necessary to achieve smaller k_1 values, and this led to processing problems; it became more difficult to control the CD, and it created an intolerably low DOF. The RETs discussed in Chapter 1 enhance resolution and the effective DOF, but, as we discussed, they are often not very manufacturer-friendly (people only half-jokingly refer to RET as "real expensive technology"). With EUVL, on the other hand, one surmounts these problems because of its shorter wavelength. The technique is capable of printing sub-100-nm features while maintaining a DOF of 0.5 μm or larger, and has k-values that make the process control less demanding. Unfortunately, things are not that simple—EUV is strongly absorbed in virtually all materials, and, consequently, imaging must be carried out in a vacuum; also, all camera optics and masks used must be reflective rather than refractive. New resists and processing techniques must be developed as well.[10–12]

In Figure 2.5 a schematic of an EUVL setup is shown. A laser is directed at a xenon gas and heats up the gas to create a plasma, radiating light at 13.6 nm—too short for the human eye to see. That EUV light is directed onto a condenser, gathering the light and directing it onto the mask. The mask is a representation of one level of the IC under construction and is made by patterning an absorber on some parts of a mirror but not on others (Figure 2.6). The pattern on the mask is reflected onto a series of four to six curved mirrors, reducing the size of the image and focusing the image onto the resist-coated silicon wafer. The entire process takes place in a vacuum because at these short wavelengths even air absorbs the light.

With respect to EUVL reflectivity, it is well known that most materials have very low reflectivity for near-normal incidences at those short wavelengths; therefore, multilayer Bragg reflectors with multiple reflecting coatings are used, as illustrated in Figure 2.6. The concave and convex mirrors in EUVL, including the mask, are coated with multiple layers (e.g., 80 of them) of molybdenum and silicon (another pair of material used is Mo-Be) with dissimilar EUVL optical constants, providing a resonant reflectivity when the period of the layers is close to λ/2. With magnetron-sputtered Mo-Si-based reflectors, peak reflectivities of up to 70% at 13.4 nm

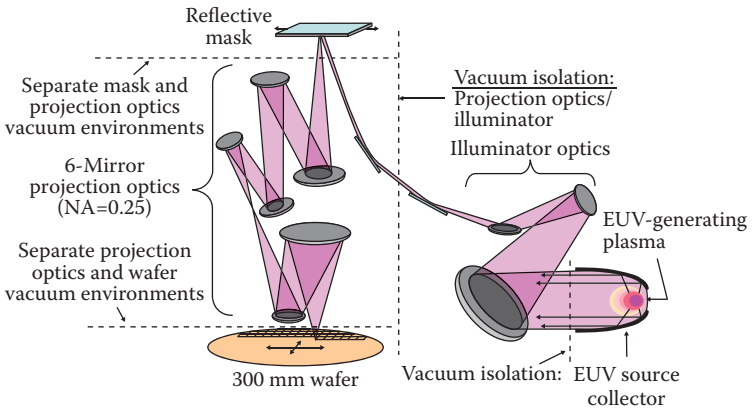

FIGURE 2.5 Schematic of an EUVL lithography setup. (From SEMATECH's Next Generation Lithography Workshop brochure.)

have been achieved (the other 30% is absorbed by the mirror). Without the coating, the light would be almost totally absorbed before reaching the wafer. The mirror surfaces have to be nearly perfect; even small defects in coatings can destroy the shape of the optics and distort the printed circuit pattern.[10]

The multilayer stacks in EUVL masks today have a demonstrated defect level of ~10^{14} defects/cm^2, still two orders of magnitude above target. Prototype EUVL cameras designed for 13.4-nm radiation have an numerical aperture (NA) = 0.1 and a four-mirror set with multilayer Mo-Si-reflecting coatings.[10] These step-and-scan 4× cameras have a resolution better than 100 nm with a ring field of 26 × 1.5 mm. In the step-and-scan system, the mask and wafer are simultaneously scanned in opposite directions, with the mask moving four times faster than the wafer. The camera wave-front error at 13.4 nm needs to be less than 1 nm so that the surface figure (that is, the basic shape of each of the mirrors) will be accurate to 0.25 nm rms or better. Achieving these accuracies will also require improved metrology techniques because current ones cannot confirm the accuracies required. The fact that EUVL masks are reflective has advantages and disadvantages. Advantages are that no thin and brittle membranes are needed as required in the case of x-ray lithography—just a solid substrate (e.g., a Si wafer) coated with the required reflective coatings and a patterned EUVL absorber; because of the 4:1 reduction, mask making is also easier than with x-rays. A major disadvantage is that the defect density in the reflective coating needs to be made so small that there are few techniques available yet to accomplish such defect-free films. Current resists absorb all the EUVL photons within less than 100 nm. Approaches for EUVL resists include silylated single-layer resist, refractory bilayer resists, and trilayer resists.

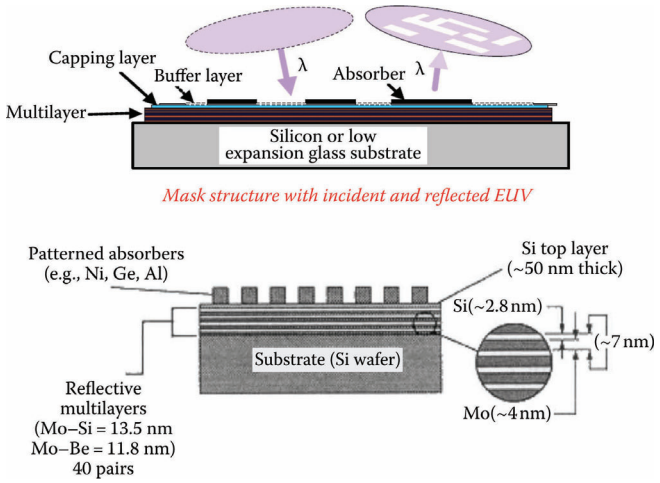

FIGURE 2.6 Two schematic representations of EUVL reflective masks. In EUVL, only reflective optics will work (see text).

The Extreme Ultraviolet LLC (EUV LLC) was created to spearhead the research involved in bringing EUVL to the marketplace. The consortium includes Intel Corporation, Motorola Corporation, Advanced Micro Devices Corporation, IBM, Infineon, Micron Technology, and the Sandia and Lawrence Livermore National Laboratories (http://www.sandia.gov/media/NewsRel/NR2001/euvlight.htm). Intel is leading this consortium, and an introduction of EUVL is planned for 2009. For the past couple of years there has been a growing realization that the resolution capabilities of the EUVL wavelength are being

countered by the effects of electrons released after absorption, and it is feared that a 13.4-nm resolution might be impossible. On the other hand, on May 30, 2007, NEDO announced, that using EUVL, it had drawn circuit patterns with just 26-nm line widths (isolated and dense lines) using EUVL (http://www.nedo.go.jp/english/archives/190820/190820.html).

X-Ray Lithography

Introduction

X-ray lithography uses a shadow printing method similar to optical proximity printing. The x-ray wavelength (4–50 Å) is much shorter than that of UV light (2,000–4,000 Å) (Table 2.2). Hence diffraction effects are reduced and higher resolution can be attained. For example, for an x-ray wavelength of 5 Å and a gap of 40 µm, R is equal to 0.2 µm. In contrast with electron lithography and ion-beam lithography, no charged particles are directly involved in x-ray exposures, which makes the need for vacuum less stringent (see Figure 2.7).[13] Like with all high-energy radiation (see EUVL), a vacuum is preferred to avoid absorption of photons by gas molecules, formation of ozone, and corrosive reactions with the exposure station's hardware. Another advantage of x-rays is that one can use flood exposure of resist-coated wafers, ensuring higher throughput than when writing with a thin electron or ion beam. The method is also referred to as deep x-ray lithography (DXRL).

Table 2.2 Light Sources for Various Types of Lithography

Wavelength (nm)	Source	Range
436	Hg arc lamp	g-line
405	Hg arc lamp	h-line
365	Hg arc lamp	i-line
248	Hg/Xe arc lamp, KrF excimer laser	Deep UV (DUV)
193	ArF excimer laser	DUV
157	F2 laser	Vacuum UV (VUV)
~10	Laser produces plasma sources	Extreme UV (EUV)
~1	x-ray tube, synchrotron	x-ray

The three main classes of sources for x-ray lithography are electron impact tubes, laser-based plasmas, and synchrotrons (Figure 2.8). In miniaturization science, we are mainly concerned with synchrotron radiation. For reasons that are explained below, in the case of ICs, less-expensive alternative x-ray sources might suffice.

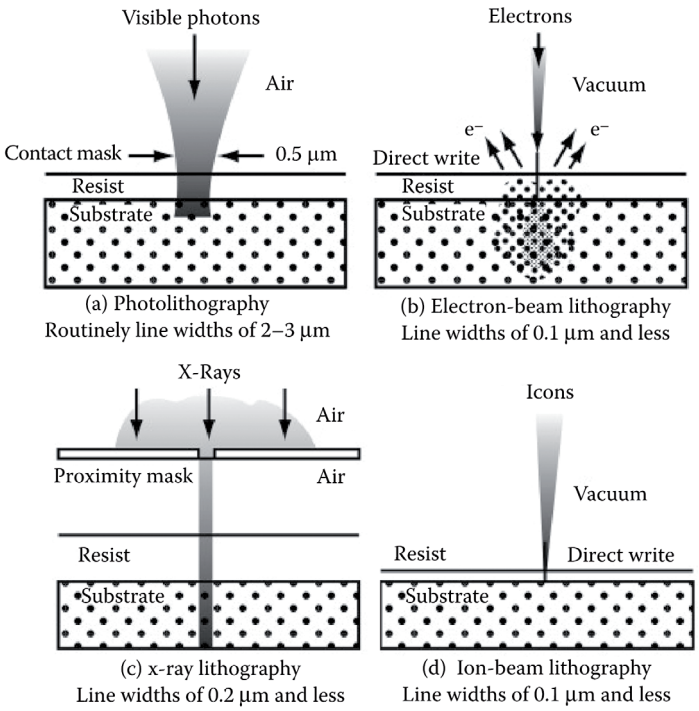

FIGURE 2.7 A comparison of (a) photolithography, (b) electron-beam, (c) x-ray lithography, and (d) ion-beam. (Based on Brodie, I., and J.J. Muray. 1982. *The Physics of Microfabrication*. New York: Plenum Press. With permission.[13])

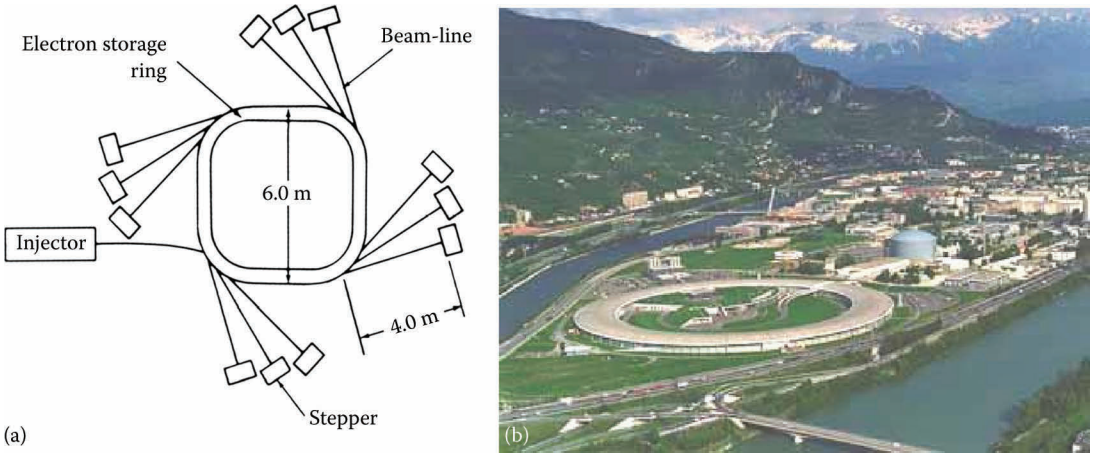

FIGURE 2.8 (a) Schematic of a synchrotron. (b) Grenoble synchrotron (http://www.esrf.eu).

Major Features of X-Ray Lithography

X-ray lithography is superior to optical lithography because of its use of shorter wavelengths and its very large DOF, as well as because exposure time and development conditions are not as stringent. Reproducibility is high because results are independent of substrate type, surface reflections, and wafer topography. Another important benefit is that x-ray lithography is immune to low atomic number (Z) particle contamination (dust). With an x-ray wavelength on the order of 10 Å or less, diffraction effects generally are negligible, and proximity masking can be used, increasing the lifetime of the mask. With a standard 50-µm proximity gap and using synchrotron x-rays, 0.25-µm patterns can be printed; by decreasing the proximity gap to 25 µm, patterns of 0.15 µm can be resolved.[14] The obtainable aspect ratio, defined as the structural height or depth to the minimum lateral dimension, reaches more than 100. With UV photolithography, under special conditions, an aspect ratio of about 25 is possible at most (see SU-8 in Chapter 1). An aspect ratio of 100 corresponds to the aspect ratio attainable by wet chemical anisotropic etching of monocrystalline Si (see Chapter 4).

In x-ray lithography, there are essentially no optics involved, and although this sounds like an advantage, it also presents one major disadvantage because one can only work with 1:1 shadow printing. No image reduction is possible, so the mask fabrication process is very complicated. In the United States, IBM remains the only major champion of x-ray lithography for NGL.[15] At the end of 1999, IBM fabricated several PowerPC 604e microprocessor batches to demonstrate the viability of the method.[16] In Japan, there are still many players involved, such as NTT, Toshiba, Mitsubishi, and NEC.[17]

LIGA

The LIGA technique (a German acronym for *Lithographie*, *Galvanoformung*, *Abformung*) was invented about 25 years ago.[18] LIGA exploits all of the advantages of x-ray lithography listed above, and the process is schematically illustrated in Figure 2.9. The LIGA process involves a thick layer of resist (from micrometers to centimeters), high-energy x-ray radiation, and resist development to make a resist mold. By applying galvanizing techniques, the mold is filled with a metal. The resist structure is removed, and metal products result. Alternatively, the metal part can serve as a mold itself for precision plastic injection molding. Several types of plastic molding processes have been tested, including reaction injection molding, thermoplastic injection molding, and hot embossing. The so-formed plastic part, just like the original resist structure, may also serve as a mold for fast and cheap mass production because one does not rely on a new x-ray exposure. LIGA enables new building materials and a wider dynamic range of dimensions and possible shapes. A showpiece structure for LIGA technology is pictured in Figure 2.10, in which an ant holds a Ni gear.

Of particular interest to miniaturization science is the possibility of creating 3D shapes with slanted

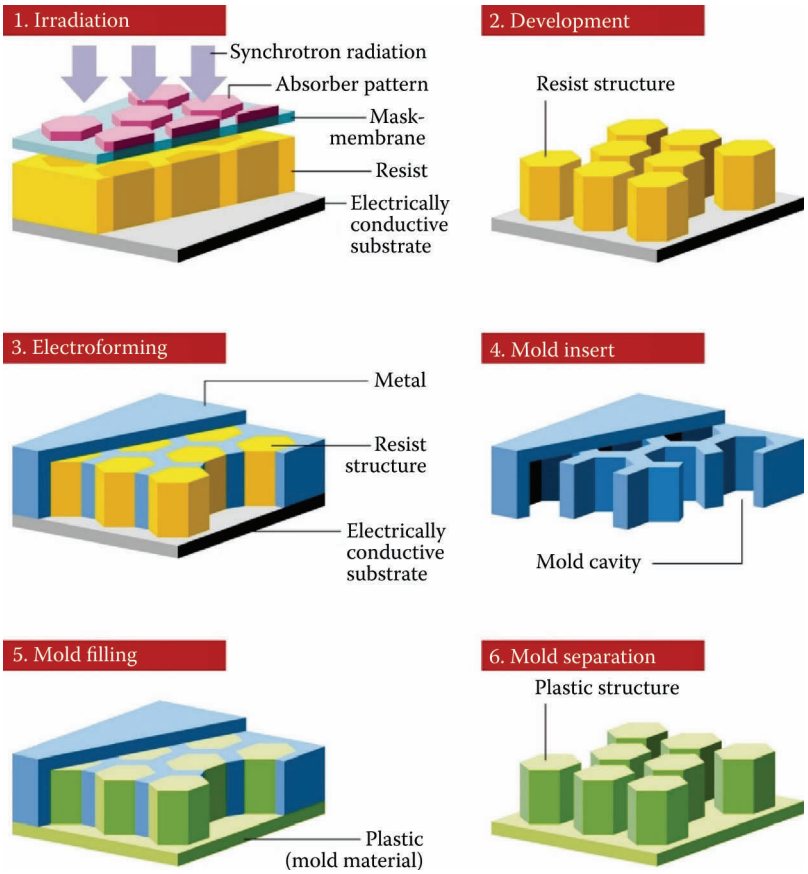

FIGURE 2.9 The LIGA process.

sidewalls (see Figure 2.11)[19] and step-like structures. Two German companies, IMM (http://www.imm-dueck.de) and Jenoptik Mikrotechnik GmbH (http://www.jo-mikrotechnik.com), have developed an x-ray scanner that allows for continuous tilt angles of the mask/substrate assembly with respect to the x-ray beam, rotation of the mask/substrate, and that contains an internal mask alignment system for different masks for multiple exposures. The unprecedented precision attainable with LIGA makes this technique stand out against other 3D lithography methods such as DUV with SU-8 (see Chapter 1). Using the IMM/Jenoptik scanner, a vertical resist wall with a precision better than 0.05 µm was demonstrated, and even resist walls inclined at a 45° angle were made with an accuracy of 1 µm over a height of up to 500 µm.[18] LIGA is further discussed in Chapter 10.

FIGURE 2.10 Ant with gear. (From Forschungszentrum Karlsruhe, Program Microsystem Technologies. With permission.)

X-Ray Resists

An x-ray resist should have high sensitivity to x-rays, high resolution and resistance to chemical, ion, and/or plasma etching, thermal stability of >140°C, and a matrix or resin absorption of less than 0.35 μm^{-1} at the wavelength of interest. No presently available resist meets all those requirements. One material predominantly used in x-ray lithography is positive poly(methylmethacrylate) (PMMA), a material better known by its trade names Plexiglas™ and Lucite™. Another name commonly used for polymers based on PMMA is *acrylics*. Clear sheets of the material are

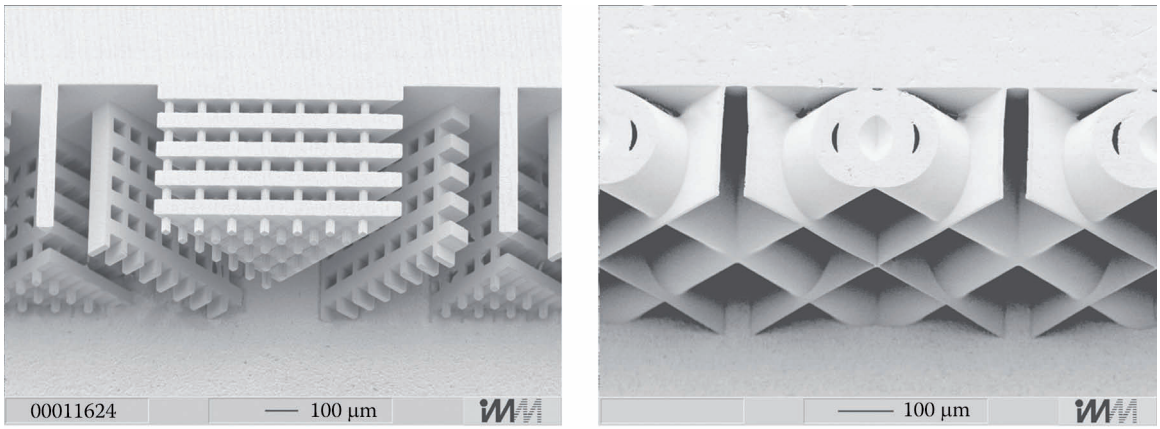

FIGURE 2.11 LIGA structures obtained at IMM using an x-ray scanner enabling continuous tilt angles of the mask/substrate assembly. (Ehrfeld, W., and A. Schmidt. 1998. Recent developments in deep x-ray lithography. *J Vac Sci Technol* B16:3526–34.[19]) (Courtesy IMM.)

used to fabricate "unbreakable" windows, inexpensive lenses, machine guards, and clear lacquers on decorative parts. At a wavelength of 8.34 Å, the lithographic sensitivity of PMMA typically hovers about 2–6.5 J/cm^2, a rather low sensitivity implying a small throughput. A possible approach to make PMMA more x-ray sensitive is the incorporation of x-ray-absorbing high atomic number atoms. Another approach, discussed in Chapter 1, involves the use of chemically amplified photoresists. Other x-ray resists explored for LIGA applications are poly(lactides)[20] and some SU-8 epoxy resin modifications.[21] These resists show a considerably enhanced sensitivity and reduced stress corrosion compared with PMMA.[19]

Negative x-ray resists exhibit inherently higher sensitivities compared with positive x-ray resists, although their resolution capability is limited by swelling. Poly(glycidyl methacrylate-co-ethyl acrylate) (PGMA), a negative e-beam resist, has been used in x-ray lithography. In general, resist materials sensitive to e-beam exposure are also sensitive to x-rays and function in the same way; that is, materials that are positive in tone for electron-beam radiation typically also are positive in tone for x-ray radiation. A strong correlation exists between the resist sensitivities observed with these two radiation sources, suggesting that the reaction mechanisms might be similar for both types of irradiation.[22]

The IC industry requires a typical resist layer not more than 1–2 µm thick. Thicker layers, between 10 and 1,000 µm, are dictated by the need for high-aspect-ratio micromachines. The technology of applying thicker layers of photoresist remains challenging. Spin coating of multiple resist layers (for relatively thin coats), resist casting with in situ polymerization of mildly cross-linked PMMA (for layers >500 µm), and plasma polymerization of PMMA with a possibility of subsequent diamond grinding of the resulting layers are some of the techniques currently in use (see also Chapters 1 and 10).

In the case of exposures with very high energy x-rays (hard x-rays), the associated wavelength is measured in angstroms, not in nanometers. At those energies, almost every type of polymer becomes a "resist," and even "resistless" lithography becomes possible as thin films can be etched, vaporized, or ion-implanted directly.

X-Ray Masks

Another challenge in x-ray lithography, besides the low sensitivity of the resists and the high cost of sufficiently bright x-ray sources, is the mask making—already complex for producing DRAMs, but even more complex for 3D structures with high aspect ratios. In Table 2.3, the procedure for making an optical mask is compared with the procedure involved in making an x-ray mask. Technologies developed for manufacturing masks for submicrometer circuitry with x-ray lithography do not directly transfer to the fabrication of x-ray

TABLE 2.3 Optical versus X-Ray Mask

Optical Mask	X-Ray Mask

masks for building micromachines. An x-ray mask basically consists of a pattern of x-ray-absorbing material (a material with a high atomic number, Z, such as gold, tungsten, or tantalum silicide) on a membrane substrate transparent to x-rays (a low Z material, e.g., Ti, Si, SiC, Si_3N_4, BN, Be) (see Figure 2.12). The membrane must have windows or other features in certain areas for alignment purposes. Additionally, the material also needs to be thermomechanically stable to a few parts in 10.[23] Mechanical stress in the absorber pattern can cause in-plane distortion of the supporting thin membrane, requiring a high Young's modulus material. Also, humidity or the x-ray exposure itself might distort the membrane.

A fabrication sequence for an x-ray mask is shown in Figure 2.13. In this case, the x-ray absorber pattern is ion beam-etched in a Au-film after the pattern first has been written in a 300 Å PMMA layer with an e-beam. The absorber film typically consists of two metal layers: a thin layer of chromium for adhesion to the substrate, topped by a thicker layer of gold. The higher the required aspect ratio of the exposed resist, the thicker the gold layer of the mask absorber pattern must be to maintain a good contrast. The x-ray mask shown in Figure 2.13 only has a 400-Å-thick gold layer, which adequately covers DRAM manufacture but not high-aspect-ratio 3D structures, where 5–15 μm of gold absorber might be required for a 500-μm-thick resist and up to 50 μm for 10-cm-thick resists. A proximity x-ray mask, as shown in Figure 2.13, is placed close to the substrate, and its pattern is reproduced by exposure to x-rays. Various other schemes to make LIGA x-ray masks are explored in Chapter 10.

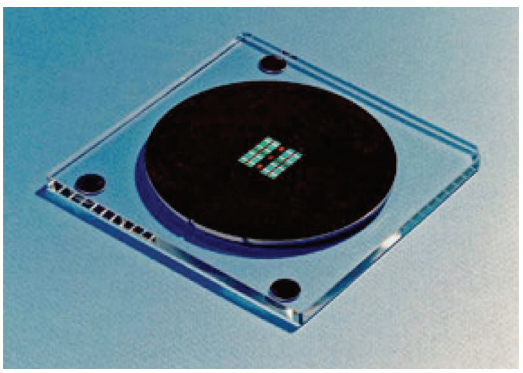

FIGURE 2.12 X-ray mask structure: Ta patterns on SiC or SiN membrane. The absorber Ta is 300 nm thick (stress ~ 0 MPa). Membrane SiC or SiN is 2 m thick (stress = 100 MPa ~ 200 MPa), 20 ~ 30 mm square. The minimum pattern width is 50 nm. Pattern position accuracy: 3σ < 30 nm (http://www.ntt-at.com/products_e/x-ray_masks/index.html).

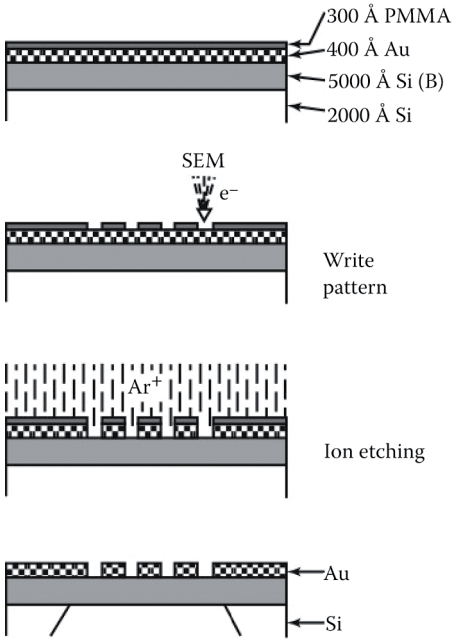

FIGURE 2.13 Fabrication of a silicon membrane-based x-ray mask with a gold absorber pattern. For use in high-aspect-ratio micromachining, the gold absorber layer must be between 5 and 15 μm. (Based on Brodie, I., and J.J. Muray. 1982. *The physics of microfabrication.* New York: Plenum Press. With permission.[13])

Why Use a Synchrotron to Generate X-Rays?

The full power of x-ray lithography for miniaturization science only materializes when using hard, collimated synchrotron radiation. To appreciate this, we will explore the procedure using a less intense, less collimated beam from an electron-beam bombardment source. A schematic diagram of an x-ray exposure system using an electron-beam bombardment-based x-ray source is shown in Figure 2.14.

The mask is typically offset above the wafer by about 10 µm after alignment. A proximity scheme, rather than a contact mask, is a useful feature, given the fact that an x-ray mask can cost up to $13,000. Because the x-ray source is finite in size and separated by a distance, *D*, the edge of the mask does not cast a sharp shadow but rather has a blurry region associated with it, known as penumbral blur, *d*. Image blurring limits the ultimate resolution power of an x-ray exposure system, as shown in Figure 2.14. As diffraction effects can be ignored, simple geometric considerations can be used for relating the image to the pattern on the mask. From Figure 2.14, we estimate that the blurring, δ, at the resist plane is given by:

$$\delta = s\left(\frac{d}{D}\right) \tag{2.1}$$

where s = mask-to-wafer gap
d = the source diameter
D = source-to-substrate distance

In a high-resolution system, δ can be controlled to within 0.1 µm. Spacing, *s*, should allow the accommodation of large-diameter masks while avoiding the high risk of contacting the resist and greatly increasing the occurrence of defects. The x-ray source must be sufficiently collimated. In practice, this translates into a small source diameter d (e.g., a few millimeters) and a large source-to-mask distance (*D*). All these factors contribute to minimizing penumbral blurring. Conventional e-beam-generated x-ray sources have sizes of a few millimeters and are about 40 cm away from the mask. Unfortunately, a large distance required for adequate collimation results in prohibitively

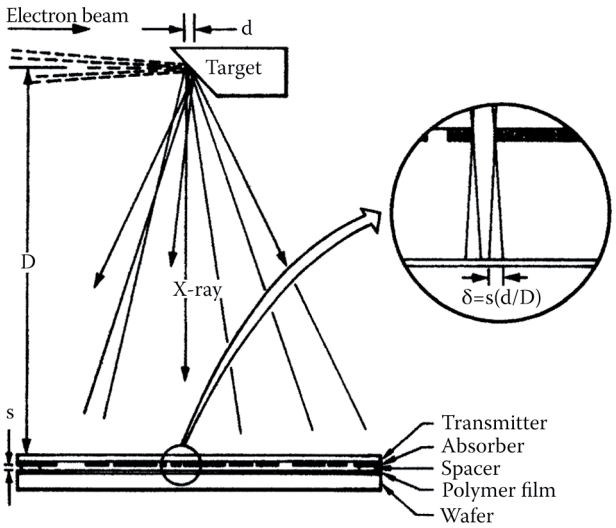

FIGURE 2.14 X-ray lithography with an electron-beam x-ray source. Inset, extent of penumbral effect calculated from geometric considerations. (Based on Brodie, I., and J.J. Muray. 1982. *The physics of microfabrication.* New York: Plenum Press. With permission.[13])

long exposure times (e.g., hours) as a result of the weak intensity of these sources. With synchrotron radiation, on the other hand, penumbral blurring does not limit the spatial resolution. Because of the high collimation of synchrotron radiation, rather large distances between the mask and the wafer can be tolerated (about 1 mm for 1-µm line width patterns). In the electron storage ring or synchrotron, a magnetic field constrains electrons to follow a circular orbit, and the radial acceleration of the electrons causes electromagnetic radiation to be emitted forward. Thus, the radiation is strongly collimated in the forward direction and can be assumed to be parallel for lithographic applications. Because of the much higher flux of usable collimated x-rays, shorter exposure times become possible. The Advanced Light Source (ALS) synchrotron in Berkeley, for example, can deliver a flux of 0.4 W/cm^2 at 30 m for 3–9-keV radiation (http://www.als.lbl.gov). Especially if one wants to generate a highly collimated photon flux in the spectral range required for precise deep-etch x-ray lithography in thick resist layers, synchrotron radiation comes close to being the ideal source because of its intensity, tunability, small source size, and small divergence.[24]

As mentioned in Chapter 1, the IC industry today favors improved photolithography over x-rays. Despite huge efforts, until recently, x-ray lithography

seemed abandoned as a candidate for NGL. The prohibitive cost of introducing a new type of industrial lithography remains a strong deterrent, pushing existing photolithography to its absolute resolution limit. For example, by using UV phase-shifting mask lithography, planar IC features approaching x-ray lithography resolution have been made. Even in the micromachining field, there are continued attempts to squeeze more out of classical photolithography. Using techniques such as DUV lithography and deep dry etching with dense plasmas, LIGA-like, high-aspect-ratio features have been produced, hemming in the potential for broader use of x-ray lithography even for building 3D miniaturized machines. But x-ray lithography might well make a comeback.[25] At recent lithography conferences, four in five NGL presentations were on x-rays. Highlights are there is no need for a synchrotron anymore as new types of light sources have been developed (e.g., from a laser); x-ray masks are cheaper than EUV masks; and 15-nm resolution has been established.[17]

Charged-Particle Beam Lithography

Introduction

In this section, we introduce lithographies based on charged-particle beams. Charged-particle versus non–charged-particle approaches were compared earlier in Figure 2.7. Both narrow-beam direct writing and flood exposure projection systems with electrons and ions will be considered. The mask fabrication process is significantly simpler in the case of narrow-beam lithography compared with flood exposure-based lithography.

In direct write systems, the computer-stored pattern is directly converted to address the writing charged particle beam, enabling the pattern to be exposed sequentially, point by point, over the whole wafer. In other words, the mask is a *software mask*. Electron-beam (e-beam) and ion-beam (i-beam) lithographies involve high current density in narrow electron or ion beams. The smaller the beam sizes, the better the resolution, but more time is spent writing the pattern. This sequential (scanning)-type system exposes one pattern element or pixel at a time. Within that area, the charged-particle beam delivers maximum current (i), which is limited primarily by the source brightness and column design. The experimental setup imposes a limit on the speed at which the writing beam can be moved and modulated, resulting in a "flash" time in seconds (t). The maximum dose (in coulombs/cm^2) deliverable by a particular beam is given by:

$$D_{max} = it/A \qquad (2.2)$$

with A the pixel area in square centimeters. It will then be necessary to work with resists that react sufficiently fast at D_{max} to produce a lithographically useful, 3D image (latent or direct image). The e-beam method displays a large DOF, as active focusing over various topographies is possible. The continued development of better charged-particle beam sources keeps widening the possibilities for nanoscale engineering through direct write lithography, etching, depositing, analyzing, and modifying a wide range of materials, well beyond the capability of classical photolithography. Table 2.4 lists some i-beam and e-beam applications.

Flood exposure of a mask in a projection system (that is, parallel exposure of all pattern elements at the same time, as we saw in DUV) is possible with ions and electrons as well. In principle, these methods can take advantage of the excellent resolution of charged-particle beams while providing the throughput levels necessary for IC manufacture. Exposure masks are fabricated from heavy metals on semitransparent organic or inorganic membranes. We will learn how SCALPEL and IPL have the potential of making e-beam and i-beam high throughput. The high cost

Table 2.4 Electron- and Ion-Beam Applications

Electron-Beam Applications	Ion-Beam Applications
Nanoscale lithography	Micromachining and ion milling
Low-voltage scanning electron microscopy	Microdeposition of metals
Critical dimension measurements	Maskless ion implantation
Electron beam-induced metal deposition	Microstructure failure analysis
Reflection high-energy electron diffraction (RHEED)	Secondary ion mass spectroscopy
Scanning auger microscopy	

of mask fabrication and the instability of the mask as a result of heating have postponed commercial acceptance of these high-energy exposure systems. Moreover, with i- and e-beams, flood exposure is limited to chip-size fields because of difficulties in obtaining broad, collimated, charged-particle beams. The most prevalent use of charged-particle beams remains the narrow-beam scanning mode.

Electron-Beam Lithography

Overview Electron beam lithography (EBL) refers to a lithographic process that uses a focused beam of electrons to form the circuit patterns needed for material deposition on (or removal from) a substrate. In contrast with optical lithography, which uses light for the same purpose, electron lithography offers higher patterning resolution than optical lithography because of the shorter wavelength associated with the 10–50-keV electrons that it uses. Electrons are easily generated and can be used to either directly write the desired structure to the resist in electron-beam direct write or in electron projection lithography (EPL) flood exposure where a much wider beam is used (such as in SCALPEL). We also analyze the status of micromachined electron emission sources and electron emission source arrays.

Direct Write e-Beam Lithography Direct write EBL is a high-resolution patterning technique in which high-energy electrons (10–100-keV) are focused into a narrow beam and used to expose electron-sensitive resists. There are two basic ways to scan an electron beam. In raster scanning, the patterns are written by an electron beam that moves through a regular pattern. The beam scans sequentially over the entire area and is blanked off where no exposure is required. On the contrary, in vector scanning, the electron beam is directed only to the requested pattern features and hops from features to features. Therefore, time is saved in a vector scan system. The direct write technique was first developed in the 1960s using existing scanning electron microscope (SEM) technology. A typical setup involves 30-keV electrons from a Hitachi HL-700F EBL. As a research solution, several groups are still "Rube Goldberging" their standard SEM to create customized e-beam writing systems. For example, Rosolen[25] modified a Hitachi S2500 with a purpose-built pattern generator and alignment system (see also Figure 6.14 in Volume III for a schematic of an SEM and a photo of a commercial SEM machine). The instrument did not require alignment marks on the sample and was able to compensate for positional errors caused by the sample stage and mask tolerances. The EBL method, like x-ray lithography, does not limit the obtainable feature resolution by diffraction because the quantum mechanical wavelengths of high-energy electrons are exceedingly small. EBL exhibits some other attractive attributes compared with photolithography. These include:

1. Precise control of the energy and dose delivered to a resist-coated wafer
2. Deflection and modulation of electron beams with speed and precision by electrostatic or magnetic fields
3. Imaging of electrons to form a small point of <100 Å, as opposed to a spot of 5000 Å for light
4. No need for a physical mask; only a *software mask* is required
5. The ability to register accurately over small areas of a wafer
6. Lower defect densities
7. Large DOF because of continuous focusing over varying topography; at 30 keV, electrons will travel on average >14 μm deep into a PMMA resist layer

Some of the disadvantages of EBL include:

1. Electrons scatter quickly in solids, limiting practical resolution to dimensions >10 nm
2. Electrons, being charged particles, need to be held in a vacuum, making the apparatus more complex than for photolithography
3. The slow exposure speed: an electron beam must be scanned across the entire wafer (for a 4-in. wafer with a high feature density this requires ~1 hour)
4. High system cost

The resolution of EBL tools is not simply the spot size of the focused beam; it also is affected

by forward scattering of the e-beam inside the resist and substrate (at relatively smaller angles) and by backscattering from the substrate exposing the resist over a greater area than the beam spot size (Figure 2.15). This phenomenon is called the "proximity effect," and hence the developed pattern is wider than the scanned pattern due to the interactions of the primary beam electrons with the resist and the substrate, as illustrated in Figure 2.16. Line width variations caused by local feature density are an immediate result. Proximity correction algorithms are used to achieve more uniform resist exposure with EBL. Such corrections are computer intensive and time consuming, however, and make a slow technique even slower.

The biggest disadvantage of direct write electron lithography is its low throughput (approximately 5 wafers/hour at less than 0.1-μm resolution). As a result, the use of EBL has been limited to mask making and direct writing on wafers for specialized applications, for example, small batches of custom ICs.

Writing with an e-beam can be additive or subtractive. In lithography the technique is subtractive; as an example of additive e-beam writing, e-beam-induced metal deposition from a metal organic gas [e.g., W deposition from $W(CO)_6$] has been used for the formation of microstructures of various geometries (see Figure 9.29). These devices are made one by one rather than in a large batch. Usually, this type of slow, expensive fabrication technique prohibits commercial acceptance. Some microstructures, especially intricate microsystems, might be worth the bigger price tag. In that case, serial microfabrication techniques may not be as prohibitive as they would be in the case of ICs.

Electron Emission Sources Three types of electron emission (field, thermionic, and photoemission) (Figure 2.17) underwrite the principle for electron emission source construction.[26] Schottky emission (SE) and cold field emission (CFE) have been in common use, especially for nanometer-sized beams for electron focusing systems. Emission of electrons from a metal under the influence of a field occurs in both SE and CFE. During SE, a blunt tungsten emitter tip coated with a low work function material (ZrO) is heated to 1800 K, and thermionic emission takes place; that is, heat thermally excites the electrons enough to bring them out of the material. In other words, the field emission is helped along by thermal excitation of the electrons (the current in this case is given by the Richardson-Dushman equation).[27] During CFE, a much smaller tungsten wire (radius of <0.1 μm) is used, and a very high field causes electrons to tunnel out of the material. In CFE sources, electrons tunnel from various energies below the Fermi level. With SE cathodes, thermally excited electrons (nontunneling electrons) escape over a field-lowered potential energy barrier (the current in this case is given by the Fowler-Nordheim equation).[27] Both SE and CFE sources display similar energy spreads, but their energy distributions are mirror images (Figure 2.18).[26]

With photo emitters, energy is transferred to electrons by incident photons, and photoelectrons generated close to the surface are able to escape.

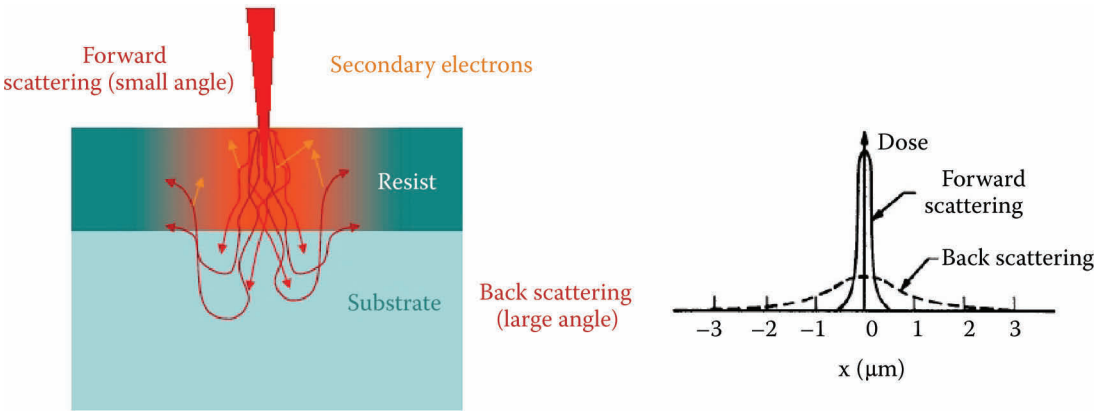

FIGURE 2.15 Scattering of the e-beam inside the resist and substrate and backscattering from the substrate exposing the resist over a greater area than the beam spot size.

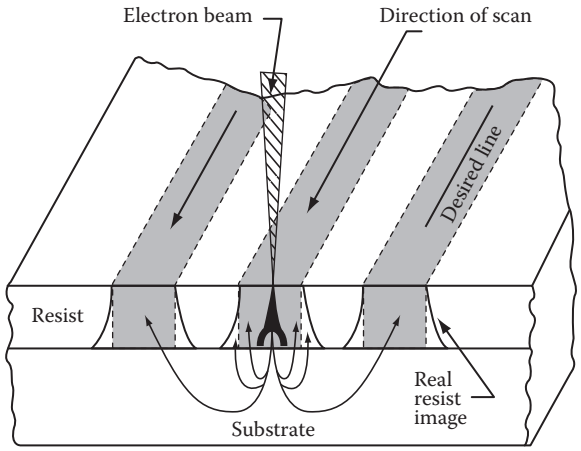

FIGURE 2.16 Proximity effect in direct write e-beam lithography.

Attaining high current levels in a submicrometer electron beam at low voltages (500 eV–1 keV) is of interest for EBL and SEM (see also Chapter 6 in Volume III). When sensitive biological samples or electron beam-sensitive resists are involved, SEM pictures must be made at voltages less than 1 keV. At these low voltages, high currents are required to attain the needed detail and to minimize edge effects. Traditional SEM cathodes using tungsten hairpin filaments are very limited at low voltages; they cannot supply enough current in submicrometer beams at the low-voltage end. The high brightness SE and CFE sources, including LaB_6 and CeB_6, can do the job (Table 2.5). SEM instruments with beam diameters of 1 nm have been made using such cathodes. For further reading about EBL, refer to Brewer.[28]

Electron emission in a water bucket

THE THREE MECHANISMS used by field emission sources all basically involve emitting electrons and ions from a metal surface under the influence of a strong electric field.

Understanding these mechanisms is where the water bucket comes in.

In this analogy, the water level in a bucket represents the Fermi level—the highest occupied energy level in a cathode material. The work function is the energy required to get the water droplets (electrons) from the top of the liquid out of the bucket. This is the distance equivalent to the potential energy barrier.

In photoemission, photon energy excites electrons at the Fermi level of the cathode material and can impart enough kinetic energy to allow the electrons to escape from the bucket.

In thermionic emission, heat thermally excites the electrons, providing enough energy to boil the electrons off and out of the bucket.

In field emission a high electric field can thin the side of the bucket enough so that the electrons can tunnel through it.

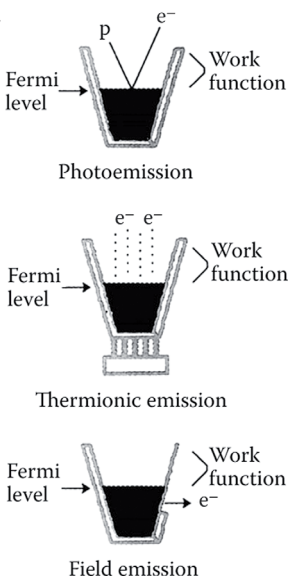

FIGURE 2.17 Photoemission, thermionic emission, and field emission.

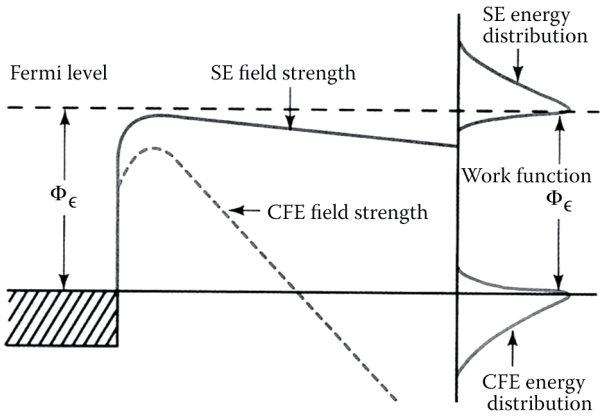

FIGURE 2.18 SE and CFE energy distributions.

Electron-Beam Resists Numerous commercial e-beam resists are produced for mask making and direct write applications. Bombardment of polymers by electrons causes bond breakage; thus, in principle, any polymer material can function as a resist. However, the important considerations include sensitivity, tone, resolution, and etching resistance. PMMA exemplifies an inexpensive positive e-beam resist with a high-resolution capability and a moderate glass transition temperature T_g (114°C). Microposit SAL601 (Shipley) is an often-used negative e-beam resist. SAL601, being novolak based, has much better dry etch resistance than PMMA resists. The same materials act as x-ray resists as well. This is not coincidental, as there is a strong relation between x-ray and e-beam sensitivity. A copolymer of glycidyl methacrylate and ethyl acrylate (COP) is another frequently used negative resist in mask manufacture. This material, although exhibiting good thermal stability, has (as is typical for acrylates) poor plasma-etching resistance. The measured G value (see Chapter 1) of representative polymers in the COP family is about 10. Whelan et al.[29] developed a low-energy electron beam top surface imaging chemically amplified (AXT) resist. This AXT positive-mode resist incorporates a poly(hydroxystyrene) base resin, achieves sub-100-nm resolution with 2-keV electrons, and features a sensitivity less than 1 μC/cm^2.

TABLE 2.5 Comparisons of Electron Sources

Working Principle	Gun Material	Brightness (B) (A/cm^2 Sr)	Energy Width (eV)	Filament Temperature	Gun Vacuum (torr)

Streblenchenko et al.[30] patterned FeF_2 and CoF_2 with 100-keV electrons from a scanning transmission electron microscope using a 0.5-nm diameter electron probe. The fluoride resist films are prepared by thermal evaporation on thin carbon films. During electron bombardment, fluorine escapes and the transition metal coalesces. The resolution in a 20-nm-thick, very small-grained CoF_2 film is about 5 nm. An electron dose of 1000 C/cm^2 at 100 keV removes 90% of all the fluorine in the 20-nm-thick CoF_2 film. Arbitrarily shaped nanometer-scale magnetic structures have been written in such CoF_2 films.

For further reading, see *Handbook of Microlithography Micromachining and Microfabrication*, edited by P. Rai-Choudhury (published by SPIE Press), and Joe Nabity's web site (http://www.jcnabity.com) describing the Nanometer Pattern Generation System. This system is the top-selling SEM lithography system at research institutions in North America, and its use is becoming widespread worldwide.

Electron Projection Lithography: Scattering with Angular Limitation Projection Electron Beam Lithography Electron projection lithography (EPL) is electron beam lithography (EBL) with a wide electron beam, using a mask for high throughput. Scattering with angular limitation projection lithography or SCALPEL, a projection electron beam technique, using a 4× reduction and a step-and-scan writing strategy, is the most prominent EPL technique. The aspect of SCALPEL (1995, Bell Laboratories and Lucent Technologies) that differentiates it from previous attempts at projection EBL is the use of a mask as illustrated in Figure 2.19. As in the case of x-ray lithography, the mask consists of a low atomic number membrane covered with a layer of a high atomic number material: the pattern is delineated in the latter. Although the mask is almost completely electron-transparent at the energies used (100 keV), using the difference in electron-scattering characteristics between the membrane and the patterned material generates contrast. The membrane scatters electrons weakly and to small angles, whereas the patterned layer scatters them strongly and to high angles. An aperture in the back-focal (pupil) plane of the projection optics blocks the strongly scattered electrons, forming a high-contrast aerial image at the wafer plane.

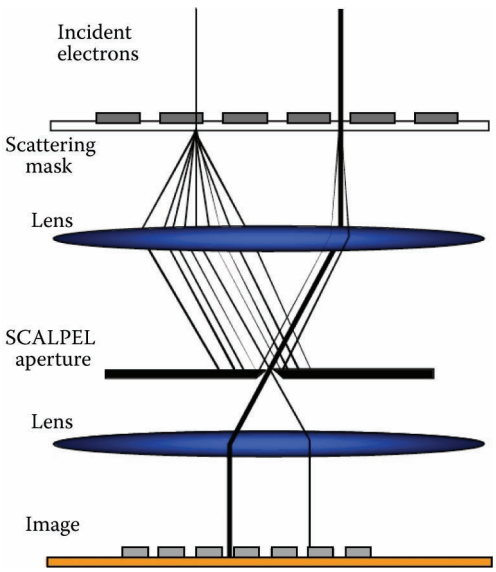

FIGURE 2.19 Scattering with angular limitation projection lithography or SCALPEL, a projection electron beam technique.

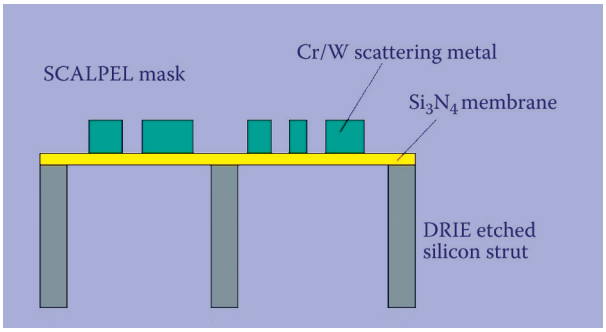

FIGURE 2.20 SCALPEL mask.

The mask is a continuous thin membrane (~100 nm) made of a low atomic number material like silicon nitride, patterned with a 25–50-nm-thick layer of a high atomic material such as tungsten (Figure 2.20). To minimize image distortion, thick silicon struts support the thin silicon nitride membrane. A broad beam (2–3 mm in diameter) of high-energy electrons (~100 keV) passes through both membrane and W pattern with minimal energy loss, leading to minimal heating effects. In SCALPEL, the aperture, rather than the mask, absorbs unwanted energy. Thus, the functions of contrast generation and energy absorption are divided between the mask and the aperture. This means that very little of the incident energy is absorbed by the mask, minimizing thermal instabilities in the mask. It should be noted that, although the membrane scatters electrons weakly compared with the scatterer, a significant fraction of the electrons passing through the membrane are scattered sufficiently to be stopped by the SCALPEL aperture. Image field is still limited today to 1 × 1 mm at the mask level. The small images at the wafer are assembled (also stitched together) from the individual portions on the mask through a combination of interferometrically monitored mechanical motions of the mask and wafer stages and electronic deflections of the beam (see Figure 2.21). The relatively low cost masks in SCALPEL [$27,000 vs. $40,000 for a phase shift mask (PMS), $40,000–59,000 for an EUV mask, and $5,000–10,000 for standard binary masks] may make this technique a cost-effective solution for lithography at 130 nm and less.[31,32]

In 1999, IBM introduced Projection Reduction Exposure with Variable Axis Immersion Lenses (PREVAIL).[33] In this system, the optical axis of the electron system is shifted, so aberrations are reduced, enabling larger scan fields. The lens system shifts the electron optical axis along a preset curvature and precisely deflects the electron beam to follow the variable axis curvature. The SCALPEL

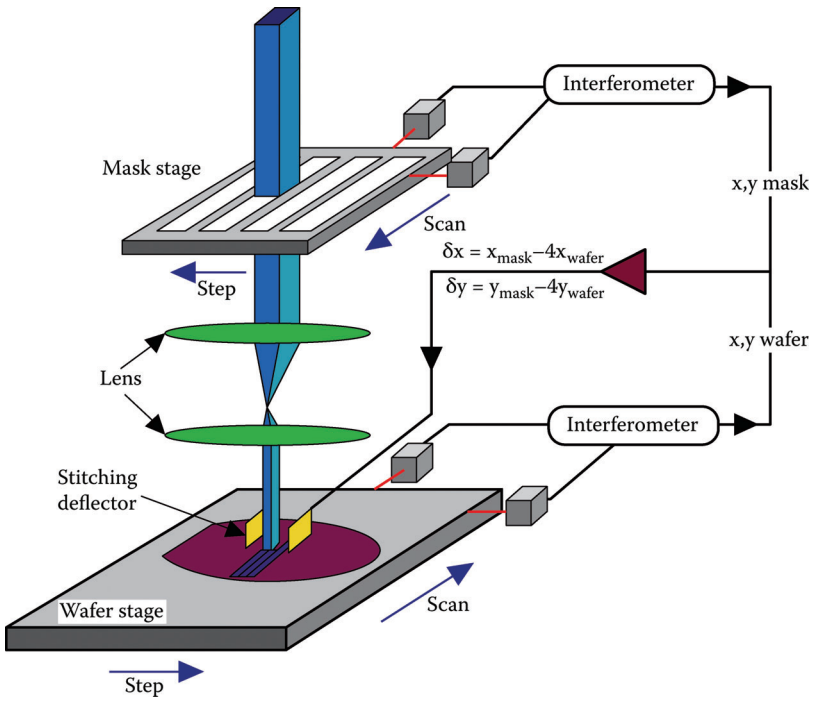

FIGURE 2.21 SCALPEL writing strategy involves step-and-scan writing.

proof-of-concept system was the first system to implement sequential illumination of the mask in an e-beam reduction projection system by mechanical scanning of reticle and wafer at a 4:1 speed ratio underneath a stationary beam. PREVAIL carries this concept further by combining electronic beam scanning with continuous stage motions.[34] This approach provides a significantly larger effective field size needed to achieve commercially viable throughput levels.

Micromachined Electron Emission Sources There have been many attempts at decreasing the accelerating voltage in direct write EBL because lower energy electrons have a more confined lateral backscattering range. Moreover, it was found that low-energy EBL leads to higher sensitivity—that is, for a given resist, a lower exposure dose is required than with higher energy electrons.[35] Low-energy e-beams require thinner resist layers, as the penetration depth falls off very quickly (e.g., in a typical resist, 2 keV will penetrate more than 120 nm). Micromachining is ideally suited to deliver these low-energy electron writing tools. We only present some examples here of micromachined e-beam tools. A first example involves the work by Zlatkin et al.,[36] who developed an elegant array of focused electron writing beams operating at 300 eV or less. The emitters used are cold field emission (CFE) sharpened tungsten tips, although thermionic or Schottky emitters would be feasible as well (for a description of different types of emission sources see above). The emitters are positioned several millimeters above the micromachined extraction holes of a lens array fashioned in a single crystal Si substrate. Because of the relatively large distance between the emitter and the extraction anode (a 1-µm aperture), no precise alignment is necessary. The setup and a detail of the lens system are shown in Figure 2.22.

Each lens has a total area of 1 × 1 cm on a 500-µm-thick silicon wafer and is generally built up from two 0.5-µm thin Si layers. The two thin Si layers are separated from each other and the Si substrate by insulating silicon oxide. An anisotropic etch into the single crystal Si side opposite the thin layered sandwich structure exposes the oxide/Si/oxide/Si/oxide thin layered structure. A short isotropic etch of the exposed oxide is followed by a 1-µm dry-etch bore in the first thin Si layer (first aperture, 1-µm diameter). The small aperture is used to extract electrons from the emitter and to spatially confine the initial electron beam. Another isotropic etch through the second oxide is followed by the larger dry etched aperture (50 µm) in the second thin Si layer. This

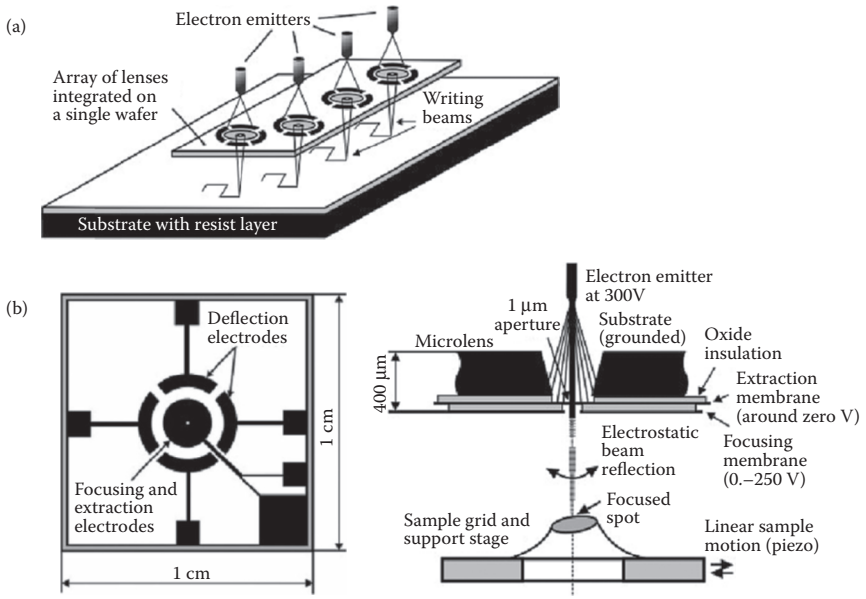

FIGURE 2.22 Array of focused electron writing beams operating at 300 eV or less. Setup (a) and detail of the lens system (b). (Redrawn from Zlatkin, A., and N. Garcia. 1999. Functional scanning electron microscope of low beam energy with integrated electron optical system for nanolithography. *Microelectron Eng* 46:213–17.[36])

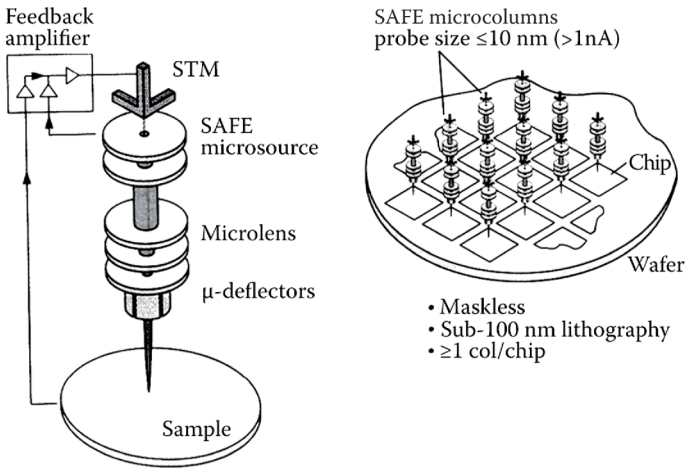

FIGURE 2.23 A microcolumn based on STM aligned field emission (SAFE) and arrayed microcolumn lithography. (From Editorial. 1993. Novel electron-beam lithography system being explored at Cornell's NNF. *Solid State Technol* 36:25–26. With permission.[37]) Acronyms are explained in the text.

second aperture is used to focus the electron trajectories and is well aligned with the first aperture. Changing the voltage on the extraction and focusing electrodes on the thin Si membranes can change the focal length. To deflect the electron beam for scanning, a set of four electrodes symmetrically placed around the extraction and focus apertures is energized. The four electrodes are placed on top of another insulator layer on the focusing membrane. Applying potentials to opposite pairs of deflection quadrants deflects the electron beam laterally, and the focused spot can be swept over an area either to create an SEM image or to pattern a design in EBL mode. The aim is to eventually be able to image and write in the sub-100-nm range. Imaging in the 30-nm range was demonstrated already, but writing is still inadequate (limited to >200 nm).

Micromachining presents other potential solutions to make "nanolithography" a cost-effective and adequately fast proposition in the future. The next example addresses the issue of speed in writing with small e-beam systems by introducing massive parallelism. At Cornell's National Nanofabrication Facility, a research group has been working on arrays of microfabricated, miniaturized electron lithography systems based on STMs. In this STM aligned field emission (SAFE) system, the physical dimension of the electron beam column (length and diameter) are on the orders of millimeters. A field emission tip is mounted onto an STM; the STM feedback principle is used for precision x, y, and z piezoelectric alignment of the tip to a miniaturized electron lens to form a focused probe of electrons as shown in Figure 2.23.[37] Because many electron-optic aberrations scale with size, microfabrication techniques enable lenses with negligible aberrations, resulting in exceptionally high brightness and resolution. STM controls also allow for stability of the emission by automatically adjusting the z-position via a piezo element.

An array of these microcolumns, each with a field emission tip as the source with individual STM sensors and controls, can generate patterns in parallel, one or more columns per chip (see Figure 2.23). The low voltage of operation of these tips obviates the need for proximity-effect corrections, as low-voltage operations have proven to eliminate proximity effects.[37,38] For example, low-energy electrons (15–50 eV) from a SAFE system have been used to write patterns with 23-nm feature sizes, more than four times smaller than can be written on the same substrate and in the same resist with a tightly focused 50-kV e-beam.[38]

Nanolithography with ultrasharp field emitters as discussed above needs to be distinguished from scanning probe lithography (SPL), discussed further below. SAFE is based on an emission technology, whereas tunneling is the mechanism in SPL. The key differences are the distance between tip and substrate (1 nm with SPL vs. 100 nm or more with sharp field emitter tips) and the electron generation mechanism (tunneling vs. emission).

Besides the application described above, micromachined emission sources are also used or are intended to be used for flat panel displays (see Spindt cathodes in Figure 2.42), high-temperature and high-radiation amplifiers, vacuum gauges, and radio frequency oscillators and amplifiers.[39]

Ion-Beam Lithography

Introduction In ion-beam lithography, resists are exposed to energetic ion bombardment in a vacuum. As in the case of e-beam systems, ion-beam lithography offers direct write and flood exposure fabrication opportunities. Direct write ion-beam lithography consists of point-by-point exposures with a narrow beam scanning source (e.g., 20 nm in diameter) of liquid gallium metal. In ion projection lithography (IPL), flood exposure, with a broad ion beam of H^+, He^{2+}, or Ar^+ (e.g., 1–2 cm^2 in size), of a stencil mask is used to pattern a substrate. Ion-beam lithography uses ions of a kinetic energy from a few keV up to several MeV. Ion lithography achieves higher resolution than optical, x-ray, or electron beam techniques because ions come with a smaller wavelength and therefore undergo almost no diffraction and scatter much less than electrons because the secondary electrons produced by an ion beam are of lower energy and have a short diffusion range. The total spread including forward and backward scattering of the "stiffer" ion beams is typically less than 10 nm, and they only require about 1–10% of the electron dose to expose a resist. The resist can be an ordinary PMMA resist that absorbs most of the ions during exposure. Therefore, radiation damage to sensitive, underlying structures is minimized and smaller compared with EBL and x-ray lithography. There is also the possibility of a resistless wafer process. However, the most important application of focused ion beams remains the repair of masks for optical or x-ray lithography, a task for which commercial systems are available.

Focused Ion-Beam and Deep Ion-Beam Lithography For ion-beam construction, liquid metal ion (LMI) sources are becoming the choice for producing high-current-density submicrometer ion beams. With an LMI source, liquid metal (typically gallium) migrates along a needle substrate. By applying an electrical field, a jet-like protrusion of liquid metal forms at the source tip. The gallium-gallium bonds are broken under the influence of the extraction field and are uniformly ionized without droplet or cluster formation. LMI sources hold extremely high brightness levels (10^6 A/cm^2 sr) and a very small energy spread, making them ideal for producing high-current-density submicrometer ion beams. Beam diameters of less than 50 nm and current densities up to 8 A/cm^2 are the norm. In addition to Ga, other pure element sources are available, such as indium and gold. By adopting alloy sources, the list expands to dopant materials such as boron, arsenic, phosphorus, silicon, and beryllium.

Compared with photons (x-rays and DUV light) or electrons, ions chemically react with the substrate, allowing a greater variety of surface modifications such as patterned doping. The ion-beam spot size is the smallest possible—smaller than UV, x-ray, or electron-beam spots. The smallest focused ion-beam (FIB) spots reached are about 4–8 nm, accomplished by using a two-lens microprobe system and a single-isotope gallium ion source.[40, 41] Ion-beam lithography experiences the same drawbacks as an electron-beam system in that it requires a serially scanned beam and a vacuum.

FIBs can be used to perform maskless implantation and metal patterning with submicrometer dimensions. FIB also has been applied to milling in IC repair, maskless implantation, circuit fault isolation, and failure analysis (see Table 2.4). In Figure 2.24, deposition, milling, and imaging are illustrated. Micromachining applications of ion-beam technology are reviewed in more detail in Chapter 6 on mechanical energy-based removing (see Figure 6.32). As a machining tool, FIB is very slow. Except for research, it may take a long time to become an accepted "micromachining tool." For additional reading on ion-beam lithography in general refer to Selinger et al.[42]; for more specific reading on FIB-induced deposition, see Brodie.[13]

Using high-energy (2 MeV) protons, deep ion-beam lithography (DIBL) in PMMA produces submicrometer (300 nm) walls with an aspect ratio approaching 100. Three-dimensional complex microstructures with smooth walls and corners have

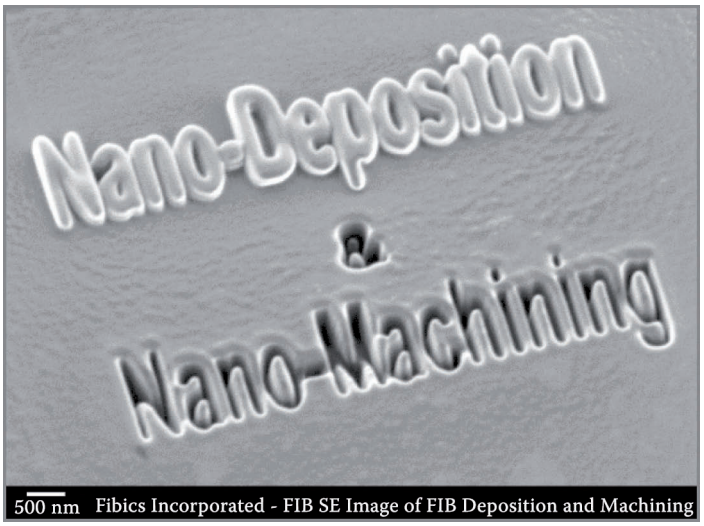

FIGURE 2.24 FIB deposition can produce features 200 nm or less in thickness. FIB milling can produce even finer results. Approximately 30 minutes of FIB time was required to produce this structure (http://fibics.com/Micromachining.html).

been produced this way. The range of 2-MeV protons in PMMA is 63 µm.[43] Multiple exposures at different ion energies (e.g., 0.6 MeV and 2 MeV) allow production of multilayer structures in single-layer resists such as SU-8.[44]

FIB systems have been produced commercially for approximately 20 years, primarily for large semiconductor manufacturers. FIB systems operate in a similar fashion to an SEM. When operated at low-beam currents, the system can be used for imaging, and when operated at high-beam currents, it can be used for site-specific sputtering or milling (see Figure 2.24).

Ion-Projection Lithography Ion projection lithography (IPL), illustrated in Figure 2.25, is another of the candidates for high-throughput lithography dedicated to future 32-nm and sub-32-nm IC generations. In ion projection lithography, a stencil mask, consisting of an Si membrane with a fine pattern of holes, is illuminated with a uniform beam of hydrogen or helium ions at about 10 kV. The image of this mask is projected through an ion optical column and demagnified by 4× on the wafer. Ions are very efficient at exposing resists so that the exposure time per die is well under a second even for comparatively insensitive (1 µC/cm^2) resists. Protons or helium ions are generated by a radio frequency-driven filament (ion source). An extraction system consists of

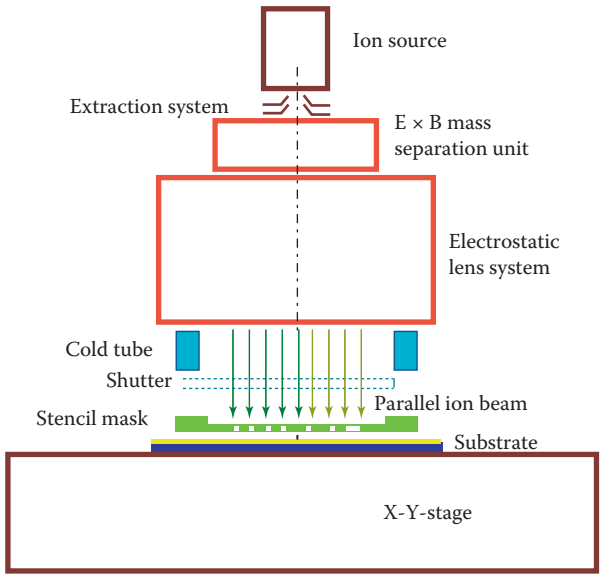

FIGURE 2.25 Ion projection lithography (IPL).

an **E** × **B** mass separation unit and an electrostatic lens system.

The ion flood lithography mask typically consists of a silicon membrane a few micrometers thin (3 µm) with pattern openings that allow protons to pass through.[45] The mask fabrication process involves silicon-on-insulator (SOI) and dry etching.[46] The holes are defined by EBL and reactive ion etching, whereby an oxide is used as a mask. Current IPL approaches, like SCALPEL, are 4× technologies. DOF is large and may reach up to 500 µm. The optics in IPL are all electromagnetic, and the

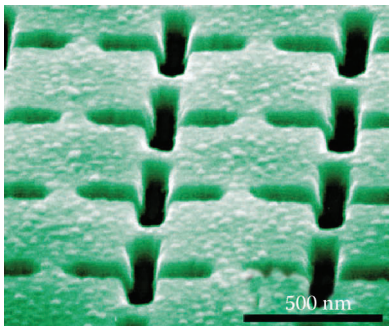

FIGURE 2.26 IPL mask 80-nm feature sizes etched into a Si membrane mask. The patterns were defined using a Leica VB6 EBL. (From http://www.cnf.cornell.edu/image.)

potential for a 50 × 50-mm exposure field exists. The membranes for this work typically consist of low-stress silicon nitride or Si. An example of a Si stencil mask created at the Cornell Nanoscale Science and Technology Facility for masked ion-beam lithography is shown in the electron micrograph in Figure 2.26.

Ion-beam lithography has at least two advantages over EBL: 1) it has almost two orders of magnitude higher resist sensitivity, and 2) it has negligible ion scattering in the resist and very low backscattering from the substrate. A major problem is the potential for damage to sensitive electronic functions from the high energy ions.

Efforts in IPL are especially strong in Europe (e.g., at IMS, http://www.ims.co.at).

Imprint Lithography

Nanoimprint lithography (NIL) and step-and-flash imprint lithography (SFIL) are techniques that use hard molds instead of the soft molds used in soft lithography (see below). Stephen Chou at Princeton University invented NIL in 1994, with the aim of overcoming the diffraction-limited minimal feature sizes obtained in semiconductor manufacturing based on DUV lithography (http://www.princeton.edu/~chouweb). It is possible to break through the diffraction-controlled size limit of photolithography, for example, by using electron beam lithography (EBL). But the infrastructure of this approach, we know by now, costs billions of dollars. NIL patterns a resist by deforming the resist shape through embossing (with a mold/stamp/template) rather than by altering resist chemical structures through radiation (with particle beams). After imprinting the resist, a dry anisotropic etch is used to remove the residual resist layer in the compressed area to expose the substrate underneath. In NIL, a template (the mold/stamp/template) is made of a hard material (usually Ni or Si) and is pressed against a layer of polymer. High temperature and pressure conditions mold and harden the polymer layer. As illustrated in Figure 2.27, the NIL technique is based on the craft of hot embossing, with an adaptation to modern semiconductor needs. In this example the technique is used to pattern a metal film via liftoff. The method relies on the excellent replication fidelity obtained with polymers and combines thermoplastic molding with common pattern transfer methods. Once a solid stamp with a nanorelief on the surface is fabricated, it can be used for the replication of many identical surface patterns. The resolution of the NIL process is a direct function of the resolution of the original template/stamp fabrication process.

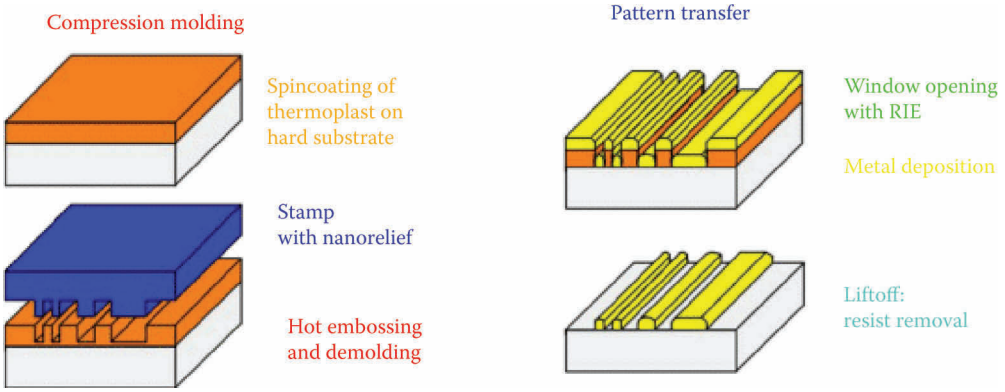

FIGURE 2.27 Schematic illustration of the nano imprint lithography (NIL). The technique is used here to pattern a metal film via liftoff.

Electron beam writers that provide high resolution but lack the throughput required for mass production are used to make them.

The University of Texas–Austin developed its own version of nanoimprint lithography, i.e., step-and-flash imprint lithography (SFIL), in 1998.[47] In 2001, the SFIL concept was licensed to Molecular Imprints, Inc., a company that develops SFIL-capable tools (S-FIL® systems) and related processes (http://www.molecularimprints.com). The SFIL method is distinct from the original NIL in its use of UV-assisted nanoimprinting that molds photocurable liquids in a step-and-repeat, die-by-die fashion rather than by heat-assisted molding of full, polymer-coated wafers. As shown in Figure 2.28, in SFIL, a hard but transparent template/stamp/mold (fused silica) is used to mold a polymer photoresist layer. The fused silica surface of the stamp, coated with a release layer, is gently pressed into the thin layer of low viscosity photoresist. The photoresist is subsequently exposed to UV light through the transparent template to harden it. On separation of the fused silica template, one layer of the circuit pattern is left on the wafer surface. Molecular Imprints uses a family of photocurable, low viscosity materials called MonoMat™ as its imprint resists. MonoMat™ is composed of an organic monomer that polymerizes in seconds using low-cost, broadband UV light sources. Whereas other imprint tools use spin-on imprint resist, S-FIL® systems dispense low viscosity imprint resist in very small droplets, one field at a time, immediately before the imprint step. Consequently, both the monomer dispenses and imprint functions happen in a step-and-repeat fashion. A residual layer of polymer between features is eliminated by a dry etch process, and a perfect

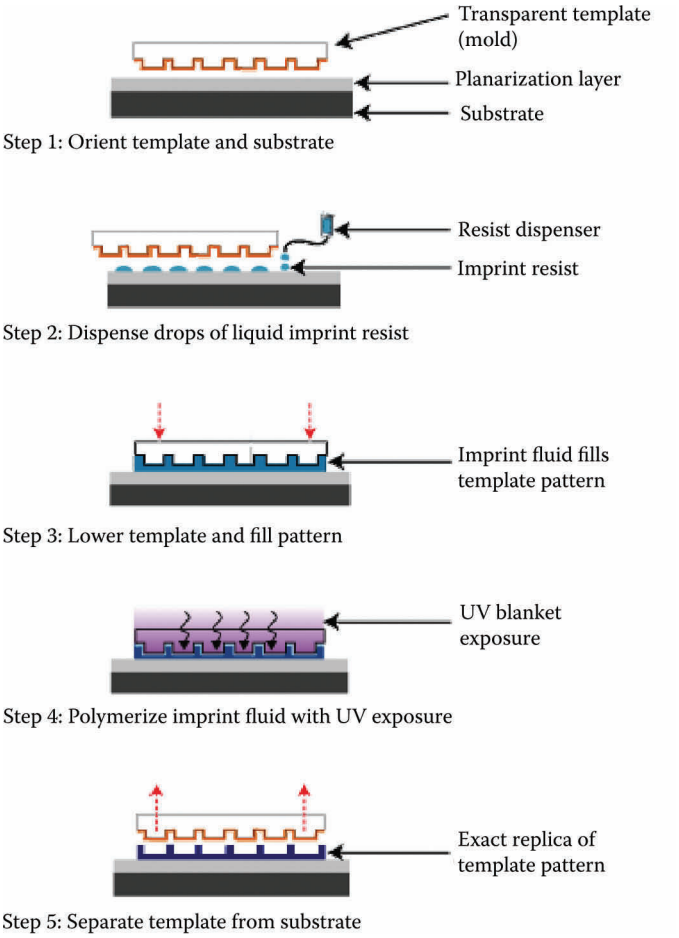

FIGURE 2.28 Schematic of step-and-flash imprint lithography (SFIL). (Colburn, M., S. Johnson, M. Stewart, S. Damie, T.C. Bailey, B. Choi, M. Wedlake, T. Michaelson, S.V. Sreenivasan, J. Ekerdt, and C.G. Wilson. 1999. Step and flash imprint lithography: a new approach to high-resolution patterning. *Proc SPIE* 3676:379–89.[47])

replica of the pattern is ready to be used in semiconductor processing for etch or deposition. Only the template fabrication process, typically accomplished with an e-beam writer, limits the resolution of the features. It has been demonstrated that the mold templates do not deteriorate even after 1500 imprints with sub-100-nm feature sizes. Although more progress is needed for widespread adoption of NIL and SFIL, sub-100-nm feature size devices can be reliably fabricated at a reasonable throughput. Implementing SFIL for high-volume manufacturing of the gate or contact level of transistors is not feasible in the near term, but it is one of the few methods currently available for low-volume prototyping at the 32-nm node. Sub-20-nm features have been made already that exceed the present requirements of the ITRS. For example, using Molecular Imprints' Imprio 250 system, Toshiba was able to print 18-nm isolated features and 24-nm dense features with <1-nm critical dimension uniformity and <2-nm line edge roughness.[48] The Toshiba demonstrations also showed lower defectivity and improved results for imprint lithography. Defectivity levels of as low as <0.3 defects/cm^2 are approaching those of immersion lithography, and device overlay results were also within Toshiba's required specifications. However, the approach faces alignment challenges, and critics say the cost of making the reticles will be high. Unlike conventional lithography, with mask patterns that are four times larger than the printed image, nanoimprint is a 1:1 template technology.

Others argue that imprinting processes are economical because of the simplicity of the equipment involved and the potential for high throughput. As the rate of improvements in optical lithography decelerates and as the costs of manufacturing continue to escalate, there is an increased interest in printing and molding as alternative processes for microfabrication. As imprint lithography depends on another lithography technique (perhaps an NGL) to make the master, it does not really qualify as an NGL itself. Whereas it may initially have targeted semiconductor applications, the SFIL process is now being explored for manufacturing of several emerging technologies, such as photonic crystals, micro/nano-optical components, and nanopatterned magnetic media for future hard disk drives. Progress in these new areas has been such that SFIL is likely to find its first commercial manufacturing application in one of these emerging technologies well before it would be required for high-volume, sub-50-nm semiconductor lithography. A notable feature of nanoimprint technologies is their relatively low cost, which allows researchers to explore applications of nanopatterning that would never be economically feasible given the extraordinary cost associated with EUV lithography or even current-generation 193-nm steppers. This is very similar to the current applications of soft lithography (see below) with this difference that using a hard stamp renders NIL and SFIL more industrial manufacturing capable.

Thermal NIL using thermoplastic polymer films is focused on applications such as biochips, life sciences, storage media, and optical devices, whereas SFIL is focused on LSI and magnetic storage applications, as summarized in Figure 2.29. Hitachi, with NEDO support, has also developed a sheet or roll-to-roll prototype NIL machine and demonstrated the capability to process 15-m sheets.[49] The goal is to create a continuous imprinting process by using belt molding (nickel-plated molds) and polystyrene sheets for large geometry applications, such as membranes for fuel cells, batteries, and possibly for displays. Currently the prototype tool does not

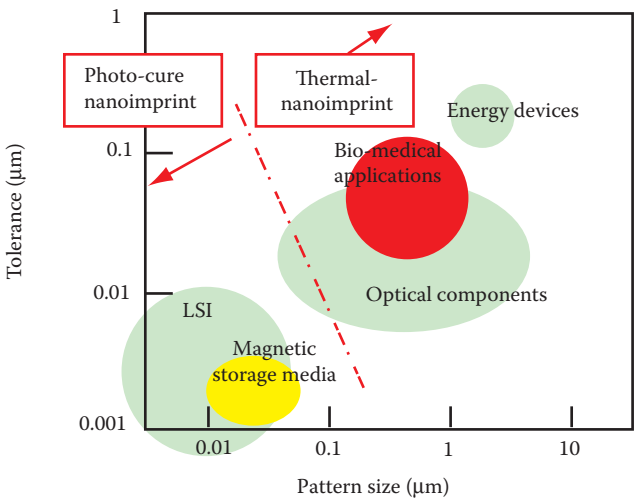

FIGURE 2.29 Usage domains of photocure (SFIL) and thermal nanoimprinting (NIL). (Based on a figure by Hitachi.)

offer the desired throughput, but the concept has been demonstrated, with future efforts focused on throughput, reliability, and repeatability.

Lithography Techniques in the Research and Development Stage

Introduction

In this section we cover the more futuristic lithography methods, some of which could cause a paradigm shift in the improvement of CD printing capability by perhaps a factor of 10. These might eventually enable devices that are a few nanometers in size and have switching speeds in the terahertz range. We review lithography with ultrathin resist layers and block copolymers, zone plate array lithography (ZPAL), proximal probe-based lithographies such as atomic force microscopy (AFM), scanning tunneling microscopy (STM), dip-pen lithography (DPL), quantum lithography (two-photon 3D lithography), near-field scanning optical microscopy (NSOM), apertureless near-field scanning optical microscopy (ANSOM), holographic lithography, plasmonic lithography, and lithography with superlenses. In terms of an important lithography method that is capable of patterning resist on nonplanar substrates (e.g., patterning a resist on the surface of a cylinder), we detail soft lithography, in which a soft mask can be bent around nonplanar substrates.

Very Thin Resist Layers

Introduction

Radiation scattering during exposure of a resist limits its resolution to no better than the resist thickness. Using ever thinner resist layers further improves the resolution and renders a low DOF—associated with high NA lenses and short wavelength lithography—less critical. It is in this context that physisorbed Langmuir-Blodgett (LB) resists, self-assembled chemisorbed monolayer (SAM) resists, and ultrathin film (UTF) resists are explored.

Langmuir-Blodgett Resists

LB resist films were considered for some time for the finest lithography applications such as ultraresolution nanolithography. In this method, LB resist films are prepared by transferring organic monolayers floating on a water surface onto solid substrates. The procedure is explained in Chapter 8 on chemical, photochemical, and electrochemical-based forming (see Figure 8.13). Multilayer films of PMMA deposited by the LB technique, for example, have been investigated as a potential e-beam resist for nanolithography. The range of backscattered electrons limits the resolution of e-beam resists through the proximity effect, and nanometer-thick layers minimize this effect. Despite extensive work in the early 1980s to automate LB resist deposition systems, the technology is not envisioned as a viable manufacturing option because of its low mechanical and chemical stability.[50,51] Other major problems concerning LB films need to be addressed before the method can become viable, and research in this area focuses on speeding up the coating process, simplifying surface cleaning procedures, and improving etching resistance. Because the bonding of an LB film with the substrate is based on physisorption, the adhesion is weak, and chemisorbed SAMs have become much more popular (see next section).

Self-Assembled Monolayers

Molecular self-assembly is a chemical process in which molecules spontaneously organize to form larger ordered structures. Self-assembly is one aspect of supramolecular chemistry, i.e., chemistry beyond the molecule or the chemistry of the intermolecular bond.[52] Self-assembly is studied extensively with an eye toward mimicking nature's spectacular use of this bottom-up, automated manufacturing approach (see Volume III, Chapter 4 on packaging, assembly, and self-assembly). In one special type of self-assembly, self-assembling precursor molecules, from a solution or the vapor phase, react at interfaces to produce layers of monomolecular thickness that are chemically bonded to solid surfaces. Such layers belong to a class of materials known as *self-assembled monolayers*. The thermodynamically favorable bond formation involves chemisorption, which results in monolayers that are more stable than those possible with physisorbed LB films (see above). Therefore, SAMs potentially make for better resist candidates.

Homogeneous and densely packed molecular layers incorporate reactive groups that form bonds with the substrate on one side, whereas an organic group (e.g., an alkyl group, R) on the other side imparts the desired chemical functionality to the surface modified with the thin film. Changing even one atom at the end group of self-assembling molecules is sufficient to dramatically alter macroscopic properties such as wettability, biocompatibility, and adhesion. For example, fluorinated SAM precursors form monolayers ~1-nm thick with the same low wettability and resistance to adhesion typical of thick samples of Teflon™.[53] Many SAM films can be molecularly engineered to be patterned by various types of energetic radiation, including DUV, soft x-rays, ion beam, and low-energy electrons.[54] Scratching and microcontact printing (see below) can also be used to pattern SAMs. Structures less than 20 nm have been obtained by exposure with STMs and conventional EBL systems.[55] SAMs have successfully been deposited on metals like gold, aluminum, titanium, zirconium, silver, copper, and platinum, as well as on SiO_2, GaAs, and other surfaces.[53] The quality of the films depends strongly on surface pretreatment. Pinhole density on a Au surface of less than 5/mm^2 has been reported (see Müller and references therein[55]). Alkane-thiols and dialkyldisulfides are typical precursor materials for SAMs on gold, the most extensively studied substrate. The formation of long chain ω-substituted dialkyldisulfides on gold was first demonstrated in 1983.[56] Films of better quality are formed by the adsorption of alkylthiols.[57] Alkanethiols and dialkyldisulfides are lipid-like organic molecules having the general formula HS-$(CH_2)_n$-X and X-(CH_2)-SS-$(CH_2)_m$-Y, respectively, where n and m indicate alkyl chain length and X,Y the end groups (e.g., -CH_3, -azobenzene, -OH).[58] Organosilanes are often used to form SAMs on Si. These molecules form a Si-O-substrate siloxane bond on the Si surface, and the alkyl group R is responsible for the ordered nature of the film. For $n > 6$ (n is number of carbon groups in the R chain), SAMs have substantial crystalline order at the air/monolayer interface.[53, 58]

Microcontact printing, discussed below, also takes advantage of SAMs, and so does DNA and protein patterning, discussed in Chapter 8. Microcontact printing can be considered a merging of top-down manufacturing techniques (i.e., traditional lithography used to make the elastomeric stamp) with bottom-up manufacturing (i.e., proteins used to ink the stamp as building blocks). Protein and DNA patterning has evolved into an important research application for lithography. It is easy to imagine arrays with several different enzymes, antibodies, or DNA probes immobilized precisely onto a small transducer surface as a diagnostic panel for clinical applications. Different approaches for patterning organic materials are reviewed in Chapter 8.

Ultrathin Film Resist Layers

Polarity changes are at the heart of the newest ultrathin film (UTF) resist strategies. UTF resists represent the next evolutionary step in surface imaging technologies (see Chapter 1). In UTF, only the top monolayer of the resist changes, opening up the potential for further resolution improvement. Calvert et al.[59] use a few monolayers (<10 Å) of organosilanes, which are chemisorbed onto a substrate. These chemisorbed films are easier to prepare and more robust than the physisorbed LB films (see above). DUV irradiation of these films cleaves organofunctional groups from the film and produces an extremely hydrophilic surface (water contact angle < 10°) to which colloidal Pd/Sn catalyst does not adhere. Subsequent electroless deposition occurs only on those surface regions that were not irradiated. Thus, patterns of electroless Ni, Co, and Cu are produced on a variety of substrates, including silicon, quartz, alumina, metals, and polymers. These metal patterns serve as an efficient plasma-etching mask for pattern transfer. Fabrication of 0.3-μm line widths has been demonstrated in this way.[50, 59]

Block Copolymer Lithography

Block Copolymers Background

Self-assembly of block copolymers is widely investigated as a simple, inexpensive means for patterning high-density arrays of nanoscale features.[60] Block copolymers comprise two or more different monomer units, strung together in long sequences, which

can self-assemble into highly ordered lattices with unit cell dimensions of 10–100 nm. This length scale reaches well below the limits of conventional optical lithography. The simplest block copolymer architecture is the diblock. In diblock copolymers, two different types of polymer chains are connected at one end with a covalent bond (in a triblock copolymer, three different polymer chains are involved, etc.). The immiscibility between the unlike segments drives them to self-assemble into periodic domains, a process termed "microphase separation." This self-assembly process is driven by an unfavorable mixing enthalpy and a small mixing entropy while the covalent bond between the two blocks prevents macrophase separation. The size and shape of the periodic domains are dependent on the molecular weight and composition of the copolymer and typically assume morphologies of spheres, cylinders, and lamellae. These morphologies that represent different phases are dictated by the Flory-Huggins interaction parameter χ, the degree of polymerization N (i.e., number of monomers per chain, proportional to the polymer molecular weight), and the volume fraction f of the blocks.[61] The Flory-Huggins interaction parameter χ is a dimensionless parameter, which expresses, in units of kT, the energy change when one takes a molecule of pure A from an environment of pure A and puts it in an environment of pure B; it is inversely proportional to temperature and reflects the interaction energy between the different segments of the polymer chains. As χ increases, phase separation becomes more likely, and as N increases, phase separation becomes less so. From Figure 2.30, we glean that if the volume fractions of the blocks are close to equal, a layered morphology is observed. When moving toward less equal block ratios, the observed morphologies go through a bicontinuous gyroid structure, hexagonally packed cylinders, and finally body-centered cubic-packed spherical domains. Thus, microphase separation leads to a wonderful variety of exotic ordered phases, increasing rapidly with the number

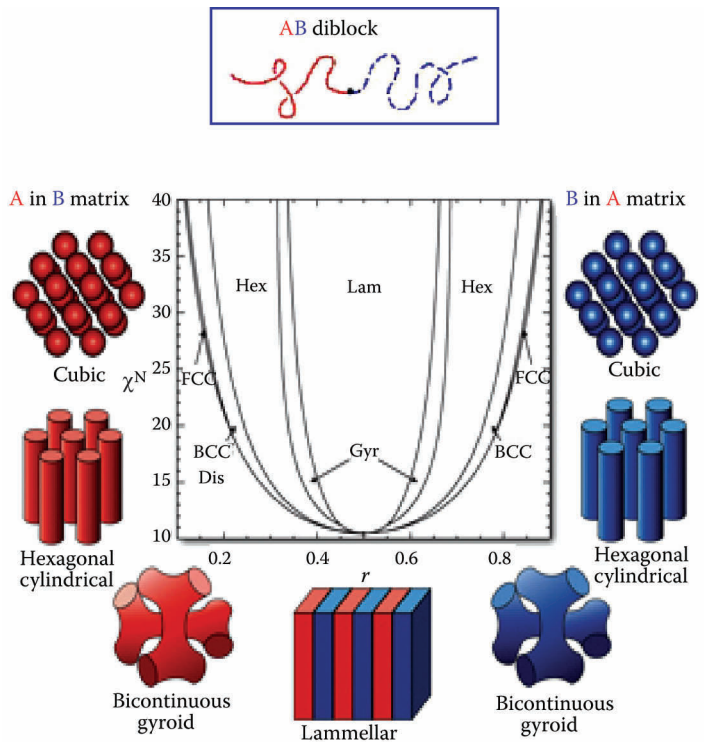

FIGURE 2.30 Schematic diblock copolymer phase diagram: f = volume fraction of A in B, χ = Flory-Huggins interaction parameter, N = diblock degree of polymerization. Known equilibrium mesophases are spheres, cylinders, gyroid, and lamellae, as well as the disordered (homogeneous) state at small interblock segregation strength (χN). (Diagram adapted from Matsen, M.W., and F.S. Bates. 1996. Unifying weak- and strong-segregation block copolymer theories. *Macromolecules* 29:1091–98.[62])

of blocks (with a triblock copolymer, a veritable "zoo" of structures results).

Block Copolymers Lithography

The previous section applied to bulk block copolymers. What about applying thin layers of block copolymers to surfaces? On surfaces, the microphase separation also results in nanoscale structures (domains) with sub-100-nm length scales, unless the surface has too strong an interaction with the polymer blocks that it prevents them from assembling. Block copolymer lithography refers to the use of block copolymers in the form of thin films, in which the domain structure provides a template for additive or subtractive pattern transfer operations, as illustrated in Figure 2.31. The idea of using block copolymer thin films as lithographic masks, as shown here, was first proposed in 1995 by Mansky et al.[63] In Figure 2.31, we compare traditional lithography with block copolymer lithography. The material chosen for the block copolymer lithography demo is from IBM work, where a diblock copolymer, in which polystyrene and PMMA are tied together in one chain (referred to as PS-b-PMMA, with total molecular weight in the range of 60,000 g/mol), is used.[64] When spun onto the surface of a silicon wafer, the two polymers separate, and although the molecules stretch out, the chemical bonds keep them attached. Subsequent heat treatment above the polymer glass transition temperature completes the microphase separation. Typical annealing conditions are 200°C (in a vacuum or N_2) for times ranging between 30 minutes and 24 hours, depending on the application. In the end, PMMA ends up concentrated in small cylinders surrounded on all sides by polystyrene. Thus, the diblock copolymer forms on its own into a nearly

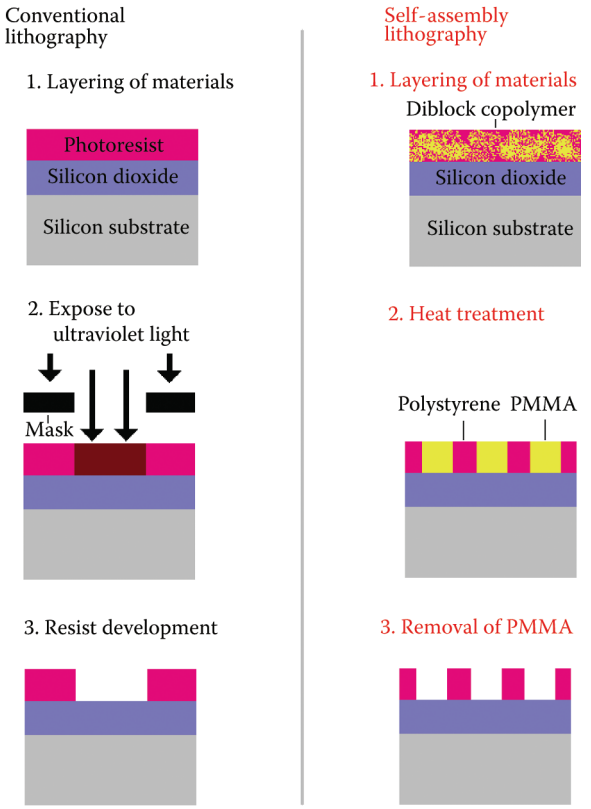

FIGURE 2.31 Traditional lithography compared with block copolymer lithography. Conventional lithography exposes a photoresist to ultraviolet light. A solvent etchant then removes the exposed part of the photoresist (for a positive type photoresist). Self-assembly patterning occurs when a diblock copolymer is heated, thereby separating the two polymers in the material into PMMA and polystyrene domains. The PMMA can then be selectively etched away, and the template of cylindrical holes can be transferred into the silicon dioxide. (Adapted from Stix, G. 2004. *Nano patterning: IBM brings closer to reality chips that put themselves together.* http://www.fractal.org/Fractal-Research-and-Products/Nano-patterning.htm.[65])

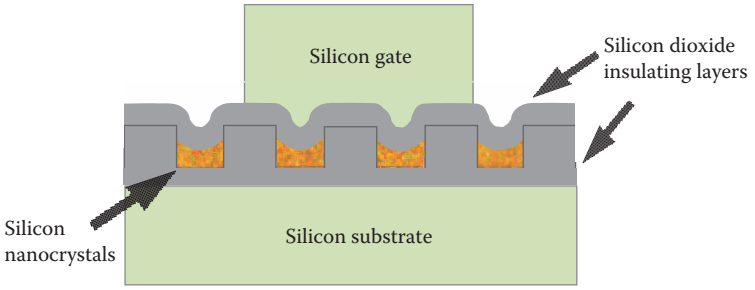

FIGURE 2.32 Flash memory: a layer of self-assembled silicon nanocrystals is inserted into an otherwise standard device as part of a novel IBM manufacturing process. Ruiz, G. Breyta, J.Y. Cheng, M.E. Colburn, K.W. Guarini, H.-C. Kim, and Y. Zhang. 2007. Polymer self assembly in semiconductor microelectronics. *IBM J Res Dev* 51: 605–33.[65,64])

perfect honeycomb-like template without the need of UV exposure or a mask.

Finally, the IBM team created an array of 20-nm-wide pores in the polystyrene matrix by removing the PMMA using an organic etching solvent (acetic acid). The same team used the thus-obtained perforated polystyrene structure to create the flash memory cells illustrated in Figure 2.32.[64] After the PMMA etch, a subsequent etching step was used to transfer the same honeycomb pattern into an underlying layer of silicon dioxide. Next the polystyrene template is removed, and subsequently, nanocrystal formation is accomplished by conformal a-Si (amorphous or nanocrystalline Si)* deposition over the whole wafer, and a dry anisotropic a-Si etch is used to remove all the deposited silicon except for that deposited in the holes in the oxide matrix. All that is left in the end are nanocrystalline cylinders surrounded by silicon dioxide. The final steps place an insulating layer of silicon dioxide (7-nm-thick control or program oxide) over the top of the Si nanocrystal islands and a polysilicon control gate is defined on top of the control oxide using conventional lithography. These flash devices are programmed by injecting charge into the nanocrystals (through the program oxide) and erased by expelling charge from the nanocrystals.

Creating closely spaced holes for a flash memory as demonstrated here is exceedingly difficult to accomplish with ordinary lithographic and deposition methods. Forming nanocrystalline silicon using these conventional techniques creates elements of different sizes. In contrast, the self-assembled nanocrystals are evenly spaced and of uniform size, improving their durability and their capacity to retain a charge while allowing the cylinders to shrink to dimensions even smaller than 20 nm.

For most lithography applications, we must also be able to control the orientation of the self-assembled pattern with respect to the underlying substrate surface. Whereas the self-assembly process itself is driven by microphase separation of the constituent copolymer blocks, the ultimate pattern orientation is determined by the relative strength of the surface affinity for each block. Control of block copolymer film thickness plays a critical role in determining vertical and lateral ordering and alignment of the nanostructures. A variety of approaches for controlled domain orientations have been attempted, including topographic prepatterns and/or chemical prepatterns, an external electric field, thermal field, and several other methods as reviewed by Segalman,[66] Hawker and Rusell,[67] Black et al.,[64] Stoykovich and Nealy,[68] and Hamley.[60]

In Figure 2.33, the patterned wettability (polar vs. nonpolar stripes) of the surface is used to align the nanodomains. Substrates are often preferentially wetted by one of the blocks of the copolymer, and the domains, e.g., lamellae or cylinders, tend to orient parallel to the substrate (see Figure 2.33a and b, where all the lamellae align parallel to

* Nanocrystalline silicon (nc-Si) is an allotropic form of silicon that is similar to amorphous silicon (a-Si), in that it has an amorphous phase. However, nc-Si has small grains of crystalline silicon embedded within the amorphous phase. This is in contrast to polycrystalline silicon (poly-Si), which consists solely of crystalline silicon grains, separated by grain boundaries. The term nanocrystalline silicon refers to a range of materials around the transition region from the amorphous to the microcrystalline phase in a silicon thin film.

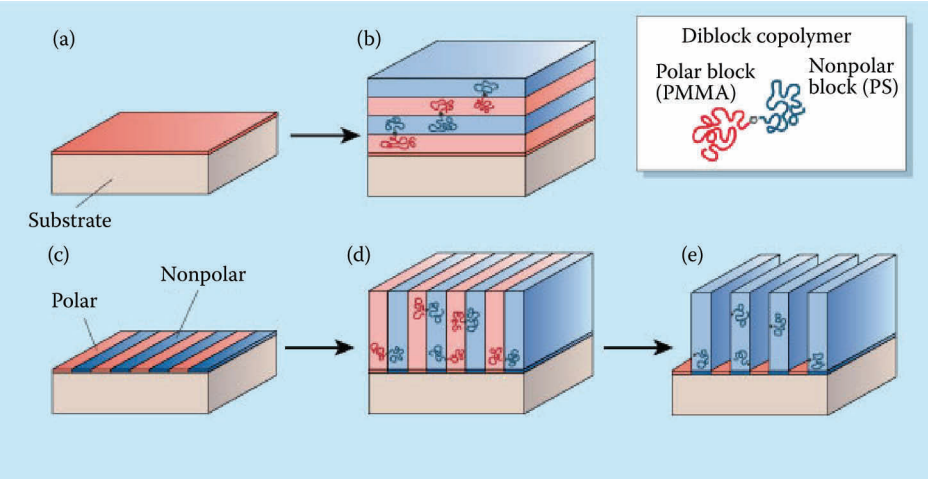

FIGURE 2.33 Patterned wettability of the surface causes the alignment of the nanodomains of a block copolymer. PMMA, polymethylmetacrylate; PS, polystyrene.

the substrate). Chemical modification can be used to neutralize or overcome surface and interfacial forces that tend to drive the domains to form parallel to the plane of the film. Controlling the interactions at the interfaces and scaling of the prepatterns can achieve parallel and perpendicular alignments of the lamellae achieved as shown in Figure 2.33c and d: the polar PMMA block aligns over the polar stripes and the nonpolar polystyrene blocks over the nonpolar stripes. The block copolymers on the surface arranged themselves into the underlying pattern without imperfections. In Figure 2.33e we show a finished structure after etching away the PMMA.

In a significant accomplishment, Kramer's group[69] (University of California, Santa Barbara) has patterned single crystals of 10-nm block copolymer spheres across an entire 2-in.-diameter silicon wafer. The silicon wafer was first patterned with photolithography to produce 12-µm-wide hexagonal wells. A single layer of block copolymer spheres was then self-assembled inside those wells. Assessing the quality of the self-assembly of the block copolymer in perfect crystal patterns is very challenging because of the small feature size. Whereas high-resolution microscopy can resolve individual block copolymer domains, this technique is limited to extremely small sampling areas (~10^{-6} mm^2). The Santa Barbara team used grazing-incidence small-angle x-ray scattering (GISAXS) to check for the crystal quality over macroscopic areas (~2 mm^2), and they established it as nearly perfect, demonstrating that single crystals resulted in each well. These results clarify why copolymers constitute a viable avenue toward building photonic crystals.

Summary/Applications

The obvious interest in using block copolymers for patterning is derived from the fact that they can self-assemble to form dense arrays of nanostructures with dimensions and spacings that are difficult or even impossible to create by other means or are prohibitively expensive to fabricate using conventional lithographic materials and processes. Polymer self-assembly can define only a limited set of pattern geometries. However, within these constraints the materials provide a straightforward means for achieving feature sizes (<20 nm), pitches (<40 nm), and densities (~$10^{11}/cm^2$) that are currently not achievable by optical lithography.

The use of block copolymer films to pattern dense arrays of features is more than a decade old, and other reviews have covered this topic in more detail (for example, see Segalman,[66] Hawker and Rusell,[67] Stoykovich and Nealy,[68] and Hamley[60]). These review articles reveal that patterns of dense periodic arrays fabricated with block copolymer templates have been demonstrated, and in some cases are being commercialized for the fabrication of quantum dots, magnetic storage media, flash memory devices (see Figure 2.32), semiconductor capacitors, nanowires, photonic crystals, and

nanopores. At IBM, a polymer self-assembly process was successfully integrated into a 200-mm semiconductor fabrication facility at the IBM Thomas J. Watson Research Center in Yorktown Heights, New York.[64]

Zone Plate Array Lithography

Fresnel Zone Plate

Before getting into the details of zone plate array lithography (ZPAL), we take a look at the building blocks of a ZPAL, i.e., Fresnel zone plates. A Fresnel zone plate, invented by the French physicist Augustin-Jean Fresnel, is a single plate consisting of alternating opaque and transparent circular zones as illustrated in Figure 2.34. Zone plates use constructive interference of light rays from adjacent zones (Fresnel zones) to form a focus. The zones are spaced so that diffracted light constructively interferes at the desired focus. The Fresnel zone plate is a relative of the pinhole camera in that it does not use mirrors or lenses for its imaging properties. Because a diffraction lens can be manufactured using planar technologies, it is easier to make than a traditional refractive lens. The zone plate is especially useful in the UV and x-ray regions of the spectrum, for which other imaging devices are hard to find. Self-supporting gold zone plates have been manufactured for these spectral regions. Moreover, it comes with a higher refractive index, allowing for better contrast at the image plane. Unfortunately, the zone plate has low efficiency and suffers from veiling glare because most of the light incident on the zone plate passes through it undiffracted and falls onto the image plane.

The focal length f of a zone plate with many zones is a function of the radius of the outermost zone, r_n, and its width, Δr_n, where n is the number of zones and depends also on the wavelength λ (see Figure 2.34), or:

$$f = \frac{2r_n \Delta r_n}{\lambda} \tag{2.3}$$

To get constructive interference at the focus, the zone boundaries in a zone plate should switch from opaque to transparent at radii where:

$$r_n^2 = n\lambda f + \frac{n^2\lambda^2}{4} \tag{2.4}$$

$$r_n = \sqrt{n\lambda f + \frac{n^2\lambda^2}{4}} \tag{2.5}$$

and simplifying when the zone plate is small compared to the focal length:

$$r_n = \sqrt{n\lambda f} \tag{2.6}$$

where n is a positive integer, r_n is the radius of the nth zone, f is the primary focal length, and λ is the wavelength of the illumination source. A Fresnel zone plate functions very much like an optical lens. Its optical properties do not depend on the material used, though, but are determined at the design time. For example, the diffraction limited resolution for

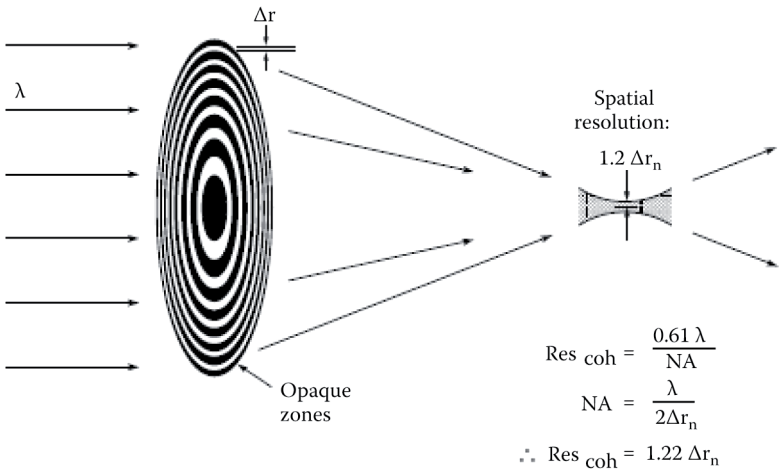

FIGURE 2.34 A Fresnel lens. (From http://xradia.com.)

coherent light Res_{coh} of a zone plate is governed by the Rayleigh principle as:

$$\text{Res}_{coh} = 0.61\frac{\lambda}{NA} \text{ and with}$$

$$NA = \frac{\lambda}{2\Delta r_n} \text{ we obtain:} \quad (2.7)$$

$$\text{Res}_{coh} = 1.22\Delta r_n$$

The resolution depends only on Δr_n, the outermost zone width. NIL and EBL can be used for the fabrication of large arrays of high NA diffractive Fresnel lens arrays.

In optical lithography, further increasing the NA of a lens is difficult and costly (see Figure 1.80 where a maximum NA of around 0.9 is projected). In diffractive optics, making a high NA lens is not significantly different than making a low NA lens. At MIT, Fresnel lenses with an NA of 0.7–0.9 have been achieved.[70]

Zone Plate Array Lithography Detailed

Zone plate array lithography (ZPAL) requires no masks but rather uses arrays of individually targetable optical beams as shown in Figure 2.35. Beamlets of photons, which can be rapidly turned on and off,

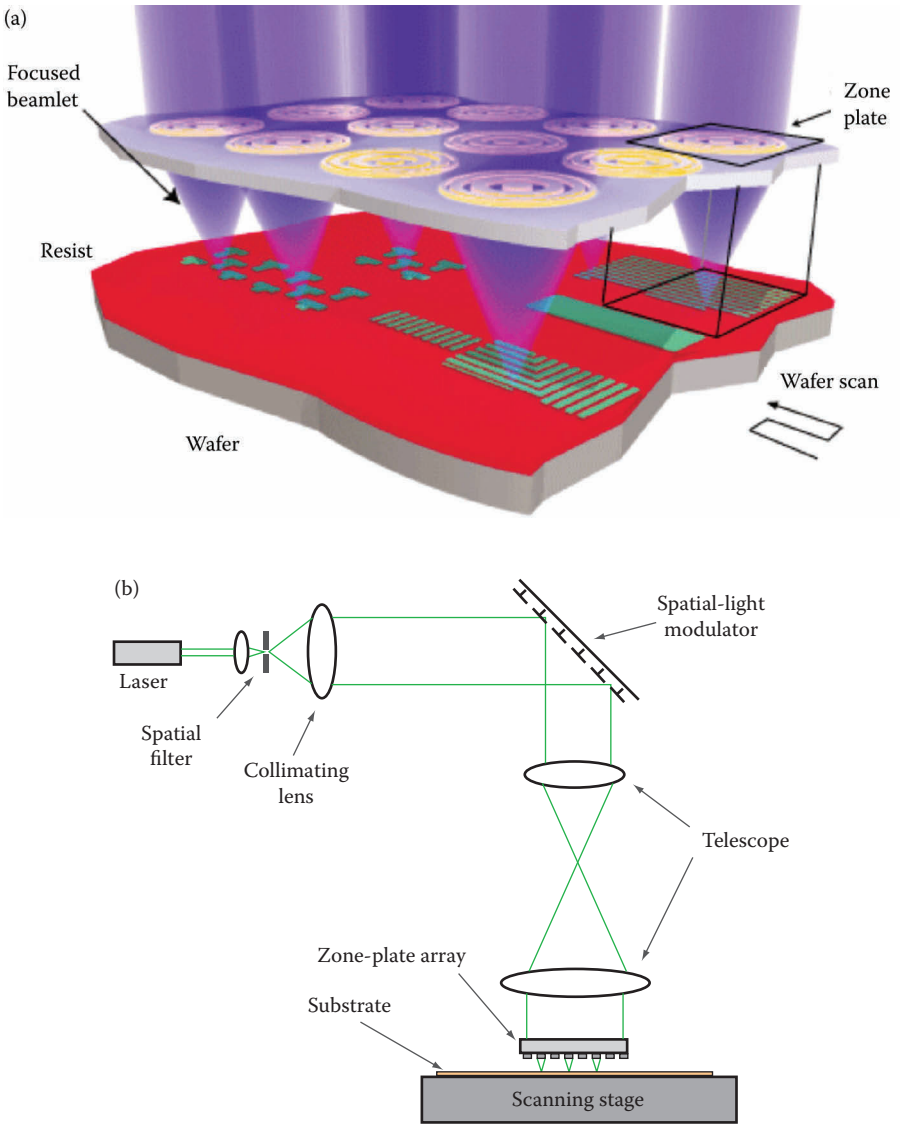

FIGURE 2.35 (a) Lumarray (http://www.lumarray.com) has demonstrated fully multiplexed ZPAL writing. (b) A laser beam is passed through a spatial filter and a collimating lens onto a digitally controlled programmable spatial light modulator (SLM), which replaces the photomask.[70,71]

are projected through diffractive Fresnel zone plate lenses (see above), allowing myriad complex shapes to be fabricated. The zone plates are made using lithography techniques, and the shutters for each beamlet are micromechanical movable mirrors. ZPAL was originally developed at MIT's nanostructures laboratory in the mid to late 1990s.[70] As shown in Figure 2.35a, each zone plate is responsible for one unit cell of photoresist exposure corresponding to the diameter of one individual zone plate. The writing with the shutters on and off results in dot-matrix-type lines, and moving the wafer in a serpentine fashion under the focused beamlets results in a full pattern.

ZPAL is an example of maskless optical projection lithography (MOPL, see Chapter 1); a laser beam is passed through a spatial filter and a collimating lens onto a digitally controlled programmable spatial light modulator (SLM), which replaces the photomask (see Figure 2.35b). In one of the MOPL systems described in Chapter 1, the SLM used is the Texas Instrument micromirror array (see DMD™, Example 7.10). In operation, a desired pattern is fed into the SLM, and the movable mirrors create the desired image. This image is demagnified and focused by a single reduction lens on the wafer to expose the photoresist. The use of refractive optics prevents the extension of this type of MOPL to wavelengths much shorter than 157 nm.

In the ZPAL system, the MIT team uses the Grating Light Valve™ (GLV)* from Silicon Light Machines (http://www.siliconlight.com) as the light modulator. In contrast to MOPL, not a single refractive reduction lens is used. Instead, an array of (high NA) diffractive Fresnel lenses ("the zone plates") is used to focus the incident light onto an array of spots on the photoresist-coated substrate. The light source in the ZPAL system preferably is a continuous wave laser (a pulsed laser source, as used in MOPL, severely limits system throughput). Light from the laser is passed through a collimating lens to create a uniform beam incident on the SLM, and the SLM breaks that beam up into individually controllable beamlets. A telescope is placed such that each beamlet is normally incident on one zone plate in the array. A Fourier filter within the telescope ensures that there is sufficient contrast between the on and off states. Each zone plate behaves like a microscopic lens focusing the light into a tight on-axis spot in its focal plane. The diffractive Fresnel lens optics in ZPAL allow the technique to scale to much shorter wavelengths than what is possible with MOPL (even x-rays are feasible).

In Chapter 1 we used a dimensionless constant k_1 to define the practical limiting resolution R in projection printing as:

$$R = k_1 \frac{\lambda}{NA} \tag{1.16}$$

where k_1 depends on resist parameters, process conditions, mask aligner optics, and so on. The MIT team and a startup company called Lumarray (http://www.lumarray.com) have demonstrated fully multiplexed ZPAL writing, multilevel alignment, and resolution corresponding to $k_1 < 0.3$ [this is without any resolution-enhancing technology (RET) applied to it].[71] In theory, ZPAL could use 193-nm optical lithography to inexpensively produce 45-nm chips. Moreover, this technology should theoretically work with 157-nm lithography and EUVL to create 20-nm ICs. ZPAL's main competition at this point is regular 193-nm lithography enhanced with immersion lithography, a combination that could etch 45-nm features (see Chapter 1). ZPAL, however, might be a less-expensive and an easier solution. As in optical projection lithography, to increase NA, immersion lithography can also be applied to ZPAL; in experiments at MIT, a resolution improvement of 1.36 was achieved this way.[71]

Quantum Lithography

Background

In optical projection lithography, a reduced-size image of complicated patterns is reproduced onto a photoresist. If light always followed the law of geometrical optics, there would be a point-to-point

* The Grating Light Valve™ (GLV) technology comprises a series of microscopic ribbons on the surface of a silicon chip; the GLV device is a diffractive MEMS that acts a dynamic, tunable grating that can switch, attenuate, and modulate laser light.

relationship between the object (mask) and the image planes (resist). But, as we saw in Volume I, Chapter 5, light is a wave, and resolution is limited to a finite spot size, defined by the "point-spread function". This point-spread function determines the spatial resolution of the imaging setup and limits the ability to produce demagnified images (see Rayleigh limit of 0.6 λ/NA, Volume I, Chapter 5). It has been demonstrated that quantum lithography with entangled *N*-photon states beats this Rayleigh diffraction limit by a factor of *N*; thus, in two-photon lithography the resolution is improved by a factor of two (as if one used a classical source with wavelength λ/2).[72,73] Einstein, Poldosky, and Rosen (EPR) described the entangled two-particle state according to the principle of quantum superposition in 1935, and they pointed out a surprising consequence: the momentum ΔP_x (position Δx) for neither photon is known (see Heisenberg uncertainty principle, Volume I, Chapter 3); however, if one particle is measured to have a certain momentum (position), the momentum (position) of its "twin" is known with certainty, despite the distance between them (this is known as the EPR paradox).[74] The entangled photon pairs come out from a point of the object plane, undergo two-photon diffraction, and result in twice-narrower point-spread function on the image plane as shown in Figure 2.36.

Two-Photon 3D Lithography

Two-photon lithography is an intrinsic 3D lithography technique that enables the fabrication of structures difficult to produce by conventional single-photon processes and with far greater spatial resolution than most other 3D microfabrication techniques. As we discuss in Chapter 8 in the section on stereolithography, the use of laser rapid prototyping by polymerizing a resin point by point enables the computer-aided manufacture (CAM) of 3D polymer MEMS structures. Linear absorption of laser light by a monomer for cross-linking typically limits the resolution to the wavelength of the laser that is used. Moreover, deep penetration of the photons into the resin bulk is impossible because of the strong absorption of the light, so that the process is carried out necessarily thin layer by thin layer (see Figure 8.30). Using two-photon excitation changes all this as it enhances the resolution and can penetrate deep into the bulk of the resin. When high-intensity light shines on a material, the probability for two-photon absorption is proportional to the square of the field intensity (see Volume III, Chapter 6 for an illustration of this effect), and thus is greatest at the center of a Gaussian laser spot. Using a high NA lens, the laser spot can be made less than 1 μm in diameter, and significantly narrower structures can be obtained because polymerization starts as soon as a certain threshold of intensity has been reached.

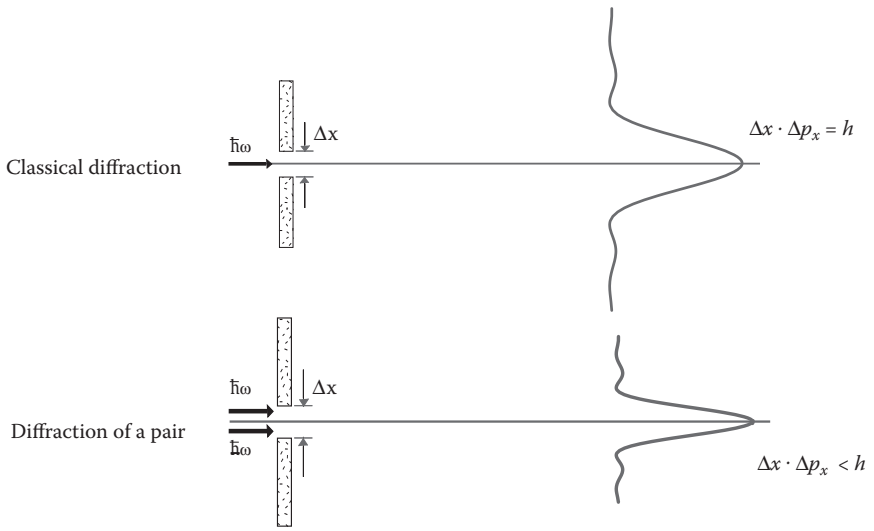

FIGURE 2.36 The entangled photon pair comes out from a point of the object plane, undergoes two-photon diffraction, and results in twice narrower point spread function on the image plane.

Therefore, by tightly focusing a femtosecond laser beam into a resin, subsequent photo-induced reactions such as polymerization occur only in the close vicinity of the focal point, allowing the fabrication of subwavelength lithography and 3D polymer structures. Importantly, because the energy required to initiate polymerization is twice that of the incoming radiation, it is possible to excite deep into the monomer as the material is transparent to one-photon excitation, whereas at the focus, where the intensity is high, two-photon excitation occurs.

Parthenopoulos and Rentzepis[75] first demonstrated the 3D microfabrication capability possible through two-photon polymerization in optical memory in 1989, and Wu et al.[76] pioneered the technique's utility for lithography in 1992. In two-photon lithography one often works with epoxy resins and urethane acrylates. Several two-photon photoinitiators with very large two-photon absorption cross-sections to be added to base polymers have been developed.[77] In these photoinitiator molecules the photon energy that is absorbed is emitted as photons of a higher energy (up-converted fluorescence). The up-converted fluorescence is then used to induce various photochemical reactions such as photopolymerization and photodissociation of the base resin. Two-photon photolithography experiments using this idea recently have achieved 120-nm spatial resolution using femtosecond laser pulses with a 780-nm central wavelength.[78] Below we will see that using two-photon lithography combined with apertureless near-field scanning optical microscopy (ANSOM), a resolution nearly a factor of 2 better than the resolution achieved in far-field two-photon lithography experiments can be achieved. We will also learn that combining a metallic ANSOM tip and femtosecond laser pulses, lithographic patterning with resolution of 70 nm in a SU-8 photoresist can be obtained.

As we clarified above, energy transferred to the photosensitive resin material by two photons of wavelength λ corresponds to that transferred by a single photon of wavelength $\lambda/2$. At the same time one takes advantage of long-wavelength exciting light with larger penetration depth, which enables 3D patterning of bulk material. Scanning the focus within the material allows one to produce microscale and submicroscale structures. Subwavelength structures can be produced because the absorption profile for the two-photon process is narrower than the beam profile. Some examples of 3D two-photon lithography are shown in Figure 2.37. The two-photon 3D lithography has also been used to make photonic crystals. In Chapter 8 on photochemical forming, we will come back to this two-photon 3D lithography process and its use in stereolithography or microphotoforming.

Quantum lithography is in its infancy, and many experimental challenges remain. The main problem is how to generate *N*-state entangled photons

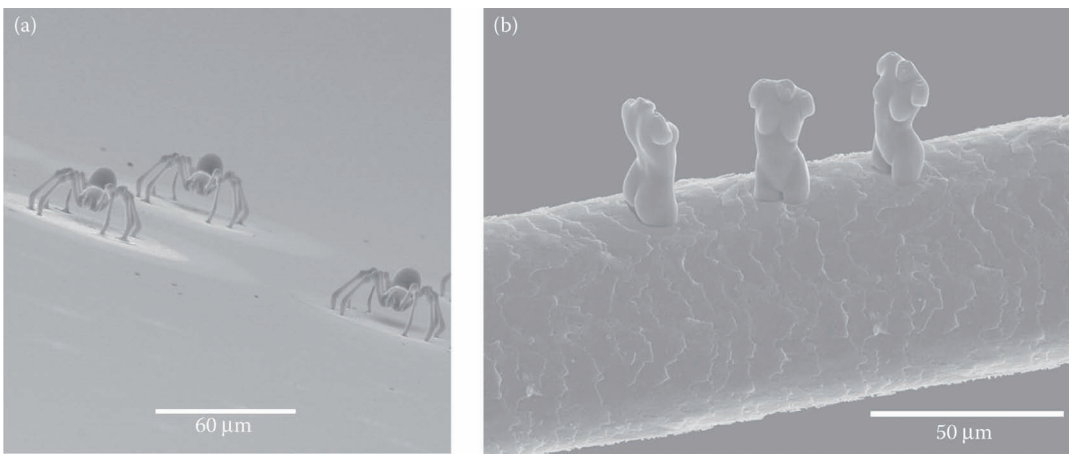

FIGURE 2.37 Two-photon 3D lithography. (a) Microspider array, the body of the spider is above the substrate; it is supported by eight 1-µm thick legs (http://www.laser-zentrum-hannover.de). (b) Venus micromodels on a human hair (http://www.laser-zentrum-hannover.de).

in a reasonable way. The next problem is how to develop an *N*-photon-sensitive photoresist. Third, the exposed field is very small. However, if we could overcome all three problems, we can beat the Rayleigh limit and approach the Heisenberg limit instead, thus approaching a resolution on the order of the atomic size.

Plasmon Lithography

Atwater and coworkers from Caltech introduced plasmon lithography in 2002. Plasmon lithography is based on plasmon resonance occurring in nano-sized metallic structures, allowing for the replication of patterns with a resolution limit considerably below the diffraction limit.[77] As we discovered in Volume I, Chapter 5 on photonics, when metallic nanoparticles are excited in an electromagnetic field, they can exhibit collective electron oscillations known as surface plasmon oscillations. With the diameter of the particle much smaller than the wavelength of the incoming light, the oscillating charges produce an oscillating dipole field around the metal particles. At resonance, i.e., when the excitation frequency coincides with the natural relaxation frequency of the nanoparticles (ω_p), this results in a strongly enhanced local electrical field. One can choose the nanoparticles such that their resonance frequency falls within the sensitivity range of an underlying photoresist. The field enhancement at the interface of the particle and the resist is then used to locally expose the resist, as schematically illustrated in Figure 2.38. A transparent mask with a configuration of metal nanoparticles deposited on it is brought into intimate contact with a thin layer of photoresist. Kik et al.[79] used spray deposition to obtain ~41-nm-diameter silver nanoparticles. To ensure that the local field intensity is enhanced directly below the metal particles, the illumination beam should be at a glancing angle to the resist (p-polarized light). Although the whole resist film is illuminated, development of the resist only affects the areas that received locally enhanced exposure. In this way an image of the mask pattern is transferred onto the resist layer. The choice of nanoparticle material and size depends on the required wavelength; as stated earlier,[79] the resonance wavelength should fall within the resist sensitivity window. For example, to be able to use standard g-line photoresist, the resonance wavelength should lie between 300 nm and 460 nm. Additionally, to obtain high-field enhancement, long electron scattering times (τ) are desirable. Silver is a good candidate, with long reported electron scattering times up to 10 fs and a resonance occurring at a wavelength of ~360 nm in air. The particles should also be small enough (<40 m) to attain confined dipolar enhanced fields at the resist interface. Particles that are too large develop multipolar oscillations as we detailed in Volume I, Chapter 5.

From Volume I, Chapter 5 we know that the resonance frequency of the metal nanoparticles is not a fixed quantity. For a spherical particle, for example, the surface plasmon resonance occurs at the wavelength λ for which ε' (dielectric constant of the particle) = $-2\varepsilon_d$ (dielectric constant of the medium). Consequently, the wavelength at which resonance occurs can also be tuned by changing the refractive index of the surrounding medium. Using this method Kik et al.[79] have shown that the local field enhancement occurring around metal nanoparticles when they are excited at the surface plasmon resonance frequency can be used to print nanoscale features in thin resist layers. Feature sizes less than $\lambda/10$ were generated in a parallel fashion using visible illumination and standard g-line photoresist. Further below we analyze ANSOM

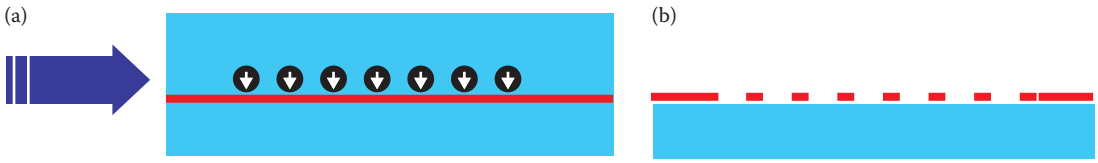

FIGURE 2.38 Schematic representation of plasmon printing showing glancing angle illumination using polarized visible light, producing enhanced resist exposure directly below the metal nanostructures in the mask layer (a), and the resulting pattern in the resist layer after development (b).

lithography, where a scanning metal tip is used to generate plasmons for exposing the underlying resist.

In Volume I, Chapter 5, we discussed how Pendry had the amazing insight that a superlens could be made from a flat slab of a negative refractive index material, which not only would bring incident rays to a focus but also has the capacity to amplify the near-field radiation so that it could contribute to image formation, thus removing the wavelength limitation completely. Thus, a superlens would prevent image degradation and beat the diffraction limit established by Abbe! We also discussed the development of a poor man's near-field superlens ($\varepsilon < 0$ and $\mu = 1$) in 2003 by Zhang's group at the University of California, Berkeley, who showed that optical evanescent waves can be enhanced as they pass through a silver superlens.[80] This team imaged objects as small as 40 nm across with their superlens, which itself is just 35-nm thick.[81] In contrast, current optical microscopes can only resolve objects down to around 400 nm. With the superlens, using 365-nm illumination, features of a few tens of 10 nm were imaged, clearly breaking Abbe's diffraction limit.

Scanning Proximal Probe Lithography

Introduction

Proximal probe techniques rely on the use of nanoscale probes, positioned and scanned in the immediate vicinity of a material surface. Their development is often viewed as a first step toward nanotechnology because they demonstrate the feasibility of building purposeful structures one atom or one (macro) molecule at a time. Proximal probes used in lithography might involve electrical methods where a scanning tunneling microscope (STM) tip generates a local field/current that modifies the region directly under the tip (e.g., SiH $\rightarrow$ Si). A second approach involves mechanical methods where a scanning force microscope (SFM/AFM) tip scrapes, thermally deforms, or transfers material at the surface; the latter material transfer method corresponds to dip-pen lithography (DPL). Third, it may involve a near-field scanning optical microscope (NSOM) tip or apertureless near-field scanning optical microscopy (ANSOM) that exposes photoresist under the tip only.

The use of single proximal probe tips for lithography poses a serious drawback in terms of processing speed. To use these techniques in the manufacture of ICs and data storage devices, it is necessary to devise a scheme for parallel processing by making arrays of these proximal probes.[82]

STM/AFM Background

The scanning tunneling microscope (STM) images the surface of conducting materials with atomic-scale detail (see Volume III, Chapter Six). STM was invented by Gerd Binnig and Heinrich Rohrer of IBM's Zurich Laboratory in 1981 (they received the 1986 Nobel Prize for their invention).[83] In general, STM works by bringing a small conducting probe tip up to a conducting surface. When the probe is very close to the surface (<10 Å) and operating voltages in the ±10-V range are applied, very small currents are produced because the electrons in the probe and the surface have wave functions extending beyond the physical surface boundaries. To the extent that these spillover wave functions overlap, a measurable current results. The interesting part about this current is that it depends exponentially on the spacing between the two conductors (as well as the voltage) (see Volume I, Chapter 3 in the section on tunneling). A piezoelectric transducer accomplishes the *z*-axis distance variation between tip and sample. By changing the distance over 1 Å, the current changes by a factor of 10. In practice, the current is kept constant through a feedback mechanism, and the probe moves up and down over the surface following the atomic contours it "sees." The images produced by the STM come from the electronic structure and from the geometry of the sample. Up to 100 times more powerful than SEMs, STMs measure objects in the angstrom range.

Over time, many proximal probe were developed, and STM belongs now to a large new family of very local, proximal probes, such as atomic force microscopes (AFMs), scanning electrochemical microscopes (SECMS), scanning thermal microscopes, scanning capacitance microscopes, magnetic force microscopes, and scanning pH probes, enabling microscopy of almost any type of material and

property (for more details see Volume III, Chapter 6 on metrology). The common feature of these instruments is that their resolution is not determined by visible light used for the interaction with the probed object, as in conventional microscopy.[84]

Besides their use for imaging and characterization of surfaces, proximal probes can also be used to modify solid surfaces. Below we introduce some examples of this type of proximal lithography.

Scanning Probe Lithography

Introduction In lithography, STM can produce nanostructures at higher resolution but at lower speed, whereas AFM can operate at higher scanning speeds but offers lower resolution. AFM can be used to image and pattern any kind of material, making AFM the more widely used technique. AFM/STM lithography can be classified as force assisted (including thermomechanical), bias assisted, and material transfer assisted.

Scratch Lithography—Mechanical Effect The simplest (and perhaps the crudest method) to pattern a surface with a proximal probe is by scratching in scratch lithography (see inset in the heading of this chapter: copy of Pablo Picasso's "Don Quixote" in polycarbonate patterned with scratch lithography). In this mechanical process, simply drawing an AFM tip across a surface with enough force may cut a trench, or the piezomechanism driving the AFM cantilever may be modulated in the *z*-direction to tap the tip on the surface as it is drawn over it. Cuts as narrow as 20 nm and 2 nm deep have been made in III–V semiconductor surfaces.[85] One difficulty with the scratching approach has been that probe tips often break following direct collision with a solid surface. As a possible solution, carbon nanotubes have been mounted on the tip of silicon cantilevers, enabling lines as narrow as 10 nm (Figure 2.39). Carbon nanotubes constitute the strongest material known along the axial direction and yet are highly elastic and flexible along the radial direction (see also Volume III, Chapter 3).[86]

The Naval Research Laboratory (NRL) worked with proximal probes to pattern thin films of chemically amplified negative e-beam resist (SAL601 from Shipley). Resist films of 30–70-nm thick were

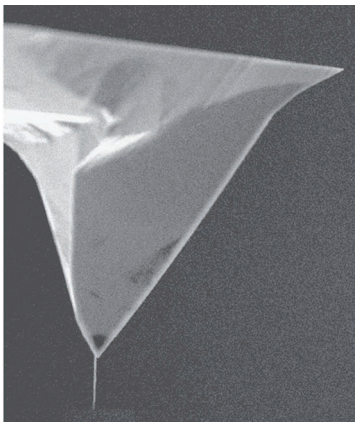

FIGURE 2.39 Nanotube mounted on the micromachined tip of a Si cantilever is used as a nanopencil for lithography of 20–10-nm lines (courtesy of Dr. M. Meyyappan, NASA Ames). SEM picture of nanotube mounted on tip of Si cantilever (http://cnst.rice.edu/pics.html).

patterned with typical tip-sample voltages from –15 to –35 V, resulting in minimum feature sizes of 23 nm.[54] Using SAMs as resists (see above), it was shown that the lower the exposure threshold energy of the film, the better the lithographic resolution. There are indications that, with these low voltages (~4 V), SAM resists will eventually yield sub-10-nm CDs.

In a variation on scratch lithography, a resistively heated AFM probe writes a data bit by scanning over a polymer surface. The combined heat and mechanical force of the tip causes the polymer to soften and flow, thus facilitating the writing of data bits in a storage medium (see the millipede chip developed by IBM for thermal writing in a polymer for memory; Figure 2.4b).

Electrical Field-Induced Chemical Modification—Electrochemical Effect In an alternative approach, surface oxides were induced on Si and GaAs by slightly increased tip voltages on samples held in a wet nitrogen atmosphere.[38] In this method, the water meniscus formed at the tip-sample gap is dissociated by the negative tip bias, and the O^- and OH^- oxidative ions react with the substrate to form localized oxide nanostructures. Because the molecular volume of the oxides is usually larger than that of the substrate materials, raised nanopatterns are formed after the oxidation reaction. These thin oxides, although only a few monolayers thick, are sufficiently robust to act as a mask for subsequent reactive ion etching of

the substrate.[54] The oxidation process is fairly general and may also be applied to Ti and Cr. At NRL, oxide features with lateral dimensions as small as 10 nm have been achieved.[54] Multilayer resist films for nanopatterning with SPL have also been developed. Sugimura et al.[87] work with a three-layer resist to pattern insulating substrates such as thermally grown SiO_2 with current injection from a scanning probe tip. The process sequence is sketched in Figure 2.40.

The bottom layer of the three-layer resist consists of 20 nm of amorphous Si (a-Si) and is prepared by ion-beam sputtering; a second layer consists of an intermediate 2-nm-thick Si oxide and is prepared by photo-oxidation of the top layer of the a-Si. The top resist layer is 2-nm thick and consists of an octadecylsilyl self-assembled monolayer (ODS-SAM). To pattern the resist on top of the insulating SiO_2, a bias voltage is applied between the AFM probe and the conductive a-Si layer, which is made positive. When a scanning probe is operated in the presence of atmospheric water vapor, the probe and sample are automatically connected via a tiny water column created by capillary forces of the adsorbed water. This assembly serves as a minute electrochemical cell. As a result of the electrochemical anodization reaction, the monolayer resist becomes degraded in the region where the probe has passed, and the underlying photo oxide grows thicker. A subsequent etch in 0.5 wt% HF removes the exposed oxide, and that pattern is then transferred to the underlying a-Si by an etch of the a-Si in an aqueous solution of 25 wt% tetramethylammonium hydroxide (TMAH). The latter solution etches Si but not SiO_2. The a-Si is etched, and the etch stops when the underlying insulator is reached. The underlying thermal oxide can now be etched in HF and the resist stripped. Minimum feature sizes reached so far are about 50 nm.

Electron Scanning Probe Lithography-Bias Effect

Lithography using electrons from a scanning microprobe offers several potential advantages over writing with a traditional e-beam source.[84,88] One important benefit is that the low energy of electrons in SPL (<50 eV) compared with those in EBL (10–100 keV) avoids the detrimental effects of electron backscattering, thereby virtually eliminating proximity effects and thus producing enhanced resolution and superior pattern fidelity.[54] Moreover, SPL using an STM can be operated in air, whereas EBL relies on a vacuum. Because of the small tip-to-sample distance,

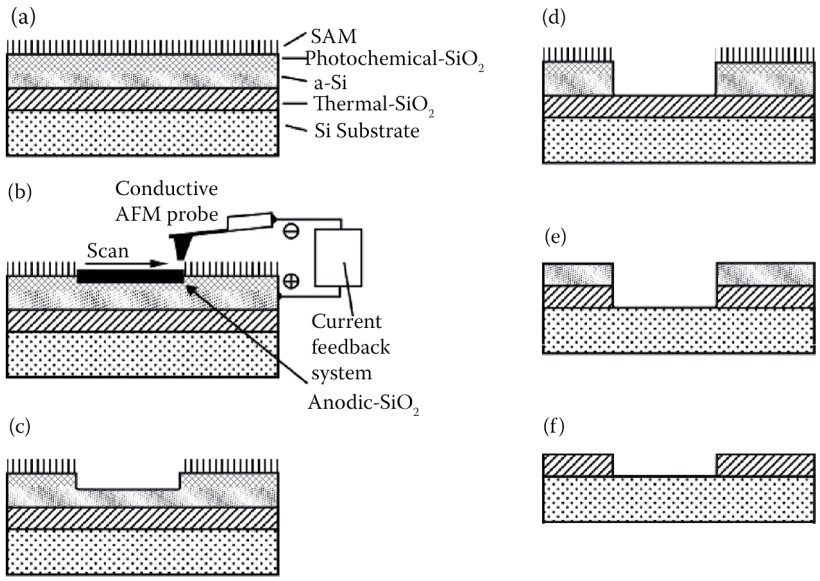

FIGURE 2.40 Schematic of AFM lithography on SiO_2 using a multilayered resist system. (a) Cross-section. (b) Exposure by drawing patterns into the ODS-SAM layer by current injection from an AFM probe. (c) First development step by HF etching to remove the SiO_2 just formed. (d) Second development step by TMAH etching to remove the a-Si in the exposed area. (e) Pattern transfer with HF to remove the thermal oxide in the exposed area. (f) Resist removal, i.e., removal of all the remaining a-Si in TMAH etch. (Based on Sugimura, H., O. Takai, and N. Nakagiri. 1999. Multilayer resist films applicable to nanopatterning of insulating substrates based on current-injecting scanning probe lithography. *J Vac Sci Technol* B17:1605–08.[87])

extremely small spot sizes are achievable so that the exposure dose may be confined to a beam diameter of less than 10 nm. The method enables wider exposure latitude than EBL, a fact demonstrated in Figure 2.41.[89] In this figure, line width is plotted versus dose for SAL601 resist using both EBL and SPL lithography systems. From the lower slope of the SPL curve, one deduces that SPL has higher dose latitude than EBL—in other words, SPL is less sensitive to dose variations. On the other hand, SPL is less sensitive and requires a higher dose to write the same feature size. The mechanism of electron bombardment in SPL is very different from that in EBL. In EBL, the mean free path of the bombarding electrons is long compared with the resist thickness. In contrast, low-energy electrons in SPL have a mean free path less than 2 nm and travel through the resist under the influence of an electrical field, undergoing a number of scattering events before reaching the resist/substrate interface.[89] The latter makes it clear why a thinner resist will result in a better resolution. The influence of secondary electrons (i.e., all electrons emanating from the resist/substrate) in proximal probe lithography was investigated, for example, by Völkel et al.[90]

Writing speeds of an SPL tool of 0.1–100 µm/s are typical, and several thousands of micrometers per second have been demonstrated.[91] However, very fast scanning will remain limited because the close tip-to-substrate distance (typically 1 nm with STM) is prone to cause tip crashes.

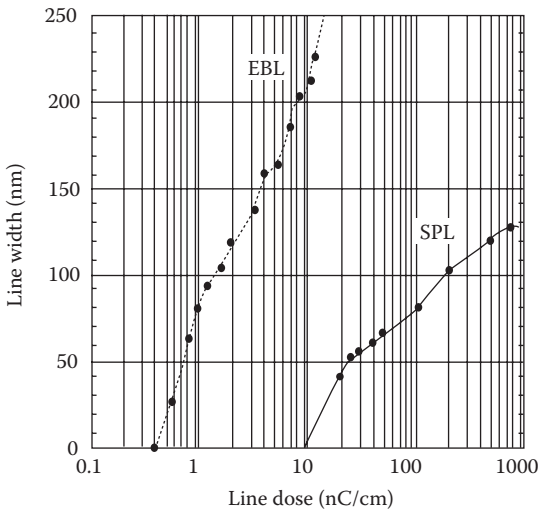

FIGURE 2.41 Line width versus dose for SAL601 resist using both EBL and SPL lithography systems. (Wilder, K., C.F. Quate, B. Singh, and D.F. Kyser. 1998. Electron beam and scanning probe lithography: a comparison. *J Vac Sci Technol* B16:3864–73.[89])

With an ultrasharp tip (radius < 10 nm) in the emission mode rather than the tunneling mode, one may stay as far as 100 nm away from the surface. This approach not only enables faster writing (limited by the response of the piezoelectric material only) without fear of crashing the tip as frequently, but the high beam current also contributes to the possibility for exposure of large area patterns. Even at a distance of ~100 nm, the beam diameter remains small at ~30 nm.[55] Structures of lateral dimension of ~20 nm have been created in SAMs using ultrasharp field emitters.[92] The use of arrays of micromachined electron emission sources to improve throughput was covered earlier (see Figures 2.22 and 2.23) as a type of lower energy EBL with less lateral backscattering. In this context a useful array of field emitters for EBL is the so-called Spindt cathode array[93] shown in Figure 2.42. The use of such an array in a field emission display is shown in Chapter 7 (Figure 7.90a). The cathode tips in Figure 2.42 are molybdenum, and electrons are extracted from the tip at gate voltages as low as 20 V (70–100 V is more typical). In the newest embodiments of Spindt arrays, the molybdenum tip is replaced with carbon nanotubes. The use of nanotubes as field emitters was first proposed by Walt de Heer, André Chatelain, and Daniel Urgate in 1995.[94] Carbon nanotubes are excellent field emitters because of their chemical, structural, and electronic properties, which afford important aspects of robustness that have been lacking in the conventional metal and silicon field emitter arrays.

Material Transfer Methods: Atom Lithography or Mechanosynthesis and Dip Pen Nanolithography

Atom Lithography or Mechanosynthesis As we just learned, proximal probe equipment locally modifies surfaces[95] and is used to expose resists and to oxidize and mechanically scribe surfaces. Also, a variety of direct atomic manipulations have been demonstrated with proximal probes.[95] The electric field strength in the vicinity of a probe tip is very strong and inhomogeneous (e.g., a field of 2 V Å^{-1} concentrated around the probe tip). This field can manipulate atoms, including sliding of atoms over

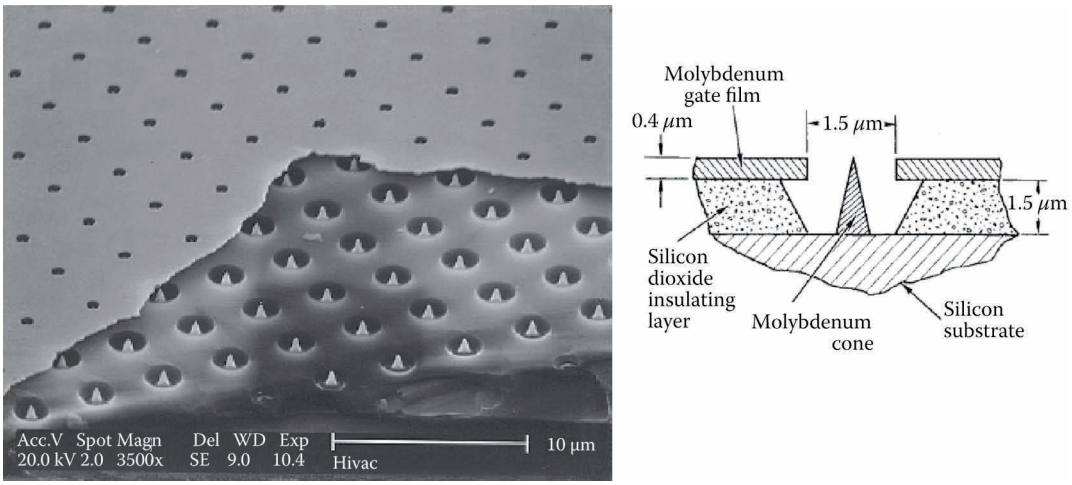

FIGURE 2.42 Spindt field emitter array. For its fabrication see Chapter 7, and for its application in a field emission display see Volume III, Chapter 10.

surfaces and transferring atoms by pick (erase) and place (write). Drexel calls this type of machining mechanosynthesis.[96] Although both positive and negative voltages have been used for the deposition, a tip with a negative polarity is usually more stable with higher transfer probability. These atomic manipulation processes may be classified in parallel processes and perpendicular processes. In parallel processes, an adsorbed atom or molecule is induced to move along the surface (sliding); in perpendicular processes, the atom or molecule is transferred from the surface to the tip of a proximal probe or vice versa. Patterning surfaces at the atomic level is demonstrated in Figure 2.43a where a 60 × 48-Å image of four Pt adatoms is shown. The four atoms were herded into a linear array.[95] Figure 2.43b shows seven Pt atoms compacted together. The theoretical resolution of a lithography technique based on these atomic probes is a single atom. Even with "only" a 100-Å resolution, a single memory bit could be stored in an area that measures 100 Å on a side. This will enable bit storage of 10^{12} bits/cm^2 as compared with 10^9 bits/cm^2 with conventional technology.

In Figure 2.44 we show linear Au chains 2–20 atoms long, written by Ho et al.[97] from the University of California at Irvine on a NiAl (110) surface via the manipulation of single atoms with an STM. Differential conductance (dI/dV) images of these gold chains reveal 1D electronic density oscillations at energies 1.0–2.5 eV above the Fermi energy. Thus, Ho et al. were able to make a direct correlation between the geometric structure and the electronic properties of the Au chains, where the former is precisely known and the latter is directly measured. The same team, again using STM, also connected Au chains to a copper phthalocyanine (CuPc) molecule.[98] A typical artificial molecule assembly is CuPc@2Au$_3$, consisting of a CuPc molecule and two Au$_3$ (three Au atoms in each chain) chains. When the separation between the Au chains is six lattice constants [of the underlying NiAl (100) substrate]

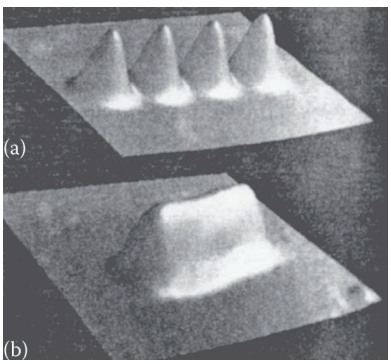

FIGURE 2.43 Atom manipulation for nanomatching. (a) A 60 × 48 Å STM image of four Pt adatoms assembled into a linear array on a Pt (111) surface. Pt atoms were herded four unit cells apart along a close-packed direction of the Pt (111) surface. (b) A 40 × 40 Å STM image of a compact array of seven Pt adatoms. (From Stroscio, J.A., and D.M. Eigler. 1991. Atomic and molecular manipulation with the scanning tunneling microscope. *Science* 254:1319–26. With permission.[95]) For more pictures of STM atom manipulation, visit http://www. almaden.ibm. com:80/vis/stm/gallery.html.

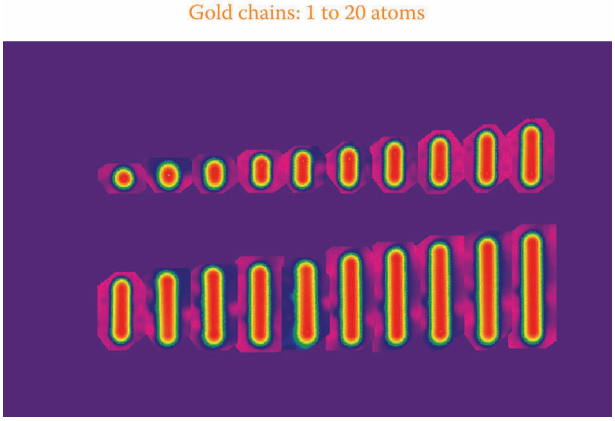

FIGURE 2.44 STM topographic images from a single Au atom to a linear chain of 20 atoms, arranged in single-atom increments from left to right. The images are cut from 20 separate scans, each taken with a sample bias voltage between 2.0 and 2.5 V and a tunneling current between 1.0 and 1.5 nA. Each chain has an apparent height between 2.4 and 2.7 Å. The chains between 12 and 20 atoms long were constructed and imaged with a tip different than the tip used to construct and image the other chains. (Wallis, T.M., N. Nilius, and W. Ho. Electronic density oscillations in gold atomic chains assembled atom by atom. *Phys Rev Lett* 89:236802-1–2-4.[97])

or more, a Pc molecule is unable to bridge the gap between the chains. With five lattice constants, the gap is small enough for a Pc molecule to fill it, and the molecule adsorbs symmetrically with two opposite benzene rings attached to the Au chains (see the schematic in Figure 2.45j).

This work by Ho's team is contributing to the detailed understanding of the electron transport through a molecule that bridges the gap between two metal electrodes. Electron transport through single-molecule junctions is determined by the local electronic structure of the nanoscale region that includes the molecule and a number of metal atoms in proximity to the molecule-metal contacts. As we will detail in Volume III, Chapter 3, a detailed understanding of the contact between metal-contacting electrodes and molecules is essential for the understanding of molecular electronics.

One major drawback to bear in mind with atom placing or removing techniques for micromachining is the time involved in generating even the simplest of features. If one wanted to deposit a metal line 10 µm long, 1 µm wide, and 0.5 µm high, 10^{16} atoms would need to be manipulated. Even at a deposition rate of 10^9 atoms/s, this would take more than 100 days. In the late 1980s, it took an IBM team 1 week to spell out the IBM logo with an STM, putting Xe atoms in place on a Ni surface. Only use of massive parallelism can help this cause.

Dip Pen Lithography AFMs suffer from an annoying problem: water from the air tends to attach itself to the tip, and the greater the relative humidity, the more water that collects. This water meniscus interferes with high-resolution AFM imaging. In 1999, Chad Mirkin, a Northwestern University researcher, realized that this meniscus could be turned into an asset. Because water is always moving from the tip to the substrate surface or vice versa, he decided to use it to float ink molecules onto the substrate. The principle of dip pen nanolithography (DPN) is shown in Figure 2.46.[99] DPN is named after the 4000-year-old dip pen, with an AFM tip for a sharp point.

A reservoir of "ink" is stored on the cantilever holding the scanning probe tip, which is manipulated across the surface, leaving lines and patterns behind. Lines as thin as 15 nm have been drawn. The attainable resolution depends strongly on the substrate roughness, the writing speed, and the relative humidity. Smooth surfaces, fast scan rates (and thus shorter pen/paper contact), and lower relative humidity (narrower water meniscus) all make for higher-resolution DPN. Thus far, most of the work has been carried out with a sulfur-containing compound called 1-octadecanethiol on gold surfaces. However, many inks and many different types of surfaces can be written on, making this an interesting nanolithography option. A review of different ink/substrate combinations in DPN was listed by Ginger et al.[100] An additional attractive feature of DPN lies in the fact that the same AFM can be used to write and image the results. The downside is that DPN is slow, but to offset this negative aspect, arrays of dip pens, similar to the millipede chip developed by IBM (see Figure 2.4b), can parallelize and speed up the technique: the newest array from Chad Mirkin's group has 55,000 pens.[101] Much needed now is the development of an automated ink-coating system for inking individual tips with its own ink; perhaps such a system

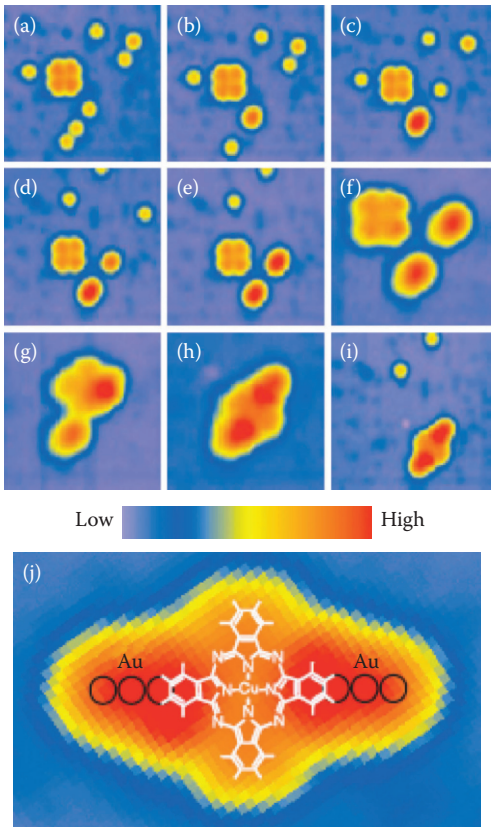

FIGURE 2.45 Assembly sequence and schematic for a structure consisting of a CuPc molecule and two Au_3 chains ($2Au_3$). All images were taken with V_{bias} = 1 V, I = 1 nA. (a) CuPc molecule (appears as a protruding four-lobe structure) on the NiAl surface together with seven Au atoms, which appear as round protrusions. Four of the atoms have been aligned along the same Ni trough. Image size is 74 Å by 74 Å. (b) One of the atoms has been manipulated along the Ni trough to create a Au_2 chain. (c) First Au_3 is created; another atom is positioned five Ni-Ni lattice sites (5 × 2.89 Å) away from Au_3, marking the starting position for another Au_3 chain. (d) A second Au_2 chain is created. (e) Assembly of the second Au_3 chain and the $2Au_3$ junction is completed. (f) Zoom-in image of the $2Au_3$ and CuPc molecule; the area of image is 47 Å × 47 Å. The image was taken with a tip modified by a CuPc molecule adsorbed on it. (g) The CuPc molecule has been moved into the junction between the two Au_3 chains. As is clear from the image, the molecule is adsorbed only on one of the chains. (h) The position of the molecule was adjusted by manipulating the leftmost lobe of the molecule in (g) toward the lower Au_3 chain. The molecule is adsorbed symmetrically between the two chains, forming CuPc@$2Au_3$. (The tip still has a CuPc molecule adsorbed on the apex.) (i) Image of same structure taken after removing the molecule adsorbed on the tip. The area corresponds to that of (e). (j) Schematic showing the relation between the internal molecular structure, adsorption geometry, and STM image. Black circles represent the Au atoms comprising the two Au_3 chains. (From Nazin, G.V., X.H. Qiu, and W. Ho. 2003. Visualization and spectroscopy of a metal-molecule-metal bridge. *Science* 302:77–81.[98])

can be achieved through the integration of microfluidic technology. Besides its use in nanolithography one can envision the use of DPN for placing of molecules on a surface precisely where one wants them as in protein and DNA arrays and to build 3D nanostructures. Mirkin et al.[102] have shown that through the use of DPN, protein nanoarrays can be constructed with high fidelity of specific protein binding to proper sites on a Si substrate. NanoInk (http://www.nanoink.net) is a start-up company commercializing the DPN technology.

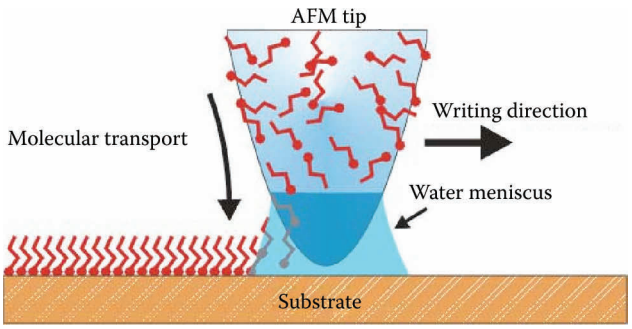

FIGURE 2.46 Dip pen nanolithography: transport of molecules to the surface via water meniscus (http://chem-groups.northwestern.edu/mirkingroup/dpn.htm).

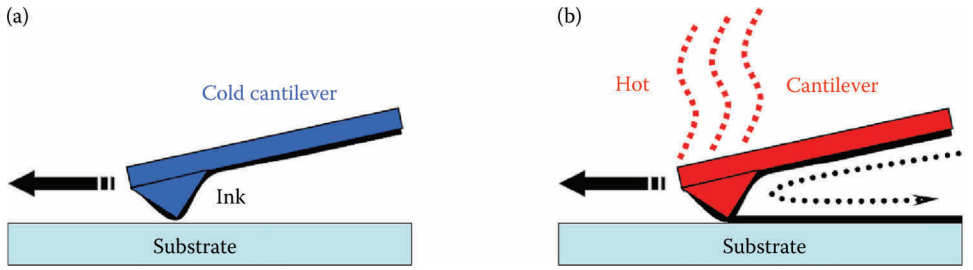

FIGURE 2.47 Diagram illustrating thermal dip pen nanolithography. When the cantilever is cold (a), no ink is deposited. When the cantilever is heated (b), the ink melts and is deposited onto the surface. (Image courtesy of Naval Research Laboratory, http://gtresearchnews.gatech.edu/newsrelease/tdpn.htm.)

In Figure 2.47, we illustrate an extension of DPN, a writing method dubbed "thermal dip pen nanolithography." In conventional DPN, the probe tip is coated with a liquid ink, which then flows onto the surface to make patterns wherever the tip makes contact. This approach has been hampered by an inability to turn the ink flow on and off. A thermal-DPN (tDPN) method developed by Georgia Tech's William King and NRL's Lloyd Whitman solves this specific problem by using easily melted solid inks and special AFM probes with built-in heaters that allow writing to be turned on and off at will.[103,104] Moreover, conventional DPN cannot be used in a vacuum because liquid inks evaporate, whereas the solid materials used in the thermal process bond to surfaces, allowing them to be used in vacuum environments that are part of conventional semiconductor manufacturing. The thermal materials also provide sharper features because they do not spread out like liquid inks.

In Figure 2.49 a topographic image of a surface scanned with a heated AFM cantilever tip for 256 sec in each of four 500-nm squares is shown. The cantilever temperature is shown for each of the four scans. No writing is observed from the two low-temperature scans. The scan at 98°C resulted in light deposition. Robust deposition occurred during the final scan when the cantilever temperature was increased to 122°C.

Combining thousands of individually controlled AFM pens into arrays could allow writing of faster and more complex semiconductor patterns. One of the first inks used in thermal writing was octadecylphosphonic acid, which melts at about 100°C. But the tDPN technique has been used also to apply other materials, including solders and polymers.

Near-Field Optical Scanning Microscope and Apertureless Near-Field Scanning Optical Microscopy

Introduction: Breaking the Diffraction Limit To obtain a resolution better than Abbe's optical microscopy limit ($\Delta x \sim \frac{\lambda}{2NA} \sim 200$ nm, based on Volume I, Equation 5.1), complicated and costly electron microscopy (with resolution of a few nanometers) or STMs (with atomic resolution) are required. Unfortunately, these techniques sacrifice many of the advantages associated with traditional optical microscopes (including nondestructiveness, low cost, high speed, reliability, versatility, accessibility, ease of use, informative contrast, spectroscopy, and

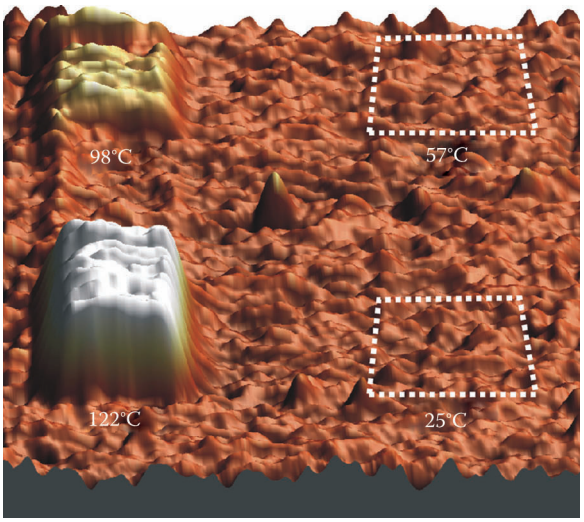

FIGURE 2.48 A topographic image of a surface scanned with a heated AFM cantilever tip for 256 s in each of four 500-nm squares. The cantilever temperature is shown for each of the four scans. No deposited material is observed from the two low-temperature scans. The scan at 98°C resulted in light deposition. Robust deposition occurred during the final scan when the cantilever temperature was 122°C. (Courtesy of Naval Research Laboratory.)

real time). As seen in Volume I, Chapter 5 on photonics, combining a scanning proximal probe technique with optical microscopy in so-called scanning near-field optical microscopy, NSOM provides an attractive solution to this dilemma. In NSOM, the sample is illuminated by a nanoscopic light source located close to the surface (10 nm), and the resolution is dictated by the source diameter *a*, or $\Delta x \sim a \leq 100$ nm. This is achieved by using nanoscale apertures in NSOM or by using apertureless techniques (e.g., a scattering metal tip) in ANSOM or scattering scanning near-field optical microscopy. A typical NSOM probe is a commercial single-mode optical fiber, tapered and coated by a thin CrAl film with an aperture of ~100 nm. In ANSOM, light interaction over nanoscale dimensions is enhanced with the use of scattering nanoscale tips, nanospheres, and so on. The conceptual idea of near-field optics and near-field microscopy came from the seminal proposal of E. H. Synge. It was Synge (in 1928) who proposed that if source or detector is scanned close to a surface, resolution is dependent on probe size and probe-sample distance instead of the Abbe limit.[105] Synge corresponded about his idea with Einstein, who accepted the concept but was doubtful that it could be reduced to practice. But Einstein was wrong; today NSOM is an important tool for nanotechnologists. NSOM constitutes a form of lensless optics with subwavelength resolution, independent of the wavelength of the light being used! The light coming from an imaged object in the near field contains a considerable amount of nonpropagating, evanescent waves containing high lateral spatial resolution, information that decays exponentially within a distance comparable to a wavelength. It is this evanescent wave information, the information-rich light, we capture in NSOM and ANSOM, thus enhancing the resolution. Several NSOM implementations using apertures and SNSOM were illustrated in Volume I, Chapter 5.

Aperture-based probes are the best developed and come with a typical resolution of 50–100 nm. Tip fabrication involves heating and pulling and chemical etching of glass optical fibers. Apertureless probes enhance local scattering and feature a 1–20-nm resolution. NSOM and SNSOM microscopy are reviewed in Volume III, Chapter 6.

NSOM and ANSOM Lithography Besides their utility for imaging applications, NSOM and ANSOM may also be used for direct write optical nanolithography.[106] From the above, near-field scanning optical microscopy refers to the interaction of light with a sample close to a metal aperture (NSOM) or a solid metal tip (ANSOM). The light source is held in place in a manner similar to those used for other scanning proximal probe microscopes. To write patterns into a photoresist, one uses aperture NSOM in illumination mode or ANSOM in plasmon mode. The first NSOM lithography results obtained in several labs dealt with nanometric tips on standard positive photoresist and on self-assembled monolayers of alkanethiols and using laser sources visible up to the UV range. The NSOM approach to improved spatial resolution in lithography unfortunately is limited because of the very small apertures, through which only a very small fraction of the light can be transmitted. ANSOM overcomes this problem by using sharp metallic tips instead of fiber apertures to achieve nanometer-scale resolution. In ANSOM, light is polarized along the sharp axis of the metallic tip, and this induces a high concentration of surface plasmons that results in strong enhancement of the electromagnetic field in the local vicinity of the tip—typically more than a few tens of nanometers (see plasmonic printing with metal nanoparticles discussed above)! Yin et al.[107] demonstrated near-field two-photon optical lithography by using 120-fs laser pulses at 790 nm in an apertureless near-field optical microscope and produced lithographic features, even without optimization, of 70 nm in a commercial SU-8 resist. Thus, combining ANSOM with two-photon absorption can provide a spatial resolution as high as $l/10\ \lambda$, nearly a factor of two better than the resolution achieved in previous far-field two-photon lithography experiments.

Limitations of NSOM and ANSOM lithography include very low working distances, very shallow depth of field, and very long scan times for patterning large surfaces with a high-resolution image.

Holographic Lithography

Holography Background

As this section concerns holographic lithography, a short reminder about what holography is, is in

order. Holography comes from the Greek words for *whole* (holo) and *graphy* (or graphic, image), standing for "the entire image." The Hungarian physicist Dennis Gabor invented holography in 1948 and received the 1971 Nobel Prize for Physics for it. However, the field of holography only took off after 1962 with the invention of the laser, providing the coherent light needed to make a hologram. In holography two laser beams are used, a reference and an object beam, to snap pictures of an object. If these two beams are coherent, optical interference between the reference beam and the object beam, as a result of the superposition of the light waves, produces a series of fringes on standard photographic film. These fringes form a type of diffraction grating on the film, which is called a hologram. To reconstruct the image in the imaging medium one can go about it two different ways. First, on using the same reference light that was used to record the hologram, one obtains a virtual image of the object. Second, if one uses the phase conjugate light of the reference light to shine through the recording medium, the image of the object is reproduced.

Holographic Lithography or Interference Lithography

As mentioned above, a hologram is a complex interference pattern that can recreate a 3D image. In Figure 2.49 we show how a generic hologram is recorded. The "partially silvered" mirror in this figure reflects and transmits fractions of the incident light. This is useful because the reflected and transmitted beams are coherent (i.e., have a definite common phase) even when the incident light has a time-varying random phase. From Volume I, Chapter 5 we indeed recall that reflection from a surface produces a "phase-flip" of 180° in the reflected light. This is true for a 180° reflection. However, when light is reflected at an angle other than 180°, the phase change in the reflected light is the same as the reflection angle. Thus, light reflected at 90° has a 90° change in phase. In holographic lithography the specific object is the mask.

In holographic or interference lithography (Figure 2.50), a holographically constructed photomask replaces the standard photomask.[108,109] In the holographic recording or construction phase of the hologram (Figure 2.49), one uses the interference of two mutually coherent beams. A well-collimated flood laser (object beam) passes through the photomask and is diffracted by the mask features. This signal beam contains the amplitude and phase information of the photomask. When this diffracted object beam passes through the holographic recording layer, it interacts with the reference beam to create the interference pattern. The reference beam converts the amplitude and phase information into intensity information, which is stored in the photosensitive holographic medium (Figure 2.50a). The light-sensitive recording layer stores the holographic image data as variations in the refractive index of the photopolymer. Pattern printing or image reconstruction is accomplished by scanning a collimated laser illumination beam—the phase conjugate of the reference beam—to create the hologram. By interaction with the recorded hologram, the latter beam generates an image of the original photomask at precisely its original position in space (Figure 2.50b). When a

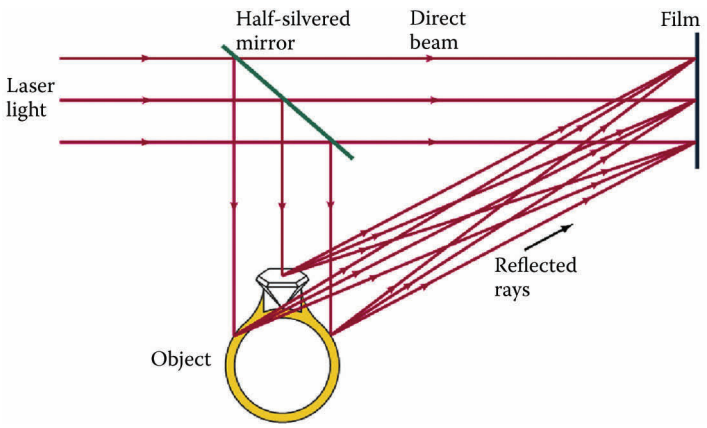

FIGURE 2.49 Recording a hologram. (From John G. Cramer.)

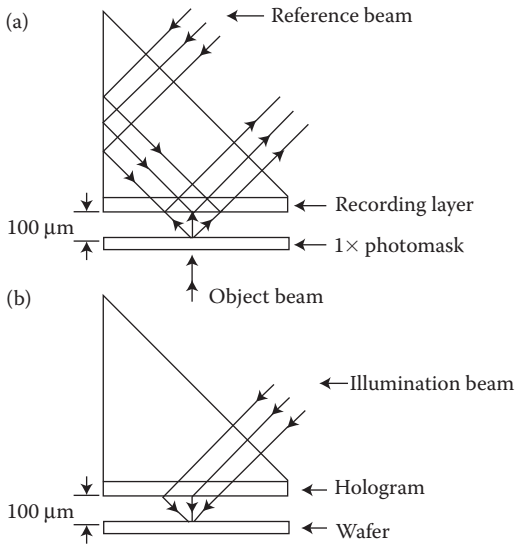

FIGURE 2.50 Basic arrangement for holographic lithography. (a) The photomask pattern forms a hologram in the polymer recording layer. (b) Using the illumination beam, the high-resolution holographic mask image is reconstructed into a printable masking layer in the resist-coated substrate. (From Brook, J., and R. Dandliker. 1989. Submicrometer holographic photolithography. *Solid State Technol* 32:91–94; and Omar, B., S. Clube, F. Hamidi, M.D. Struchen, and S. Gray. 1991. Advances in holographic lithography. *Solid State Technol* September:89–94.[108,109])

photoresist-coated substrate resides in this plane, a copy of the original mask can be printed. The image is diffraction limited, but because the holographic mask and the wafer can lie very close, a high NA and thus a very good resolution are possible (0.3 µm has been reported). Only the size of the photomask itself restricts the image field size. The holographic image of the original mask exactly overlays the wafer surface with a full field (large area recording).

Holographic lithography may also use the interference pattern of multiple coherent lasers. Simple grating patterns, 2D dot arrays, and 3D lattice patterns can be fabricated using two-, three-, and four-beam interference, respectively.

Holographic lithography is readily extendible to electrons. Spacings of a few nanometers to even less than 1 nm have been reported using electron holograms.[110] This is because the wavelength of an electron is always shorter than for a photon of the same energy. Atom lithography is also possible: the momentum of an atom is even larger than for electrons or photons, allowing even smaller wavelengths, per the de Broglie relation.

A benefit of using interference lithography is the quick generation of dense features over a wide area without loss of focus. A major drawback of interference lithography is that it is, in general, limited to patterning arrayed features. Recently, holographic lithography has emerged as a very promising technique for the inexpensive fabrication of high-quality 3D photonic crystals. Together with direct laser writing approaches, holographic lithography offers the attractive possibility of controlled incorporation of functional elements using direct laser writing in a second step.

Soft Lithography

Introduction

Soft lithography refers to a series of methods that use a patterned elastomer as a stamp, mold, or mask to generate micropatterns and microstructures instead of using a rigid photomask. Soft lithography has become an important tool in the nanofabrication arsenal.[111] Today the name is a collective term for a set of new techniques: microcontact printing (µ-CP), microtransfer molding (µ-TM), micromolding in capillaries (MIMIC), and microreplica molding.[112] The method is a very exciting research tool and may offer advantages over conventional methods for patterning of nonplanar substrates, unusual materials, and large areas.

In soft lithography, a master mold is first made by lithographic techniques, and an elastomeric stamp [e.g., polydimethylsiloxane (PDMS); see Figure 2.51] is cast from this master mold. A simple example procedure for making a PDMS (Sylgard 184, Dow Corning, http://www.dowcorning.com) stamp from a photolithographically patterned resist layer as master mold is outlined in Figure 2.52. A thin layer of SU-8 photoresist [SU-8 (50) from MicroChem, Newton,

MA] is coated on a Si wafer. The resist is patterned by UV lithography. To make things really fast (<24 h) and inexpensive (<$20), the contact mask for the UV lithography may be a transparency on which—using drawing software such as Freehand—a design is printed with a high-resolution printer (>3300 dpi). After development, the photoresist is treated with (tridecafluoro-1,1,2,2-tetrahydrooctyl)-1-trichlorosilane (Hüls Chemicals, http://www.degussa.com) vapor to facilitate PDMS removal once cured. A 10:1 ratio of a PDMS mix is cast on the photoresist film and cured for 1 hour at 60°C in an oven.[111]

PDMS has many properties that make it suitable as a stamp material. It 1) provides a surface that has a low interfacial free energy (~21.6 dyn/cm), 2) is chemically inert, 3) is nonhygroscopic (does not swell with humidity), 4) passes gas easily (don't start laughing now), 5) has good thermal stability (~186°C in air), 6) is optically transparent down to ~300 nm, 7) is isotropic and homogeneous, 8) is durable (stamps may be used > 50 times over several months without degradation), and 9) has interfacial properties that are easy to modify.[114]

Many PDMS stamps can be generated, and each one may be used many times. The rubber stamp can be used in a number of different ways. Some different soft lithography processes are outlined below. For further reading on soft lithography, consult Xia et al.[113,114] and visit the soft lithography homepage at University of Washington/Washington Technology Center (http://www.ee.washington.edu/research/microtech/cam/CAMsoftlithhome.html). Another excellent site to follow the experimental steps involved in soft lithography is on JoVE (http://www.jove.com), the "YouTube" for experimental procedures.

Microcontact Printing

In microcontact printing (μ-CP), the PDMS rubber stamp is coated with an ink of the molecules (e.g., alkylthiols or a protein) that one wants to print in selected patterns on a solid substrate. During stamping, only the raised parts of the stamp collect the "ink." The inking of the substrate consists of self-assembled monolayers (SAMs) on the solid surface formed by covalent chemical reaction. The inked areas are self-passivating and exhibit very low interfacial tension that repels additional molecular layers; therefore, SAM forms only in areas of conformal contact between polymer and substrate. STM studies of the transferred SAMs reveal an achievable monolayer order indistinguishable from that found for SAMs prepared from solution.[53] The SAM pattern acts as a highly localized and efficient barrier to some wet etches. This lithographic technique—once the master is made—is not subject to diffraction or DOF limitations. The deformability of the elastomeric stamp allows it to accommodate rough surfaces. The method even works on rounded substrates (such as optical fibers or lenses) with radii of curvature of less than 10 μm. PDMS-based elastomers do not adhere to novolak or PMMA-based polymers, allowing convenient replication of masters formed by EBL.[53] The technique has been used, for example, to build an antibody grating on a Si wafer by inking the rubber stamp with an antibody solution.[115] The antibody grating alone produces insignificant diffraction, but on immunocapture of cells the optical phase change produces diffraction.

In Figure 2.53 we illustrate a generalized scheme for microcontact printing of proteins.

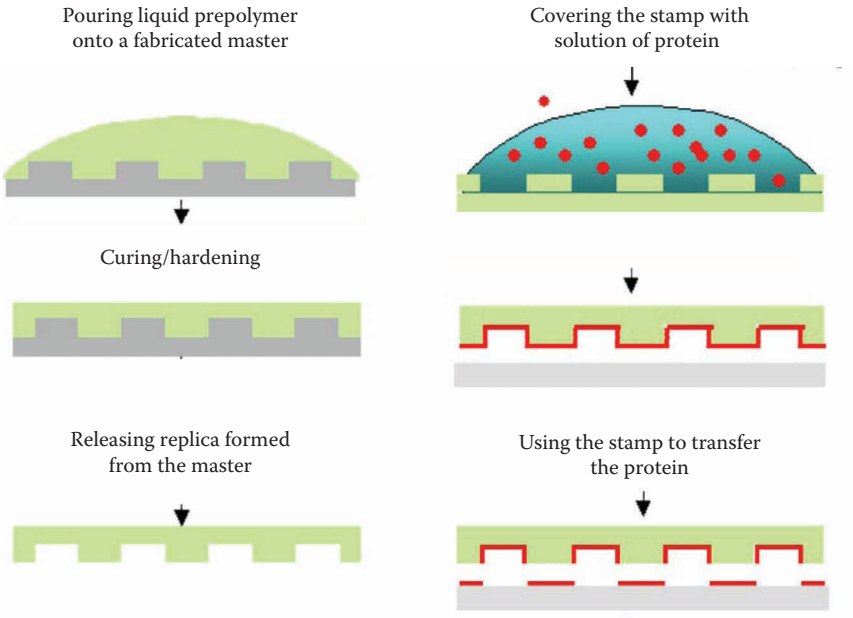

FIGURE 2.53 Microcontact printing of protein.

Microtransfer Molding

In microtransfer molding (μ-TM), illustrated in Figure 2.54, the rubber mold is filled with a polymer precursor, and the rubber stamp is pushed up against a substrate (e.g., a Si wafer or another flat sheet of PDMS).[116] The polymer in the rubber stamp relief is cured and transferred to the substrate, and the stamp is peeled off. Schueller et al.[111] used this technique to make curved glassy carbon microgrids. In this case, a photoresist was used as polymer precursor and cured while sandwiched between a patterned PDMS rubber stamp and a planar PDMS sheet. To obtain the curved carbon grid, the PDMS sandwich was deformed against a curved cylinder during curing. After removing the two thin strips of PDMS, the free-standing and curved photoresist grid was pyrolized (carbonized, see Volume III, Chapter 5) at high temperature in an argon atmosphere (Figure 2.55).

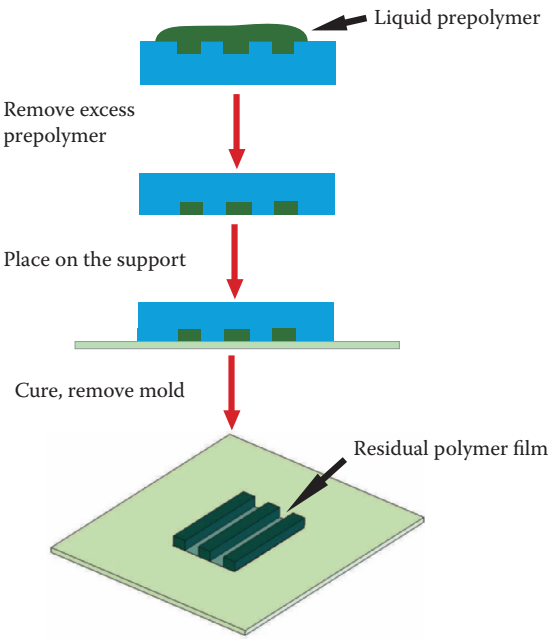

FIGURE 2.54 Schematic description of microtransfer molding (μ-TM). (Based on Xia, Y., and G.M. Whitesides. 1998. Soft lithography. *Angew Chem Int Ed* 37:550–75; and Xia, Y., and G.M. Whitesides. 1998. Soft lithography. *Ann Rev Mater Sci* 28:153–84.[113,114]) PU is prepolymer (polyurethane).

Micromolding in Capillaries

In micromolding in capillaries (MIMIC), illustrated in Figure 2.56, the rubber stamp is pushed up against a substrate, and liquid is applied to access holes in the mold. The liquid wicks into the cavities formed by the rubber mold against the substrate. Sometimes this process is pressure, electro-osmosis, or vacuum assisted.[117] The polymer is cured, and the stamp is removed. MIMIC has been used to fabricate polymeric transistors.[118]

Microreplica Molding

In microreplica molding, the master mold is replicated in PDMS by casting and curing the PDMS prepolymer (polyurethane, PU); this negative replica is then oxidized in an oxygen plasma for 1 minute and exposed to fluorinated silane for 2 hours to provide a surface with low adhesion to PDMS. PDMS is then cast against this negative replica, cured, and peeled away to reveal a positive replica of the original master.[109]

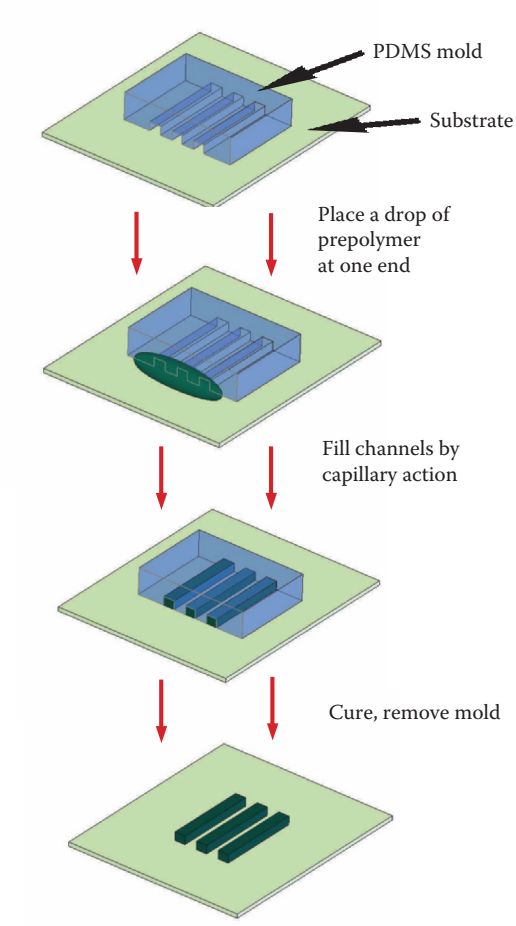

FIGURE 2.56 Schematic description of micromolding in capillaries (MIMIC). (Based on Xia, Y., and G.M. Whitesides. 1998. Soft lithography. *Angew Chem Int Ed* 37:550–75; and Xia, Y., and G.M. Whitesides. 1998. Soft lithography. *Ann Rev Mater Sci* 28:153–84.[113,114])

Soft Lithography Summary

Soft lithography is capable of generating structures as small as 30 nm and is especially attractive as a potential method for fabricating devices on nonplanar substrates. The major advantage of soft lithography is its short turnaround time. It is possible to go from design to production of replicated structures in less than 24 hours. The method is low cost, and, unlike photolithography, soft lithography is applicable to almost all polymers and thus to many materials (e.g., carbon, glasses) that can be prepared from polymeric precursors.

Some of the disadvantages of PDMS-based soft lithography include 1) shrinkage during curing (~1%), 2) swelling by nonpolar solvents such as toluene and hexane, 3) thermal expansion, 4) level of defects in printing SAMs, 5) softness of the material limits the achievable aspect ratio through sagging, and 6) deformation of the soft elastomeric stamps. These factors limit the accuracy in registration across a large area and may limit the practical utility in nanofabrication and multilayer devices.[114] Because soft materials are used, deformation of the stamp/mold, low reproducibility (because of distortion), and defects (yield) are problems that prevent this technology from being a viable manufacturing technique. The technique constitutes a very handy research tool but most likely will not reach the commercial manufacturing stage.

Soft lithography technology inspired new approaches to fabricate nanodevices that do not have commercial potential, i.e., NIL and SFIL (see above). For example, Krauss et al.[115] used NIL to fabricate a 400-Gb/in.^{2} storage device containing sub-10-nm minimum features. As we saw earlier, in NIL the master mold may be an electron beam and RIE-patterned SiO_2 layer (e.g., 10-nm-wide features with 40-nm period and 75-nm tall). This mold is then imprinted into a 90-nm-thick PMMA film on a Si disk. During the hot embossing, the mold and resist-coated disk are heated to 175°C and pressed together at 4.4 MPa for 10 minutes. After cooling to room temperature, the mold is separated from the disk, resulting in replication

of the nano-CD pattern in the PMMA film. Surface Logix, Inc. is the first commercial entity based entirely on the exploitation of soft lithography.

Questions

Most of the questions by Mr. Chuan Zhang, UC Irvine.

2.1: Extreme ultraviolet lithography (EUVL) is one of the most promising future lithography techniques. Explain why EUVL increases the resolution dramatically. The high cost is the major obstacle for the commercialization of this technology; list the major reasons for the high cost of EUVL.

2.2: Compare the differences between traditional projection photolithography and extreme ultraviolet lithography. Why do reflective optics have to be used in an EUVL system?

2.3: Why does x-ray lithography have a high depth of focus? LIGA is less promising as a future MEMS technique due to the requirement of a synchrotron source. List the competing technologies and explain why they might replace LIGA.

2.4: Is the resolution of e-beam lithography given by the spot size of the focused beam? Explain why or why not. What are proximity effects, and how can one minimize their impact on the resolution?

2.5: What are the differences between thermionic emission (also called Schottky emission or SE) and cold field emission (CFE)? What are the advantages of low-energy electron beam lithography?

2.6: What is the difference between direct write e-beam lithography and electron projection lithography? Describe the working principle of SCALPEL (scattering with angular limitation projection electron beam lithography).

2.7: Describe the major procedures in nanoimprint lithography.

2.8: How can a diblock copolymer be used in lithography? List some of the merits of block copolymer lithography.

2.9: How does a Fresnel zone plate work? What are the major merits of Fresnel zone plates over diffractive optics lenses? Can they be applied in lithography?

2.10: What is the definition of scanning proximal probe lithography? Which technologies can be counted as scanning proximal probe lithography?

2.11: How does near-field optics break Abbe's diffraction limit? What is the difference between NSOM and ANSOM lithography?

2.12: What are the major steps in soft lithography? Explain the reasons why they have not been widely used in industry.

2.13: How would you make a conical shaped PMMA structure that is 150 μm tall and features a top angle of 45°?

2.14: Design a miniaturized device incorporating both a lift-off process and a self-aligned mask step in its manufacture.

2.15: Why can only proximity masking be used in the case of x-ray lithography? What about projection printing with x-rays? Sketch the process for fabricating an x-ray mask. What are some of the positive attributes of x-ray lithography? What are the negative attributes?

2.16: Compare UV, x-ray, ion-beam, and electron-beam lithography. Summarize in a comparison Table. Which techniques are used mostly in the IC industry today? How are the photons or charged particles created in each case?

2.17: Most lithographies provide projected shapes. A truly 3D shape (e.g., a contact lens) is harder to make. Which lithographies are capable of providing 3D shapes?

2.18: How could one make scanning tunneling microscopy (STM) into a mass production ready lithography technique? What type of resists would you use?

2.19: Compare masks for the next-generation lithography. Consider the need for vacuum, materials, feature size, cost, etc.

2.20: What are the advantages and disadvantages of using e-beam lithography compared to typical photolithography?

2.21: What difficulties do you expect in trying to implement immersion lithography commercially?

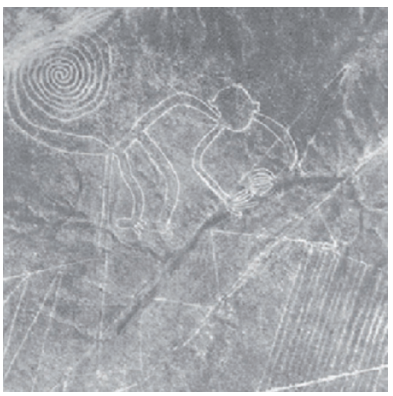
Part II

Pattern Transfer with Subtractive Techniques



Stretching across the Nazca plains—like a giant map or blueprint left by ancient astronauts lie the famous Nazca Lines of Peru.

What subtractive, removing techniques were involved in drawing the monkey above?

Marc J. Madou

Introduction to Part II

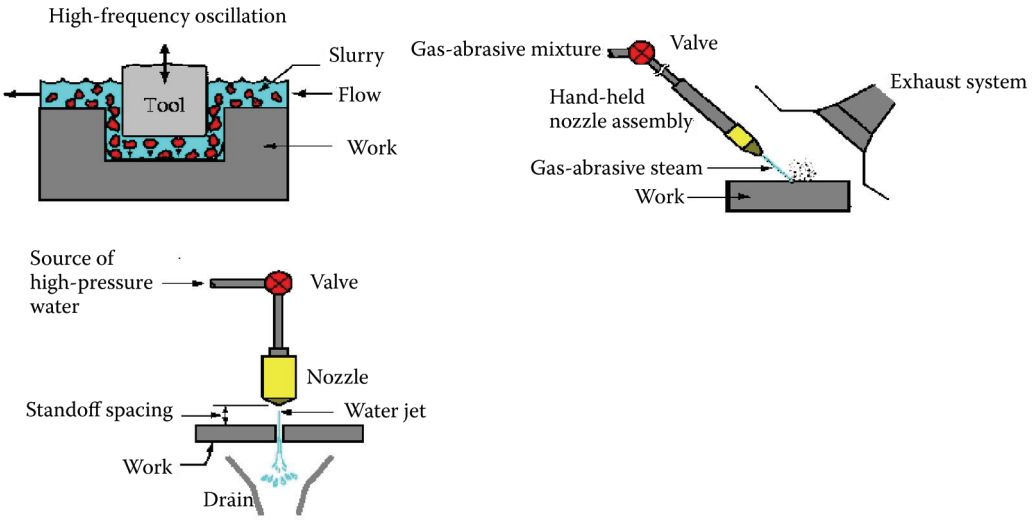
Chapter 3 Dry Etching
Chapter 4 Wet Chemical Etching and Wet Bulk Micromachining: Pools as Tools
Chapter 5 Thermal Energy-Based Removing
Chapter 6 Mechanical Energy-Based Removing

Introduction to Part II

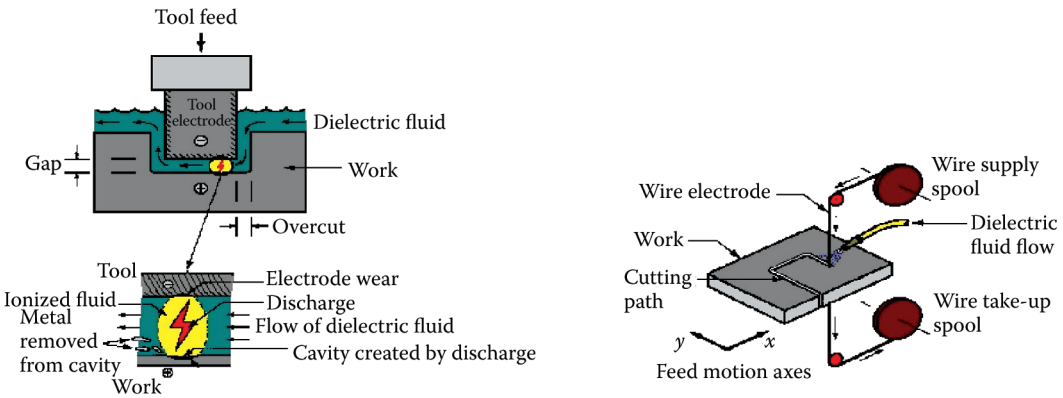
In manufacturing, removing and forming are the two primary processes. Removing processes destroy cohesion among particles as exemplified in wet chemical etching, electrical discharge machining (EDM), traditional mechanical turning, and laser drilling. Forming creates an original shape from a molten mass, a gaseous state, a solution, a plasma, or solid particles. During forming processes, cohesion is created among individual particles; examples include plastic molding, thin film deposition by evaporation or sputtering, and electrochemical metal deposition. In this book, we are interested in forming and removing processes enabling the manufacture of precision miniature machines. Materials are either removed from (subtracted) or added to (formed) a work piece or device under construction (usually in a selective manner).

Manufacturing techniques are often categorized according to the energy used at the work piece as mechanical, chemical, or thermal. Whereas mechanical machining mostly involves material removal,*

* An example of a mechanical additive technique is physical vapor deposition (see Chapter 7) where material is deposited by direct line-of-sight impingement deposition. The depositing material might be generated through the application of thermal energy (e.g., thermal evaporation) or mechanical energy to the source material (e.g., sputter deposition).

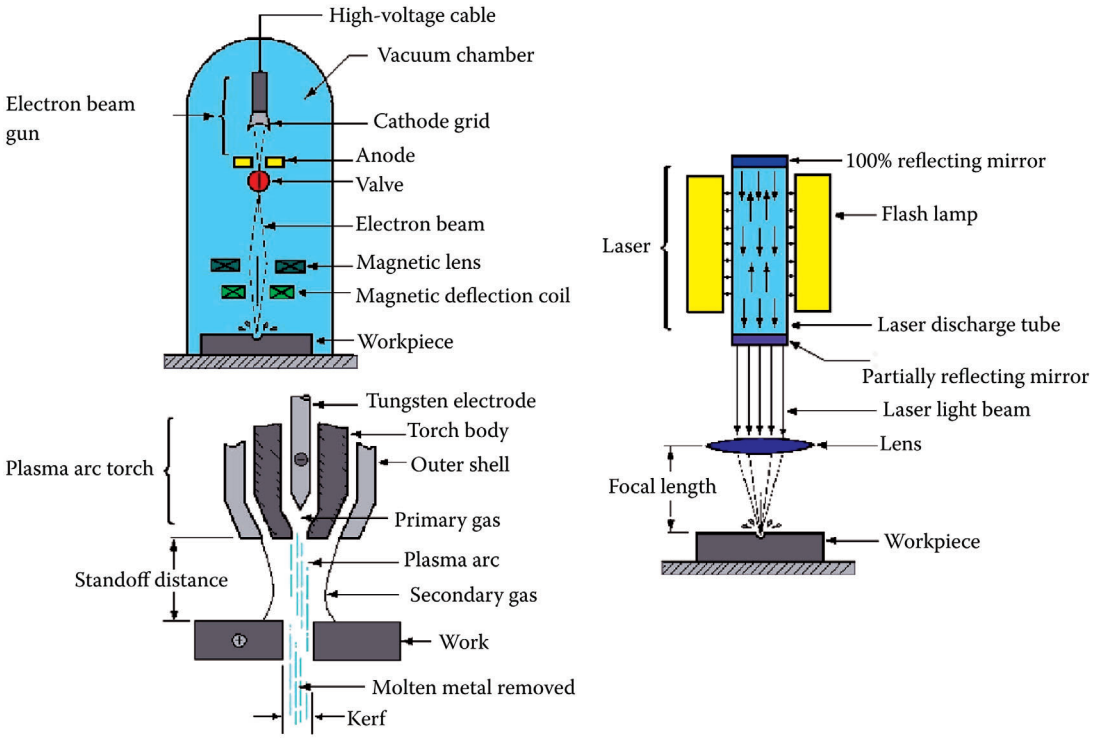


Mechanical machining: ultrasonic machining (S), abrasive jet-machining (S), and water-jet machining (S).

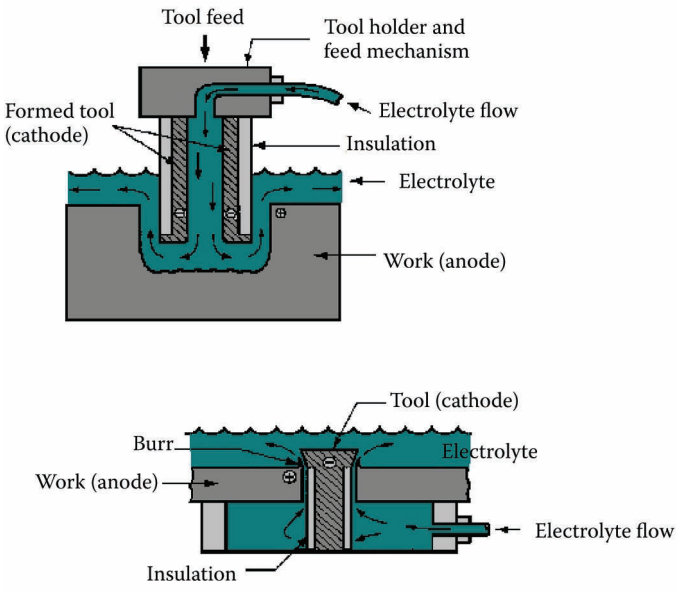


Thermal machining: electrical discharge machining (EDM) (S) and electrical discharge wire cutting (ED-WC) (S).

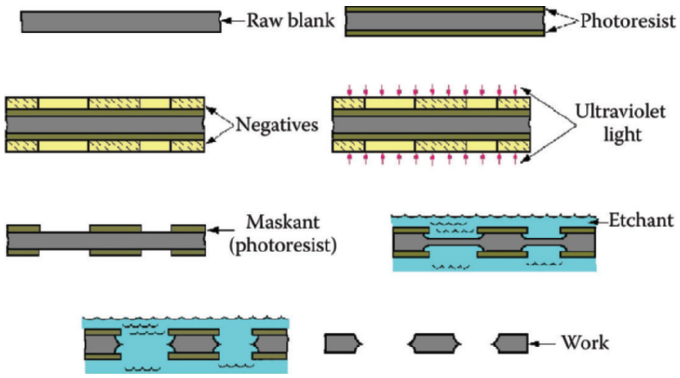
FIGURE II.1 Examples of manufacturing processes grouped according to the energy used at the work piece as mechanical, chemical, and thermal. S = subtractive, A = additive.



Thermal machining: electron-beam machining (EBM) (S shown here but can also be A), laser-beam machining (LBM) (S shown here but can also be A); also called high-energy beam machining.



Chemical machining: electrochemical machining (ECM) (S shown here but can also be A).



Chemical machining: chemical milling (CM) (S).

FIGURE II.1 (*Continued*)

chemical and thermal can be additive (A) or subtractive processes (S). In Part II of this book we deal with material removal processes only; additive technologies are the focus of Part III.

Some examples of subtractive techniques are illustrated in Figure II.1. In categorizing machining techniques, some authors group e-beam, laser, and ion-beam machining under high-energy beam machining.

Table II.1 lists the most important subtractive processes encountered in miniaturization science and includes wet and dry etching, laser machining, ultrasonic drilling, electrical discharge machining (EDM), traditional precision machining, and focused ion-beam (FIB) milling. The manufacturing category, applications (which often involve Si), typical material removal rates, relevant references, and a few remarks on the technique supplement the list.

One of the most widely used subtractive techniques for integrated circuits (ICs) and micro- and nanomachining listed in this table is etching. Etching can be described as pattern transfer by chemical/physical removal of a material from a substrate—often in a pattern defined by a protective masking layer such as a resist or an oxide. Etch parameters—dry or wet—include (for more details see Table 3.5):

1. Etch rate: Rate at which material is removed from the substrate
2. Uniformity: Etch rate constancy across the substrate
3. Throughput: Amount of substrates/wafers etched during one process cycle
4. Directional control: Control of the horizontal and vertical etch rate—isotropic or anisotropic
5. Selectivity of etch:
   a. Controlled by etchant composition
   b. Controlled by etch rate

From the etching processes listed in Table II.1, we review gas and vapor phase dry etching processes, including chemical, physical (purely mechanical), and chemical-physical (mostly chemical with some mechanical assist) in Chapter 3.

Chapter 4 consists of two parts: one deals with wet *chemical etching* and the other with *wet bulk micromachining*, the latter also being chemical etching but optimized for the manufacture of ICs, nano-, and micromachines. Chemical etching techniques cover purely chemical processes as in *chemical milling* (CM), *photochemical machining* (PCM), *electrochemical machining* (ECM) (including μ-ECM), and combinations thereof. Of these chemical etching techniques, chemical milling is the simplest: it only requires a liquid solution that selectively dissolves a specific material (pools as tools).

Chapter 5 discusses thermal removing techniques where thermal energy, provided by a heat source, melts and/or vaporizes material from the work piece. Examples of thermal techniques covered in this chapter are EDM (including μ-EDM), laser- and e-beam machining (LBM and EBM), and plasma arc cutting.

In Chapter 6, we cover traditional and nontraditional mechanical removing techniques. Traditional mechanical material removing technologies covered are mechanical precision machining and abrasive wheel machining. In nontraditional mechanical machining we deal with ultrasonic drilling, electrolytic in-process dressing (ELID) grinding, water jet, abrasive water jet, abrasive jet machining, and focused ion beam (FIB) milling. In Chapter 6, we also highlight recent developments toward miniaturized mechanical manufacturing equipment: the so-called desktop factories.

Table II.1 Subtractive Processes Important in ICs, Micro-, and Nanomachining

Category	Subtractive Technique	Applications	Typical Etch Rate	Remark	References
Chemical	Dry chemical etching	Resist stripping, isotropic features	Si etch rate: 0.1 μm/min (but with more recent high-density plasmas up to 6 μm/min)	Resolution better than 0.1 μm, loading effects	1, 2 Chapter 3
	Physical/ Chemical etching	Very precise pattern transfer	Si etch rate: 0.1–1 μm/min (but with more recent high-density plasmas up to 6 μm/min)	Most important dry etching technique	2, 3 Chapter 3
	Vapor phase etching with XeF_2 (and other interhalogens)	Isotropic Si etching in presence of Al and SiO_2	Si etch rate: 1–3 μm/min	Very selective, fast, and very simple	4 Chapter 3
	Chemical machining (CM)	Shallow removal (up to 12 mm) on large flat or curved surfaces; blanking of thin sheets; in Si spheres, domes, grooves, etc.	General 0.025–0.1 mm/min; in case of Si polishing 50 μm/min with stirring (RT, acid)	Little control, simple; low tooling and equipment cost; suitable for low production cost	5 Chapter 4
	Anisotropic wet chemical etching	Si angled mesas, nozzles, diaphragms, cantilevers, bridges	1 μm/min on (100) Si (90°C, alkaline)	With etch-stop more control, simple	5 Chapter 4
	Wet photoetching	Etches p-type layers in p-n junctions	Etches p-Si up to 5 μm/min (acid)	No electrodes required	6 Chapter 4
Electrochemical	Electrochemical etching (ECM)	Complex shapes with deep cavities; etches p-Si and stops at n-Si in an p-n junction); etches n-Si of highest doping (in n/n+)	Highest rate of material removal. V: 5–25 dc; A: 1.5–8 A/mm^2; 2.5–12 mm/min, depending on current density; etches p-Si at 1.25–1.75 μm/min [(100) plane]	Complex (requires contacts) expensive tooling and equipment; high-power requirement; medium to high production quantity	7, 8 Chapter 4
	Electrochemical grinding (ECG)	Cutting off and sharpening of hard materials, such as tungsten-carbide tools. Also used for honing	Higher removal rates than grinding; A: 1–3 A/mm^2		9 Chapter 4
	Photoelectrochemical etching	Etches n-Si in p-n junctions, production of porous Si	Si etch rate: 5 μm/min (acid)	Complex, requires electrodes and light	9 Chapter 4
Thermal	Laser machining (with and without reactive gases)	Cutting and hole making in thin materials; circuit repair, resistor trimming, hole drilling, labeling of Si wafers	Drilling a hole in Si with a Nd:YAG (400-W laser): 1 mm/s (3.5 mm deep and 0.25-mm diameter)	Expensive equipment, does not require vacuum, heat-affected zone; laser beams can focus to a 1-μm spot, etch with a resolution of 1 μm^3	10 Chapter 5
	Electron-beam machining	Cutting and small hole making in thin films; etching of circuits in microprocessors, large number of simple holes in hard to machine materials	Material removal rate is ~0.1 mg/s	Vacuum is needed, very expensive equipment, fast, drilling rates of 2000 holes/s	11 Chapter 5

(Continued)

Table II.1 Subtractive Processes Important in ICs, Micro-, and Nanomachining (continued)

Category	Subtractive Technique	Applications	Typical Etch Rate	Remark	References
	Electrical discharge machining (EDM)	Shaping and cutting complex parts made of hard materials; some surface damage may result; drilling holes and channels in hard brittle metals	V: 50–380 dc; A: 0.1–500; typical removal rate for metals: 0.3 cm^3/min	Poor resolution (>50 μm), only conductors, expensive tooling and equipment	12 Chapter 5
Mechanical	Mechanical turning, drilling, and milling	Almost all machined objects surrounding us	Removal rates of turning and milling of most metals: 1–50 cm^3/min, for drilling: 0.001–0.01 cm^3/min	Prevalent machining technique	13 Chapter 6
	Physical dry etching, sputter etching, and ion milling	Si surface cleaning, unselective thin film removal	Si etch rate: 300 Å/min	Unselective and slow, plasma damage	3 Chapter 3
	Water-jet machining (WJM)	Cutting all types of nonmetallic materials 25 mm and thicker	Varies considerably with work piece material		14 Chapter 6
	Abrasive water-jet machining (AWJM) and abrasive jet machining (AJM)	Single or multilayer cutting of metallic and nonmetallic materials; cutting, slotting, deburring, flash removal, and cleaning of metallic and nonmetallic materials	Up to 7.5 m/min	Tends to round off sharp edges; some hazards because of airborne particles	14 Chapter 6
	Abrasive grinding				15 Chapter 6
	Electrolytic in-process dressing (ELID) grinding				16 Chapter 6
	Ultrasonic drilling	Holes in quartz, silicon nitride bearing rings	Typical removal rate of Si: 1.77 mm/min	Especially useful for hard, brittle materials	17 Chapter 6
	Focused ion-beam (FIB) milling	Microholes, circuit repair, microstructures in arbitrary materials	Typical Si etch rate: 1 μm/min	Long fabrication time: >2 h including setup	18 Chapter 6

Different-colored entries correspond to different chapters where more details can be found. RT, room temperature; chem. etch., chemical etching; iso., isotropic; anis., anistropic.

Introduction

Lithography steps precede a number of subtractive and additive processes. Materials are either removed or added to a device, usually in a selective manner, transferring the lithography patterns onto integrated circuits (ICs) micro- or nanomachines. This chapter deals with material removal by dry etching processes. In dry etching, the solid substrate is etched by gaseous species. While introducing resist stripping in Chapter 1, we learned that the popularity of dry stripping of resists (ashing) and the need for better control of critical dimension (CD) precipitated major research and development efforts in all types of plasma-based dry etching

processes. The preference of dry etching over wet etching methods is based on a variety of advantages: fewer disposal problems, less corrosion of metal features in the structure, and less undercutting and broadening of photoresist features; that is, better CD control (nanometer dimensions compared with 3 μm or larger for wet etching) and, under the right circumstances, a cleaner resulting surface. With the new generations of ICs, all with sub-100-nm geometries, surface tension precludes a wet etchant from reaching down between photoresist features, whereas dry etching avoids this problem. In Figure 3.1, dry anisotropic and wet isotropic etchings for patterning a thin film of SiO_2 on a Si substrate are compared. In step (a) the photoresist protects parts of the underlying SiO_2 from dry or wet etching. In steps (b) and (c) the etching proceeds until the underlying Si substrate is reached, undercutting the photoresist in wet etching but not in dry etching. In step (d) the resist is stripped. As in IC manufacture, dry etching has evolved into an indispensable technique in miniaturization science. After the commercial successes with wet-etched Si micromachined products in the 1980s and early 1990s, the maturation of flexible, generic, and fast anisotropic deep reactive ion etching (DRIE) techniques in the late 1990s spawned a second wave of Si miniaturized commercial products.

Dry Etching: Definitions and Jargon

In dry etching, substrates are etched without wet chemicals or rinsing and enter and leave the etching system in a dry state. The term *dry etching* covers a family of methods by which a solid surface is etched in the gas or vapor phase physically by ion bombardment,

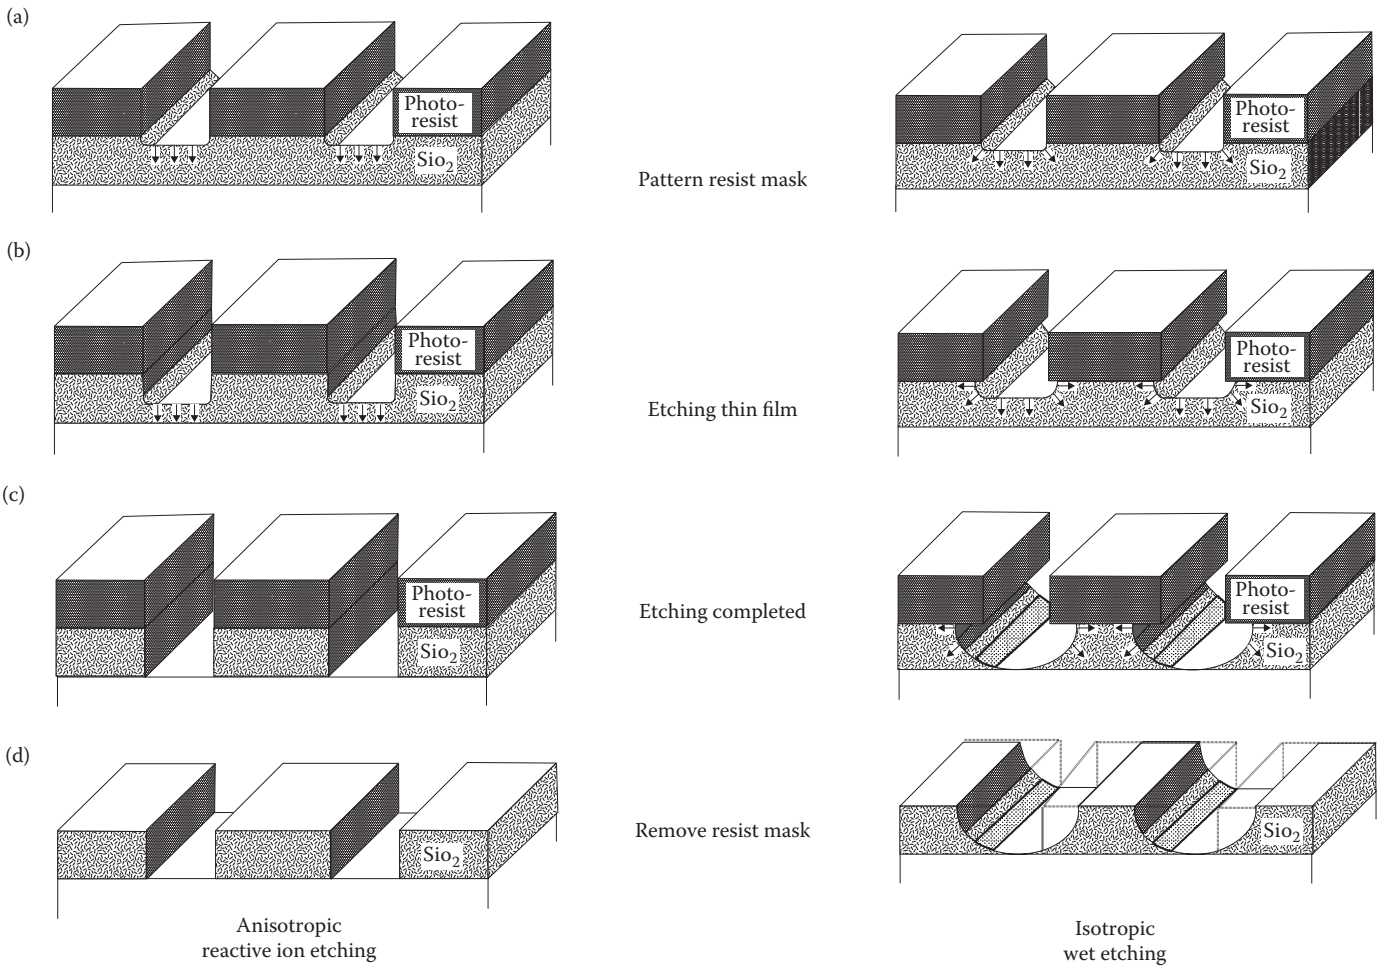

FIGURE 3.1 Comparison of dry anisotropic and wet isotropic etching to pattern a thin SiO_2 film. In step (a) the photoresist protects parts of the underlying SiO_2 from dry or wet etching. In steps (b) and (c) the etching proceeds until the underlying Si substrate is reached, undercutting the photoresist in wet etching but not in dry etching. In step (d) the resist is stripped.

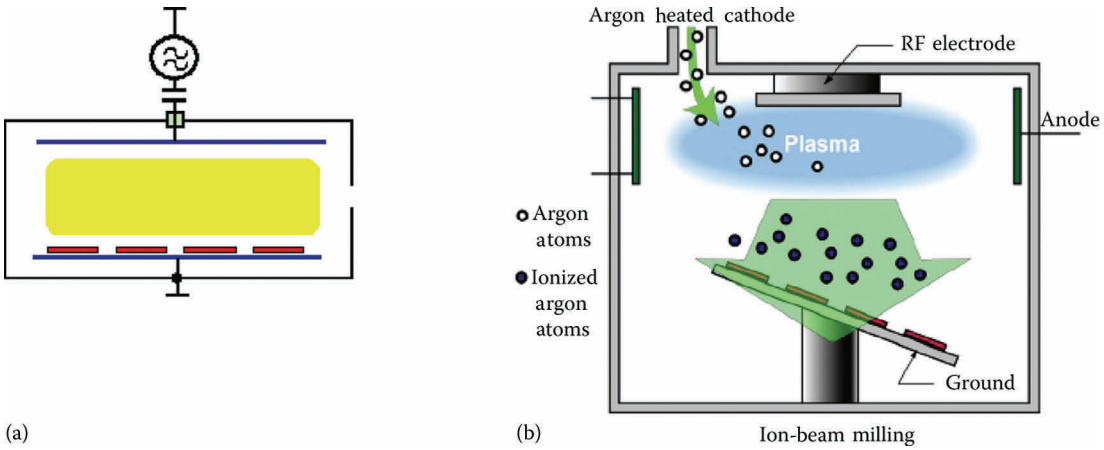

FIGURE 3.2 Plasma-assisted dry etching is categorized according to the specific setup as either *glow discharge* etching (diode setup) (a) or *ion-beam* etching (triode setup) (b).

chemically by a chemical reaction through a reactive species at the surface, or by combined physical and chemical mechanisms or reactive ion etching (RIE). A key ingredient in dry etching involves the creation of plasma. Plasma-assisted dry etching is categorized according to the specific setup as either *glow discharge* etching (diode setup) or *ion-beam* etching (triode setup). Using glow discharge techniques, a broad plasma is generated in the same part of the vacuum chamber where the substrate is located; when using ion-beam techniques, plasma is generated in a separate chamber or in another part of the same vacuum chamber from which ions are extracted and directed in a beam toward the substrate by a number of electrode grids. In Figure 3.2 we compare a dry etching diode and dry etching triode setup.[1] It is also common to differentiate between 1) physical sputter/ion etching and ion-beam etching (IBE)[2] or also ion-beam milling (IBM), 2) chemical plasma etching (PE), and 3) synergetic reactive ion etching (RIE). Each of these techniques will be discussed in detail further below, but here we present a short dry etching synopsis:

1. In physical sputter/ion etching and ion-beam milling (IBE), etching occurs as a consequence of a purely physical effect, namely, momentum transfer between energetic Ar^+ ions and the substrate surface. Some type of chemical reaction takes place in all the other dry etching methods, but not in this one.
2. In chemical plasma etching (PE), neutral chemical species such as chlorine or fluorine atoms generated in the plasma diffuse to the substrate, where they react to form volatile products with the layer to be removed. The only role of the plasma is to supply gaseous, reactive etchant species.
3. In the case of physical/chemical etching (RIE), line-of-sight-impacting ions damage the surface, inducing highly anisotropic chemical reactions of the surface with plasma neutrals, or, alternatively, a passivating layer is cleared by the ion bombardment, clearing horizontal surfaces only and again resulting in highly anisotropic etching.

We can also distinguish plasmas produced in a DC field (0 Hz), an AC field (50 kHz and up), a radiofrequency (RF) field (13.6–27 MHz), and in a microwave field (300 MHz–10 GHz). Finally, dry plasma etching systems can also be divided into single-wafer and batch reactors.

In Table 3.1, we review the most common dry etching methods and clarify the associated jargon in the legend. Of the techniques listed, PE and RIE are the most widely used in IC manufacture and micro- and nanomachining.

In selecting a dry etching process, the desired shape of the etch profile and the selectivity of the etching process require careful consideration. Figure 3.3 shows different possible dry etch profiles, where, depending on the etching mechanism used, nondirectional, i.e., isotropic, or directional, i.e., vertical, or anisotropic etch profiles are obtained. In dry etching, anisotropic etch profiles—directional or vertical—can be generated in single crystalline, polycrystalline, and amorphous materials. The anisotropy of dry etching is not a result of aniso-

tropy in the etching rate in different crystallographic directions, as in the case of anisotropic wet chemical etching in single crystal Si (Chapter 4); rather, the degree of anisotropy is controlled by the plasma conditions. Selectivity of a dry etch refers to the difference in etch rate between the mask and the film to be etched, again controllable by plasma conditions.

At low pressures, in the 10^{-3}–10^{-4} Torr range, anisotropic etching is easy, but accomplishing selectivity is difficult. The reason is that etching in this regime is mechanical in nature: the substrate is hit directionally, and atoms are ejected like a billiard ball. Physical ion-beam etching (IBE) at those pressures results in tapered profiles as shown in Figure 3.3a, low selectivity, and low etch rates because the mechanical energy transfer is inefficient. At higher pressures (1 Torr), in plasma etching (PE), chemical effects dominate, leading to better selectivity and higher etch rates than in the case of ion beams, but etched features are isotropic (Figure 3.3b). Chemical etching reactions are fast and efficient compared with mechanical etching, where atoms are ejected by mechanical force. Reactive ion etching (RIE) enables profile control as a result of the synergistic combination of physical ion sputtering with the chemical activity of neutral reactive species with a high etch rate and high selectivity. In the extreme case of anisotropic etching, perfect vertical sidewalls result (no lateral undercut) with perfect retention of

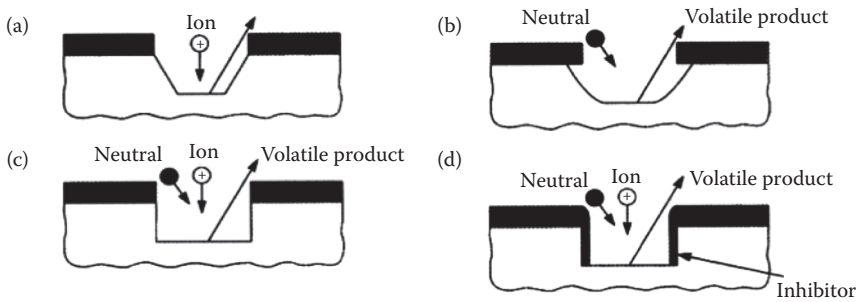

FIGURE 3.3 Important dry etching profiles associated with different dry etching techniques. (a) Sputtering. (b) Chemical etching in plasma at low voltage and relative high pressure leads to isotropic features and lateral undercuts. (c) Ion-enhanced etching: physical-chemical is the most perfect image transfer as the undercutting is limited by the combined action of physical and chemical etching. The low pressure and high voltage lead to directional anisotropy. (d) Ion-enhanced inhibitor. Sidewalls are protected from undercutting by a surface species (e.g., a polymer), which starts etching when hit by a particle such as an ion, a photon, or an electron. Because very few particles hit the sidewalls (high voltage and high pressure), undercutting is suppressed. (From Flamm, D. L. 1993. Feed gas purity and environmental concerns in plasma etching: Part I. *Solid State Technol* October:49–54. With permission.[75])

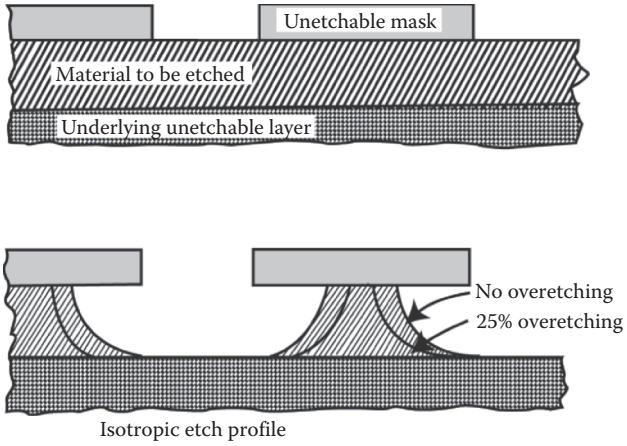

FIGURE 3.4 Example illustrating the loss of dimensionality incurred by an isotropic etch when the depth is of the order of the lateral dimensions involved. Making the initial lithography smaller compensates for the loss of dimensionality by overetching.

the CDs (see Figure 3.3c and d). In the case of isotropic etching, dimensionality losses are incurred with an etch depth the order of the lateral dimensions as illustrated in Figure 3.4. To ensure uniform etch rates over the whole wafer and between wafers, isotropic overetching may be required, further compromising the dimensionality. Figure 3.4 compares the etch profile of no overetching with a 25% overetch. Making the initial lithography smaller compensates for the loss of dimensionality incurred by overetching.

Even though isotropic etching leads to nonvertical sidewalls and loss of dimensionality, there remain some advantages to their use. Often a vertical sidewall is not the desired edge profile. For example, with line-of-sight deposition methods, such as resistive evaporation (see Chapter 7), a tapered sidewall is easier to cover than a vertical wall. Another example in which a nonvertical process has an advantage is illustrated in Figure 3.5. To take away the layer shown on the vertical walls, an anisotropic etchant would require extensive overetching, whereas an isotropic etchant will remove the material quickly.

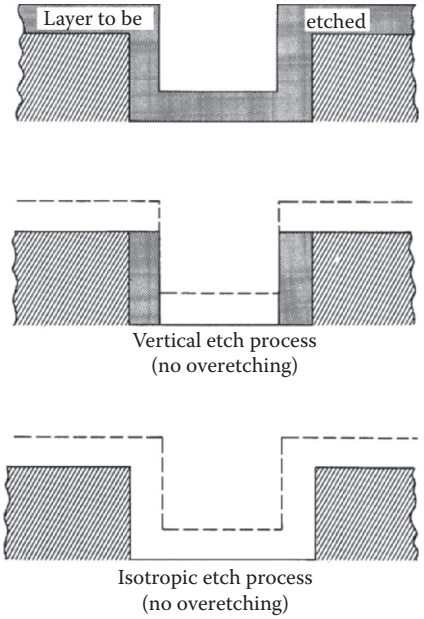

FIGURE 3.5 An example of dry etching illustrating a case where an isotropic etch is preferred to a vertical etch process. To clear the layer on the vertical walls, an isotropic etch only requires a minimal overetch, whereas an anisotropic etch requires a substantial amount of overetching.

Plasmas or Discharges

Introduction

Plasmas, defined as ionized gases that are neutral with equal numbers of ions and electrons, are commonly referred to as the fourth state of matter. A more precise definition is that plasma is a quasineutral gas of charged and neutral particles exhibiting collective behavior. The different states of matter generally found on earth are solid, liquid, and gas, and we have learned to work, play, and rest using these familiar states of matter. But in 1879, Sir William Crookes, an English physicist, identified a fourth state of matter, now called plasma. Plasmas in the stars and in the tenuous space between them make up more than 99% of the visible universe and perhaps most of which is not visible. Here on Earth, plasmas are important in film etching, sputter deposition, fluorescent lamps, welding arcs, and gas lasers (to name only a few).

Most dry etching systems also find their common base in plasmas or discharges, areas of high energy electric and magnetic fields that rapidly dissociate a suitable feed gas (e.g., sulfur hexafluoride, SF_6 for Si etching) to form neutrals, energetic ions (SF_5^+ and F^-), photons, electrons, and highly reactive radicals ($F^\bullet$). A surface in contact with plasma is exposed to fluxes of atoms, molecules, ions, electrons, and photons. This bombardment stimulates the production of outgoing fluxes of neutrals, ions, electrons, and photons, leading to a modified or etched surface layer.[3] We will start our foray into

the physics and chemistry of plasmas by looking at the simplest plasma setup—a DC-diode glow discharge in a low-pressure argon atmosphere. After a discussion of the spatial zones in a glow discharge, we explain the Paschen curve and then introduce radiofrequency (RF) plasmas.

Physics of DC Plasmas

The simplest plasma reactor consists of opposed parallel-plate electrodes in a chamber maintainable at low pressure, typically in the order of 1 mbar, as illustrated in the reactor shown in Figure 3.6a. The electrical potentials established in the reaction chamber, filled with an inert gas such as argon at a reduced pressure, determine the energy of ions and electrons striking the surfaces immersed in the discharge. To explain the generation of a DC plasma consider the setup shown in Figure 3.6a where we have simply put two electrodes (anode and cathode) at opposite ends of an evacuated glass tube and applied 1.5 kV between them. With the electrodes separated by 15 cm this results in a 100 V/cm field. Electrical breakdown (rapid ionization of a medium following the application of an overvoltage) of the argon gas in this reactor will occur when electrons, accelerated in the existing field, transfer an amount of kinetic energy greater than the argon ionization potential (i.e., 15.7 eV) to the argon neutrals. Elastic collisions deplete very little of the electron's energy and do not significantly influence the molecules because of the great mass difference between electrons and gas molecules. Inelastic collisions, on the other hand, excite the molecules of the gas or ionize them by completely removing an electron. Thus, such energetic inelastic collisions may generate a second free electron and a positive ion for each successful strike. Both free electrons re-energize, creating an avalanche of ions and electrons that results in a gas breakdown emitting a characteristic beautiful blue glow (in the case of argon; for air or nitrogen a pink color results from excited nitrogen molecules). The excitation/relaxation processes are responsible for the plasma glow. Avalanching requires the ionization of 10–20 gas molecules by one secondary electron. At the beginning of a sustained gas breakdown, a current, typically several hundred milliamps, starts to flow, and the voltage between the two electrodes decreases from 1.5 kV to about 150 V. Newly produced electrons are accelerated toward the anode, and with sufficient voltage, the gas rapidly becomes filled with positive and negative particles throughout its volume, i.e., it becomes ionized. The discharge current builds up to the point where the voltage decrease across a current-limiting resistor is equal to the difference between the supply voltage (1.5 kV) and the electrode potential difference (150 V). To sustain plasma, a mechanism to generate additional free electrons must exist after the plasma-generating electrons have been captured at the positively charged anode. Plasma-sustaining electrons are generated through the emission of secondary electrons (Auger electrons) when the

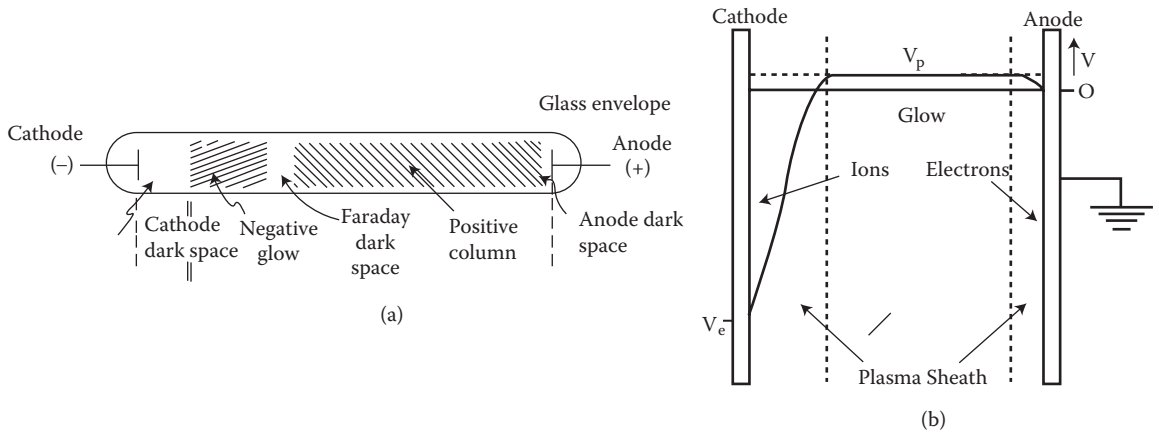

FIGURE 3.6 Voltage distribution in a DC diode discharge in equilibrium. (a) Structure of the glow discharge in a long tube-based DC diode system. (b) Voltage distribution in a real DC diode system where the anode is brought much closer to the cathode than in (a) and is positioned in the negative glow region (so-called obstructed glow).

cathode is struck by ions. The continuous generation of those "new" electrons prompts a sustained current and a stable plasma glow. The discharge reaches a steady state when electron generation and loss processes balance each other. Electrons are lost by 1) drift and diffusion to the chamber walls, 2) recombination with positive ions, and 3) attachment to neutral molecules to form negative ions. Once this equilibrium is reached, the glow region of the plasma, being a good electrical conductor, sustains a very low field only, and its potential is almost constant. Most of the space between the electrodes is now filled with a soft glow as a result of the relaxation of excited species; however, certain dark spaces are observed near the electrodes. Most of the potential drops reside at the electrode surfaces where electrical double layers are formed in "sheath fields," counteracting the loss of electrons from the plasma (Figure 3.6b). The most significant dark space is seen at the cathode. This dark space, called the "ion sheath," is a positive space charge region, which is key to most dry etching processes. The cathode sheath, the first few millimeters in front of the cathode, corresponds to the cathode dark space (also called *Crookes* or *Hittorf* region). Positive ions entering this sheath move slower toward the cathode than electrons move away from it, leaving this sheath with an excess of positive charges. Thus, if a conductor is placed on the cathode, it is bombarded with ions and may be etched. If an insulating material, such as a dielectric or an oxide-coated silicon wafer, is placed on the cathode (or the anode for that matter), the process stops. The dielectric rapidly charges up, and the field in the gas drops, causing the generation of electrons to cease. For this reason, DC plasmas are rarely useful for etching silicon wafers. The solution to this problem lies in the use of an AC power source of sufficiently high frequency to reverse polarity before the dielectric becomes fully charged. Typically, radiofrequency (RF) is used, although the minimum effective frequency is in the range of >50 kHz (see below under RF plasmas).

In Table 3.2 we summarize the cathode dark space characteristics.

The light distribution shown in Figure 3.6a is only observed when the interelectrode distance is large compared with the size of the electrodes. The "Faraday dark space" and the "positive column" are characterized by a low electric field to conduct the electrons toward the anode. These two regions are often present

Table 3.2 Cathode Dark Space Characteristics

Characteristics	Remark
Fewer electrons	Highly mobile electrons are accelerated quickly away from the negative cathode.
More positive ions	As electrons escape, they leave a high concentration of positive ions. These are attracted to the negative cathode.
Low conductivity	Positive ions move slowly. The result is that the field is higher across the cathode dark space.
Ions are accelerated	When the ions drift into the field of the dark space, they are accelerated toward the cathode.
Ions collide with the cathode and with neutral species on their way to the cathode	Therefore, the cathode is bombarded both with ions and with neutral species such as radicals and gas molecules. The ionic bombardment releases secondary electrons, which sustain the glow discharge. At low pressures and high voltages, the bombardment can cause sputtering.
Secondary electrons are created here	These electrons quickly accelerate to the ionization energy. As they leave the high field region and encounter ionizing collisions, they lose energy and then only have enough energy to excite. This is the edge of the negative glow region.
The dark space increases as the pressure is reduced (longer mean free path, higher energies, fewer collisions)	Eventually the dark space extends nearly across the chamber; the mean free path becomes too large to maintain a sufficient number of collisions and the glow is extinguished.
A conductor placed on the cathode	Will be subjected to ion bombardment.
An insulator placed on the cathode	The material charges up, and all the applied voltage exists across the material, and the plasma is extinguished.

in glow discharges used as lasers ("positive column lasers") and as fluorescence lamps. However, for most of the other applications of glow discharges (e.g., sputtering, deposition, chemical etching, analytical chemistry), the distance between cathode and anode is very short, so that normally (i.e., at typical discharge conditions) only a short anode zone is present beside the cathode dark space and the negative glow region, where the slightly positive plasma potential returns back to zero at the anode (see Figure 3.6b). This situation is termed an *obstructed glow*. Virtually all processing plasmas used in industry operate with a short interelectrode distance (e.g., twice that of the cathode dark space width) using the negative glow as principal plasma.[4] For electrodes of 12 cm in diameter, the interelectrode distance will typically be less than 1 cm. In the negative glow region, the potential is nearly constant and slightly positive, and hence the electric field is very small. It is this type of discharge that we depict in Figure 3.6b, with only a cathode dark space, negative glow, and anode dark space. If the interelectrode distance becomes significantly more than twice the dark space thickness, the discharge is extinguished. The latter characteristic can be applied to prevent discharge from contacting areas in a reactor where it is not desired.[5]

A striking characteristic of plasma is its permanent positive charge with respect to the electrodes—a result of the random motion of electrons and ions. The positive charge of plasma can be understood from kinetic theory, which predicts that for a random velocity distribution, the flux of ions, j_i, and electrons, j_e, on a surface is given by:

$$j_{i,e} = \frac{n_{i,e} \; \langle v_{i,e} \rangle}{4} \tag{3.1}$$

where n and $\langle v \rangle$ are the densities and average velocities, respectively. Because ions are heavier than electrons (typically 4,000–100,000 times as heavy), the average velocity of electrons is larger. Consequently, the electron flux is larger than the ion flux, and the plasma loses electrons to the walls, thereby acquiring a positive charge. The bombarding energy of ions is proportional to the potential difference between the plasma and the surface being struck by the ions. The reason behind the asymmetric voltage distribution at the anode and cathode as seen in Figure 3.6b is as follows: electrons near the cathode rapidly accelerate away from it because of their relatively light mass; ions, being more massive, accelerate toward the cathode more slowly. Thus, on average, ions spend more time in the Crookes dark space, and, at any instant, their concentration is greater than that of electrons. The net effect is a very large field in front of the cathode compared with that in front of the anode and in the glow region itself. Consequently, the greatest part of the voltage between the anode and the cathode, V_e, is dropped across the Crookes dark space where charged particles (ions and electrons) experience their largest acceleration. This region is also called the *cathode-fall* region.

Glow discharges represent nonequilibrium conditions as the average electron energy, $\langle v_e \rangle$, also called *electron temperature*:

$$\langle v_e \rangle = kT_e \text{ (e.g., 1–10 eV)} \tag{3.2}$$

is considerably higher, in the range of 1–10 eV, than the average ion energy, $\langle v_i \rangle$, also called *ion temperature*:

$$\langle v_i \rangle = kT_i \text{ (e.g., 0.04 eV)} \tag{3.3}$$

which is much colder, typically having energies of 0.02–0.1 eV. Thus, a discharge or plasma cannot be described adequately by one single temperature but rather by the ratio of electron and ion temperature [T_e (electrons)/T_i (ions) = 10–100]. High-temperature electrons in a low-temperature gas are possible because of the small mass of electrons (m_e) compared with ions and neutrals. In collisions between electrons and argon atoms (M_A), as a result of an m_e/M_A ratio of 1.3×10^{-5}, electrons have a very poor energy transfer and stay warmer longer than the heavier ions and neutrals. In plasma with an ionization fraction of 10^{-4}, there are many more cold gas atoms than ions, and the ions quickly reach the background gas temperature as a result of the many collisions between ions and neutrals.[4] Electrons can attain a high average energy, often many electronvolts (equivalent to tens of thousands of degrees above the gas temperature), permitting electron-molecule collisions to excite high-temperature-type reactions, forming free radicals in the low-temperature neutral gas. Generating the

same reactive species without plasma would require temperatures in the ~10^3–10^4 K range, destroying resists and damaging most inorganic films.

Plasma is typically weakly ionized: the number of ions is small compared with the number of reactive neutrals such as radicals. The ratio between ionized and neutral gas species in a glow discharge plasma is in the order of 10^{-6}–10^{-4}. This fact, as we will see below, is crucial in understanding which entities are responsible for the etching of a substrate placed in a glow discharge. There are 1 million times more radicals than ions or electrons because radicals form more easily and their lifetime is much longer. We will see that ions do not etch, but radicals do. Ions affect the process by energetic (physical) bombarding of the surface, influencing the chemical processes of etching. The degree of ionization in plasma depends on a balance between the rate of ionization and the rate at which particles are lost by volume recombination and by losses to the walls of the apparatus. Wall losses generally dominate volume recombination. Accordingly, the occurrence of a breakdown in a given apparatus depends on the gas pressure (particle density), the type of gas, electric field strength (electron velocity), surface-to-volume ratio of the plasma, and distance between the anode and the cathode (see also Paschen's law in the section below). In air at atmospheric pressure (760 Torr) the mean free path is very short, and it is difficult for electrons to acquire enough energy to ionize gases. In such case, only extremely high electric fields may create a plasma in the form of arcing (as in lightning; see Figure 3.7) instead of a steady glow discharge.

FIGURE 3.7 Discharge in lightning.

The choice of a dry etching technique depends on the efficiency or "strength" of the particular plasma. Plasma strength is evaluated by parameters such as average electron energy, $\langle v_e \rangle$ (Equation 3.2), average ion energy (Equation 3.3), electron density (e.g., between 10^9 and 10^{12} cm^{-3}), plasma ion density (e.g., 10^8–10^{12} cm^{-3}), neutral species density (e.g., 10^{15}–10^{16} cm^{-3}), and ion current density (e.g., 1–10 mA/cm^2). A quantity of particular use in characterizing plasma's average electron or ion energy is the ratio of the electrical field to the pressure:

$$kT_{i,e} \sim \frac{E}{p} \tag{3.4}$$

With increasing field strength, the velocity of free electrons or ions increases because of acceleration by the field (~E), but velocity is lost by inelastic collisions. Because an increase in pressure decreases the electron or ion mean free path, resulting in more collisions, the electron or ion energy decreases with increasing pressure (~1/P).

To use the described DC plasmas for 1) dry etching and 2) sputter deposition, one uses one of the following setups:

1. In the etching arrangement, the substrate to be etched is placed on the cathode of the DC diode system. An argon plasma in this setup produces sufficiently energetic ions (between 200 and 1000 eV) to induce physical etching, that is, ion etching or sputtering of the material on the cathode.
2. The same setup is used for sputter deposition where atoms from the target (cathode) are ejected like a billiard ball and deposited on the substrate laying on the anode (see Chapter 7).

The low pressure in sputter etching (10–200 mTorr) gives rise to a long mean free path, and the externally applied voltage concentrates across the cathode plasma sheath where ions are accelerated before hitting the cathode. Each ion will collide numerous times with other gas species before transversing the plasma sheath, as the sheath thickness is larger than the mean free ion path. As a result of these collisions, ions lose much of their energy and move across the sheath with a drift velocity that is

less than "free fall" velocity. But these vertical velocities are still very large compared with the random thermal velocities in the glow discharge region. The resulting bombarding ion flux, j_i, is given by:

$$j_i = qn_i\mu_i E \qquad (3.5)$$

where E = electric field
n_i = ion density
μ_i = ion mobility
q = charge

Reducing the pressure in the reactor increases the mean free path because particles have more of a chance to accelerate before colliding with another particle or wall. Consequently, ions accelerating toward the cathode at lower pressures can gain more energy before a collision takes place. A typical sputtering profile was illustrated earlier in the schematic in Figure 3.3a. In the opposite high pressure mode, reactive species such as radicals generated by the DC plasma may combine with the substrate to form volatile products, chemically etching the substrate in so-called *plasma etching*. In this case, ions striking the surface have lower energy (e.g., less than 10–20 eV) as a result of the lower sheath voltages and short mean free path because of the relatively high pressures (typically >0.1 Torr). Aside from generating the radicals through energetic collisions in the plasma, ions contribute very little or nothing to the etching process itself. The fast etching radicals reach the etch site via diffusion from the plasma rather than by electromigration. A typical plasma etching profile was shown in Figure 3.3b.

Spatial Zones in a DC Glow Discharge

Introducing Figure 3.6a we noticed that the structure of plasma discharges in tubes that are long compared to the electrode sizes is complex. When a DC glow discharge is sustained in a long, narrow cylindrical tube filled with a rare gas at low pressure, the visible light emitted from the glow is distributed as shown in Figure 3.6a and, in more detail, in Figures 3.8 and 3.9. In Figure 3.9 we also show the potential distribution and the ion and electron density along the length of such a discharge tube (a DC "gas diode"). Regions described as "glows" emit

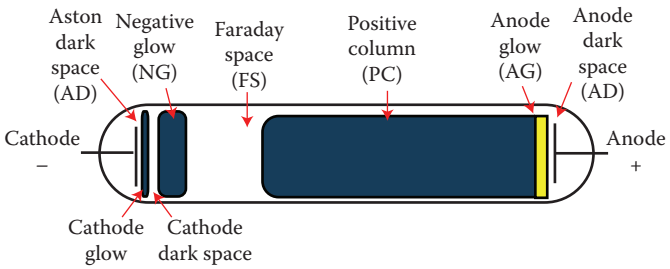

FIGURE 3.8 Detailed structure of a glow discharge in a DC gas diode.

significant light; regions labeled as "dark spaces" do not. Photons are created by the excitation/relaxation of the gas molecules, and when excitation/relaxation is the dominant process the plasma glows. The glow discharge can be subdivided into several regions between the anode and the cathode. Besides the Crookes or Hittorf dark space (cathode DS), the Aston DS, the Faraday DS, and the anode DS, a cathode glow can be observed, a negative glow (NG) region, the positive column (PC), and the anode glow (AG). The "dark" regions are not really dark, just less luminous than the bright regions. As the discharge becomes more extended (i.e., stretched horizontally in the geometry of the figure), the positive column may become striated, and for monatomic gases, the cathode glow may become striated as well. That is,

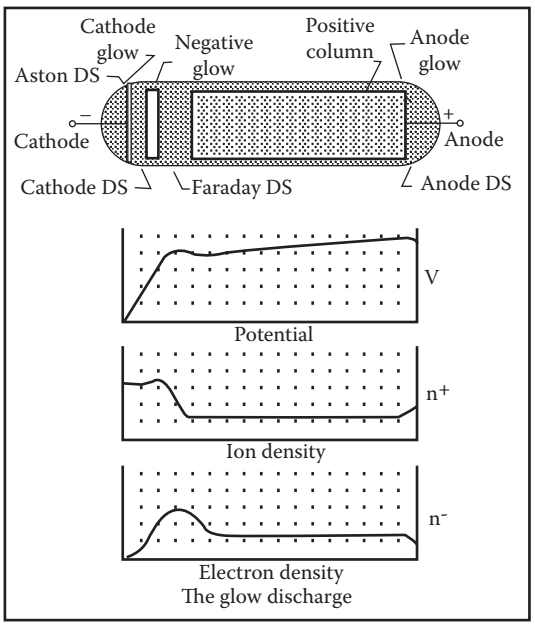

FIGURE 3.9 Detailed structure of a glow discharge in a DC diode with potential distribution and the ion and electron density along the length of the discharge tube (see also Figure 3.8).

additional alternating dark and bright regions may form. Alternatively, compressing the discharge horizontally results in fewer regions. The positive column will be compressed, whereas the negative glow will remain the same size, and, with small enough gaps, the positive column will disappear altogether.

The cathode dark space has the strongest electric field in the discharge. This region is filled with a positive space charge of ions moving in the opposite direction of the electrons. Electrons leaving the cathode with a few electronvolts of energy do not have the capacity of excitation/relaxation, resulting in a very thin first dark layer at the cathode (Aston dark space-AD). However, electrons emitted from the cathode rapidly attain energy suitable for excitation/relaxation, giving rise to a small bright layer; that is, the first cathode layer or cathode glow. After this thin excitation layer, the electrons are exhausted, and a second dark layer arises. Electrons then re-energize in the field and may form a second thin cathode layer, vaguer than the first, and so on. In Figures 3.8 and 3.9 we show one Aston dark space and one cathode glow layer only. If there is only one cathode glow, the second Aston dark space corresponds to the Crookes, Hittorf, or cathode dark space. A plurality of Aston dark spaces and thin cathode glow layers are only clearly observable in monoatomic gases; in polyatomic gases other energy dissipation processes take over.[6] In the main part of the cathode DS (Crookes or Hittorf dark space), electrons have gained too much energy from the electric field for efficient excitation, and luminescence becomes very weak.

The negative glow is the bright segment adjacent to the cathode dark space. In this brightest region of the glow discharge, there are many more electrons (a result of charge multiplication), and they do not gain any further energy, as this region is equipotential or field free.

The electron energy in the negative glow region is much more suitable for excitation/relaxation, and a bright light with a color characteristic for the discharge gas (blue in the case of argon) results. The electrons are exhausted by this effort and drift out into the Faraday dark space and the positive column at low velocity.

If the distance between anode and cathode is sufficiently large, a long positive column is present. There are now much fewer ions around, so the electrons can be accelerated in the gentle field. As they speed up, their number density goes down (the main losses are through diffusion to the walls). When they have sufficient energy to excite the molecules of the gas, the emitted light becomes evident. This light is produced with minimal excitation and consists only of light emitted by neutral atoms that have been excited above their resonance energy, which explains its different character from the light emitted by the negative glow. The positive column is less bright than the negative glow, and, although of another color, it is also characteristic of the discharge gas (purple in the case of argon). This region is of no importance in thin film processing technology but, as mentioned before, is very important for plasma discharges used as light sources (e.g., a fluorescent Hg-Ar discharge lamp) and in lasers.[4]

Close to the anode, electrons are attracted and accelerated, and positive ions are repelled. The accelerating electrons excite gas molecules, and an anode glow results.

The described discharge regions vary in radiation intensity, potential and electrical field distribution, space charge, and current density, and their occurrence and position depend on the discharge parameters such as pressure, voltage, current, kind of gas, and, as we have seen, the distance between cathode and anode. We refer to work by Coe et al.,[7,8] Raizer et al.,[9] and Bogaerts et al.[10–12] for a more in-depth study of the various phenomena involved in low-pressure noble gas discharges.

Paschen's Law

The preceding section on DC plasmas introduces the concept of avalanche and gas breakdown in a DC diode system. To enhance our understanding of plasmas in general, and specifically to understand better what happens when the electrode distance or pressure in the discharge chamber is changed, we now introduce Paschen's law.

When the electric field between a pair of metal electrodes in air (at room temperature and atmospheric pressure) increases to more than, roughly, 3 MV m^{-1}, *electrical breakdown* occurs. Analogous to the process described above for the argon-filled chamber,

free electrons accelerate in the electric field, and if they pick up enough energy before hitting air molecules, ionization results and more ions and electrons are created. This can lead to yet further ionization or an avalanche destroying the insulating properties of the air between the electrodes and leading to the passage of a high current, accompanied by the emission of heat, light, and sound—that is, a spark discharge. A spark discharge in a localized region (e.g., near a sharp point) is called a *corona* discharge.

The voltage for electrical breakdown depends on the geometry of the electrode gap, the gas, and the pressure. In 1889, Paschen published a paper describing a generalized form for that relationship, and this has become known as *Paschen's law.*[13] The law essentially states that the breakdown characteristics of an electrode gap are a function of the product of the gas pressure and the gap distance, usually written as V = f (P × d), where the breakdown voltage V is a function of the pressure P and the gap distance d. As the pressure or gap is reduced, the breakdown voltage decreases slowly to a minimum and then rises steeply, as illustrated in Figure 3.10, representing the Paschen's law curve in air and other gases. The sharp increase in the breakdown voltage on the left side in Figure 3.10 (low $P \times d$ side) occurs because the electrode spacing is too small for ionization to occur. The number of gas molecules in the space between the electrodes is proportional to $P \times d$. When the pressure is too low or the distance too small, most electrons reach the anode without colliding with gas molecules. As a consequence, the lower the pressure or the shorter the d, the higher the value of V required to give electrons enough energy to cause breakdown of the gas. For air, the minimum breakdown voltage (V_{min}) is about 300 V at ~8-μm gap distance (see also Table 3.3). On the right side of this plot (high $P \times d$ side), the slow increase in breakdown voltage with increasing electrode distances and higher pressures arises because electron collisions with gas atoms become more and more frequent so that for the electrons to gather sufficient energy to overcome the ionization potential of the inert gas, more potential needs to be applied.

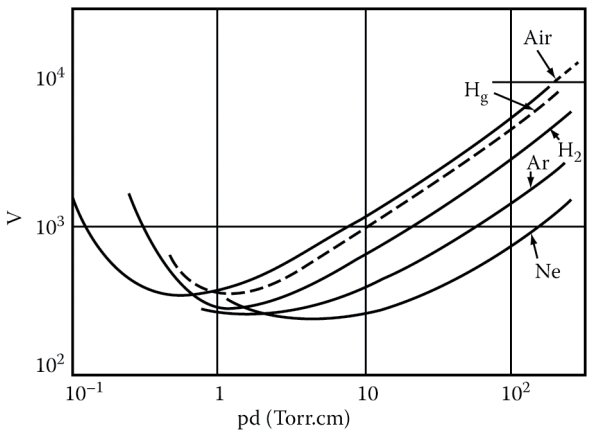

FIGURE 3.10 A DC breakdown voltage as a function of gas pressure P and electrode spacing d for plane parallel electrodes in air and some other gases. Such curves are determined experimentally and are known as *Paschen curves*.

TABLE 3.3 Minimum Breakdown Voltage (V_{min}) and Pressure/Distance Product (P × d) at That Minimum Voltage for Various Gases as Deduced from Their Paschen Law Curves

Gas	V_{min} in Volts (V)	P × d at V_{min} (Torr cm)
Air	327	0.567*
Ar	137	0.9
H_2	273	1.15
He	156	4.0
CO_2	420	0.51
N_2	251	0.67
N_2O	418	0.5
O_2	450	0.7
SO_2	457	0.33
H_2S	414	0.6

*At 1 atm = 760 mmHg or 760 Torr, d = 7.460 10^{-4} cm or ~8 μm.

Some microdevices such as electrostatic micromotors, microionizers for ion mobility spectrometers, and microswitches operate in air without sparking, as they operate on the left side of the Paschen curve (see Volume III, Chapter 8). Our intuition would tend to predict that the smaller the gap distance, the smaller the breakdown voltage. This typifies how linear scaling can be misleading when predicting the behavior of microdevices. Microstructures, with dimensions of a few micrometers, operate in air as if surrounded by a reduced pressure environment.

Different gases exhibit similar "Paschen" behavior, with the curves more or less shifted from the air curve, depending on the mean free path of the gas molecules involved (see Figure 3.10). Paschen's law—V = f(P × d)—should be more correctly stated

as V = f(δ × d), where δ is the density of gas molecules, which is, of course, affected by the temperature and the pressure of the gas. Much research has been done to provide a theoretical basis for Paschen's law and to develop a greater understanding of the breakdown mechanism. This has proven to be a formidable task, as many factors have an effect on the breakdown in a gap, such as radiation, dust, and surface irregularities. The electrode material also affects the sparking voltage, with cathodes of barium and magnesium having higher voltages than aluminum, for example.

In Table 3.3 we list the minimum breakdown voltage (V_{min}) and the product of the pressure and electrode spacing ($P \times d$) at that such voltage for various common gases as deduced from Paschen's law curves.[14]

A good text and reference book on electrical breakdown of gases, although old, is written by Meek and Craggs.[15]

Physics of RF Plasma Reactors

AC voltages overcome the problem of charge accumulation on a dielectric in a DC plasma system. The positive charge that accumulates as a result of ion bombardment during one-half of the AC cycle can be neutralized by electron bombardment during the next half cycle. The frequency of AC must be high enough so the half period will be shorter than the charge-up time of the dielectric. Although this time will vary because of conditions and dielectric materials, for most applications the frequency must be greater than 50 kHz. At low frequencies, both electrons and ions can follow the changing field, so that a glow discharge is the same as DC, except that the polarity reverses twice each cycle. At high frequency, the massive ions cannot respond to the frequency changes, whereas electrons can. By far the most common RF used is 13.56 MHz, allowed by the Federal Communications Commission (because of its noninterference with radio-transmitted signals). The RF power supply is rated between 1 and 2 kW. In RF-generated plasma, a radiofrequency voltage applied between the two electrodes causes free electrons to oscillate and collide with gas molecules, leading to a sustainable plasma. The RF-excited discharges can be sustained without relying on the emission of secondary electrons from the cathode. Electrons pick up enough energy during oscillation in an RF field to cause ionization, thus sustaining the plasma at lower pressures than in DC plasma (e.g., 10 vs. 40 mTorr). The RF breakdown voltage of an AC plasma exhibits the Paschen behavior of a DC plasma; that is, a minimum in the required voltage as a function of the pressure with the mean free path of electrons, λ_e, substituting the spacing, d, between electrodes.

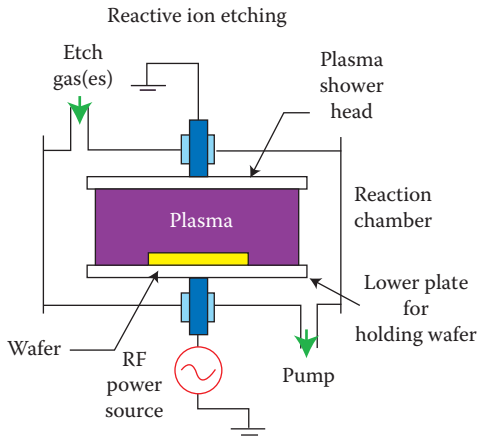

FIGURE 3.11 Two-electrode setup (diode) for RF ion sputtering or sputter deposition. For ion sputtering, the substrates are located on the cathode (target); for sputter deposition (see Chapter 7), the substrates to be coated are located on the anode.

In the simplest case of RF ion sputtering, the substrates to be etched are laid on the cathode (target) of a discharge reactor, for example, a planar parallel-plate reactor as shown in Figure 3.11. The reactor consists of a grounded anode and powered cathode or target enclosed in a low-pressure gas atmosphere (e.g., 10^{-1}–10^{-2} Torr of argon). The RF plasma, formed at low gas pressures, consists of positive cations, negative anions, radicals, and photons (the UV photons create the familiar plasma glow). As with DC plasma, neutral species greatly outnumber electrons and ions—the degree of ionization only being on the order of 10^{-4}–10^{-6} for parallel-plate gas discharges. With one of the two electrodes capacitively coupled to the RF generator, this electrode automatically develops a negative DC bias and becomes the cathode with respect to the other electrode (see Figure 3.12a). This DC bias (also called *self-bias* V_{DC}) is induced by the plasma itself and is established as follows. When initiating an AC plasma arc, electrons, being more mobile than ions, charge up the

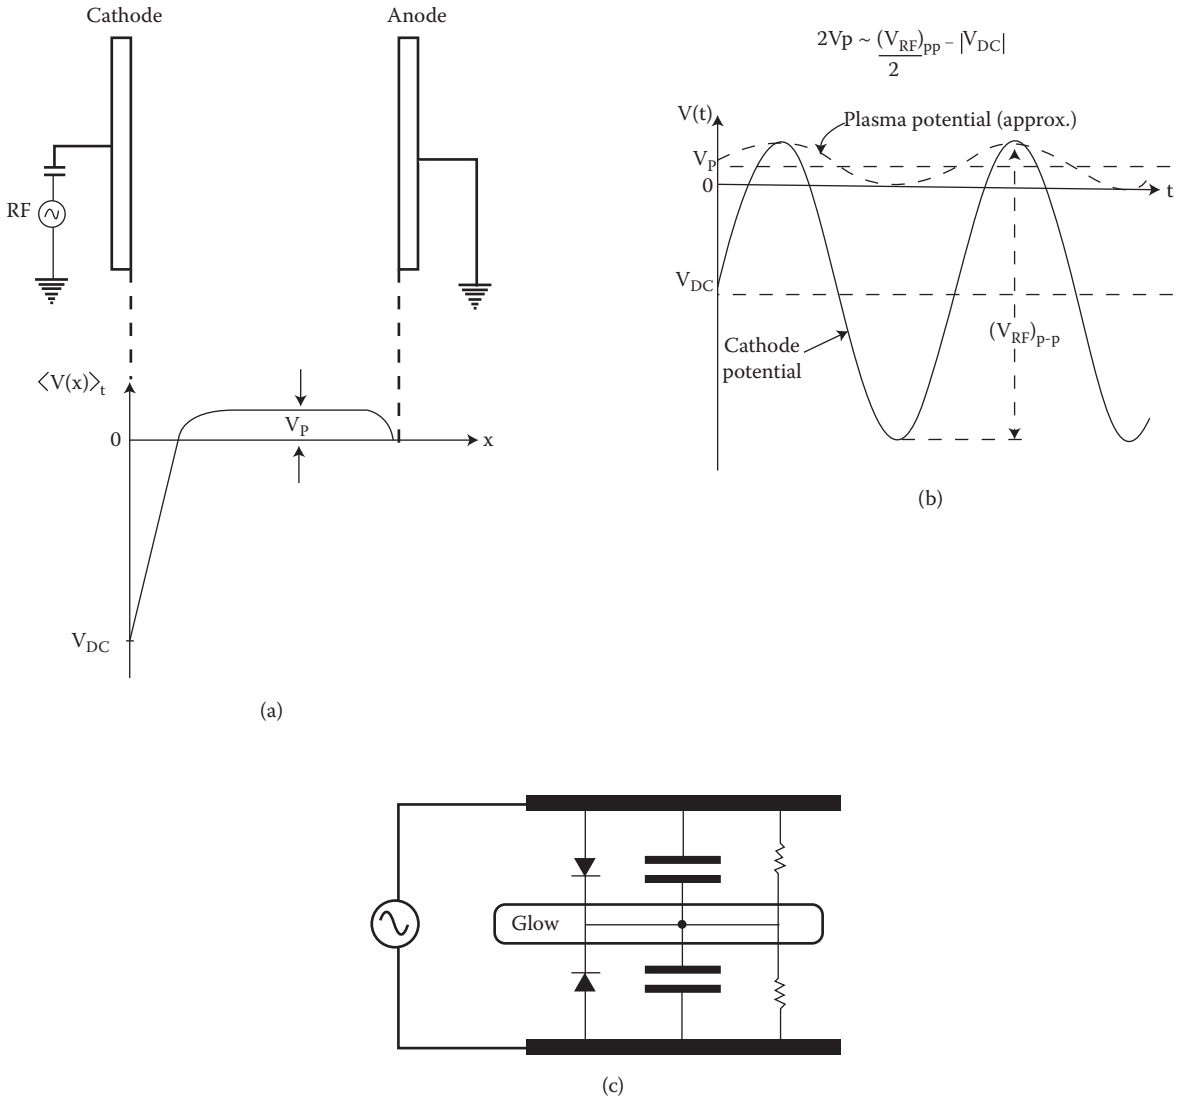

FIGURE 3.12 An RF plasma. (a) Approximate time-averaged potential distribution for a capacitively coupled planar RF discharge system. (b) Potential distribution in glow discharge reactors—V_p: plasma potential; V_{DC}: self-bias of cathode electrode; $(V_{RF})_{pp}$: peak-to-peak RF voltage applied to the cathode. (c) Equivalent electrical circuit of an RF plasma.

capacitively coupled electrode; because no charge can be transferred over the capacitor, the electrode surface retains a negative DC bias.

The energy of charged particles bombarding the surface in a glow discharge is determined by three different potentials established in the reaction chamber: the plasma potential V_p, that is, the potential of the glow region, the self-bias V_{DC}, and the bias on the capacitively coupled electrode $(V_{RF})_{pp}$ (see also Figure 3.12b). The following analysis clarifies how these potentials relate to one another and how they contribute to dry etching.

The self-bias buildup, V_{DC}, on an insulating electrode by the electron flux (Equation 3.1) is given by:

$$V_{DC} = \frac{kT_e}{2e} \ln \frac{T_e m_i}{T_i m_e} \tag{3.6}$$

where T_e and T_i are the electron and ion temperatures defined by Equations 3.2 and 3.3, and m_e and m_i are the electron and ion masses, respectively.[16] In the plasma, there are equal amounts of hot electrons ($T_e = 2 \times 10^4$ K) and cold positive ions ($T_i = T_{gas} = 500$ K). For a common RF power density of 4 kWm^{-2} the self-bias is about 300 V, so that the powered electrode (the cathode) is bombarded with 300 eV of positive ions.[17]

The electron loss creates an electric sheath field in front of any surface immersed in the plasma,

counteracting further electron losses. This sheath or dark space forms a narrow region between the conductive glow region and the cathode (the Crookes dark space) where most of the voltage (V_{DC} in Figure 3.12a) is dropped as in the DC plasma case. The cathode, being capacitively coupled, effectively acts as an insulator for DC currents. The thickness of the sheath is typically 0.01–1 cm, depending on pressure, power, and frequency. The other electrode is grounded and conductive (no charge buildup and no voltage buildup) and automatically becomes the anode with respect to the capacitively coupled electrode.

The time-average of plasma potential V_p, DC cathode potential (self-bias potential) V_{DC}, and peak-to-peak RF voltage $(V_{RF})_{pp}$ applied to the cathode are approximately related as (see Figure 3.12b):

$$2V_p \sim \frac{(V_{RF})_{pp}}{2} - |V_{DC}| \tag{3.7}$$

Clearly, the magnitude of the self-bias depends on the amplitude of the RF signal applied to the electrodes. In the RF discharge, the time-averaged RF potential of the glow region, referred to as the *plasma potential* V_p, is more significantly positive with respect to the grounded electrode than in the case of a DC plasma.

Positive argon ions from the plasma are extracted by the large field at the cathode and sputter that electrode at near-normal incidence, with energies ranging from a few to several hundred electronvolts, depending on plasma conditions and chamber construction. One of the most important parameters determining plasma condition is total reactor pressure. As pressure is decreased to less than 0.05–0.1 Torr, the total ion energy, E_{max}, increases as both the self-bias voltage and the mean free path of the bombarding ions increase. Subsequently, ion-substrate bombardment energy increases sharply with decreasing pressure. The maximum energy of positive ions striking a substrate placed on the cathode is proportional to:

$$E_{max} = e(|V_{DC}| + V_p) = eV_T \tag{3.8}$$

with $V_T = |V_{DC}| + V_p$, whereas the maximum energy for a substrate on the grounded electrode (i.e., the anode) is proportional to:

$$E_{max} = eV_p \tag{3.9}$$

Typical values are 300 eV for the cathode and less than 20 eV for the anode.[17] Equations 3.8 and 3.9 can be deduced from an inspection of Figure 3.12a. The situation where the wafers are placed on the cathode is referred to as *reactive ion etching* or *reactive sputter etching*. Chamber construction, especially the ratio of anode to cathode area, influences the rates of V_T/V_p and, consequently, as calculated from Equations 3.8 and 3.9, the energy of the sputtering ions on these respective electrodes. Etching of the anode should be avoided, that is, V_p should be kept small (e.g., <20 eV). To deduce the influence of the geometry of the anode and cathode on dry etching, we compare the sheath voltages in front of the anode and cathode using the Child-Langmuir equation, expressing the relationship between the ion-current flux, j_i, the voltage drop, V, over the sheath thickness of the dark space, d, and the mass of the current-carrying ions, m_i. The relation can be deduced from Equation 3.5, assuming the presence of a space-charge limited current:

$$j_i = \frac{KV^{\frac{3}{2}}}{\sqrt{m_i}\,d^2} \tag{3.10}$$

in which K is a constant.[18] The current density of the positive ions must be equal on both the *anode* $j_i(P)$ and cathode $j_i(T)$; that is, $j_i = j_i(P) = j_i(T)$, resulting in the following relation for the sheath voltages:

$$(\text{cathode})\frac{V_T^{\frac{3}{2}}}{d_T^2} = (\text{anode})\frac{V_p^{\frac{3}{2}}}{d_p^2} \tag{3.11}$$

The plasma behaves electrically as a diode (large blocking voltage drop toward the capacitively coupled cathode and small voltage drop on the anode/plasma interface), in parallel with the sheath capacitance. As soon as any electrode tends to become positive relative to the plasma, the current increases dramatically, causing the plasma to behave as if a diode were present in the equivalent electrical circuit of the plasma. Hence a planar, parallel setup also is called a *diode* setup. The equivalent electrical circuit representing an RF plasma is represented in Figure 3.12c. The dark spaces in plasma are areas

of limited conductivity and can be modeled as capacitors:

$$C \sim A/d \tag{3.12}$$

The plasma potential is determined by the relative magnitudes of the sheath capacitances, which, in turn, depend on the relative areas of anode and cathode. An RF voltage will split between two capacitances in series according to:

$$\frac{V_T}{V_p} = \frac{C_p}{C_T} \tag{3.13}$$

Using Equations 3.12 and 3.13, we can write:

$$\frac{V_T}{V_p} = \left(\frac{A_p}{d_p}\right)\left(\frac{d_T}{A_T}\right) \tag{3.14}$$

and substituting into Equation 3.11, we obtain:

$$\frac{V_T}{V_p} = \left(\frac{A_p}{A_T}\right)^4 = R^4 \tag{3.15}$$

where A_p is the anode area and A_T the cathode area. If there were two symmetric electrodes, both blocked capacitively, sputtering would occur on both surfaces. If the area of the cathode were significantly smaller than the other areas in contact with the discharge, the plasma potential would be small, and little sputtering would occur on the anode, whereas the cathode would sputter very effectively. Because the cathode in a setup such as that represented in Figure 3.11 usually is large (>1 m^2), allowing many silicon wafers or other substrates to be etched simultaneously, the grounded area needs to be larger yet. In sputtering systems, the anode and the entire sputtering chamber are grounded, creating a very small anode dark space where hardly any sputtering takes place. Other researchers have assumed conservation of the positive ion current; that is, $j_i(P) \times A_p = j_i(T) \times A_T$ instead of current density, and they find an exponent 2 in deriving Equation 3.15. The exponential in Equation 3.15 in practical systems is usually closer to 2.[5]

In a setup where the electrode dimensions are large compared with the electrode distance, the anode and cathode areas are considered equal, and little difference is made between V_T and V_p.[5]

Higher ion energies (V_T large) translate into lower etch selectivity and can be a cause of device damage (Table 3.4). Consequently, a key feature for good etch performance (Table 3.5) is effective ionization to produce very high quantities of low-energy ions and radicals at low pressures. Selectivity as high as 40:1 might be required in the future for ICs and even more for micromachines. It is generally believed that "radiation" damage of plasma can be minimized by keeping ion energies low. It is also generally believed that a lot of the radiation damage can be annealed out. In reality, very little is understood of the damage plasma can do. The higher the etch rate, the better the wafer throughput. Good selectivity, uniformity, and profile control are more easily achieved at lower etch rates. Trenches of various depths are made in Si in the manufacture of metal oxide semiconductor (MOS) devices. Shallow

Table 3.4 Device Damage

Some "flavors" of device damage:
• Alkali (sodium) and heavy metal contamination
• Catastrophic dielectric breakdown
• Current-induced oxide aging
• Particulate contamination
• UV damage
• Temperature excursions that can activate metallurgical reactions
• "Rogue" stripping processes that simply do not remove all the residue
• Plasma-induced charges, surface damage, ion implantation

Table 3.5 Etch Performance*

Etch performance is judged in terms of the following:
1. Etch rate: Rate at which material is removed from the substrate
2. Uniformity: Etch rate constancy across the substrate
3. Throughput: Amount of substrates/wafers etched during one process cycle
4. Directional control: Control of the horizontal (CD) and vertical etch rate (profile)—isotropic or anisotropic
5. Surface quality (residue, microloading effects)
6. Device damage
7. Particle control
8. Reproducibility
9. Selectivity of etch:
a. Controlled by etchant composition
b. Controlled by etch rate

*See also Introduction to Part II.

trenches (0.5–1.5 μm) are used to aid in reducing the effects of lateral diffusion during processing and to make flat structures (planarization). Deeper trenches (1.5–10 μm) are used to create structures that become capacitors and isolation regions in integrated circuits. For the shallowest trenches, photoresist is adequate as a mask. For deeper etching, a silicon dioxide mask may be needed. In micromachining, one would like to obtain aspect ratios of 100 and beyond; thus, the difficulty in masking keeps mounting. With aspect ratios above 2:1 or 2.5:1, *the etching action* at the bottom of a trench tends to slow down or stop altogether.

In answer to these identified needs, equipment builders have come up with low-energy, high-density plasmas, for example, magnetrons, inductively coupled plasmas (ICPs),[19] and electron cyclotron resonances (ECRs)[20] (see below Figure 3.36).

Physical Etching: Ion Etching or Sputtering and Ion-Beam Milling

Introduction

Bombarding a surface with inert ions (e.g., argon ions), in a setup as shown in Figure 3.11, translates into ion etching or sputter etching. With ions of sufficient energy impinging vertically on a surface, momentum transfer (sputtering) causes bond breakage and ballistic material ejection, throwing the bombarded material across the reactor to deposit on an opposing collecting surface, provided the surrounding pressure is low enough. The kinetic energy of the incoming particles largely dictates which events are most likely to take place at the bombarded surface, that is, physisorption, surface damage, substrate heating, reflection, sputtering, or ion implantation. At energies less than 3–5 eV, incoming particles are either reflected or physisorbed. At energies between 4 and 10 eV, surface migration and surface damage results. At energies >10 eV (e.g., from 5–5000 eV), substrate heating, surface damage, and material ejection, that is, sputtering or ion etching, take place. At yet higher energies, >10,000 eV, ion implantation, that is, doping, occurs. The energy requirements for these various processes are summarized in Table 3.6 (see also Figure 3.15).

Table 3.6 Energy Requirements Associated with Various Physical Processes

Ion Energy (eV)	Reaction
<3	Physical adsorption
4–10	Some surface sputtering
10–5000	Sputtering
10–20 K	Implantation

The deposition phenomenon mentioned above can be used to deposit materials in a process called *sputter deposition* (Chapter 7). A low pressure resulting in a long mean free path is required for material to leave the vicinity of the sputtered surface without being backscattered and redeposited.

In what follows, we shall consider two purely physical dry etching techniques at energies >10 eV, that is, sputtering or ion etching and ion-beam milling.

Sputtering or Ion Etching

The gradient in the potential distribution around the target lying on the cathode (see Figure 3.11) accelerates the ions, prompting them to impinge on the substrate in a direction normal to the surface. The etch rate in the direction of the impinging ions (V_z) becomes a strong function of E_{max} (Equations 3.8 and 3.20). The impinging ions erode or sputter etch the surface by momentum transfer. This offers some advantages: volatility of the etch products is not as critical as for dry chemical etching, and only a billiard ball effect plays a role in physical etching. As a consequence, differences in etch rates for various materials are not large (sputter yields for most are within a factor of three), and the method entails directional anisotropy. Physical etching is inherently nonselective because the ion energy required to eject material is large compared with differences in chemical bond energy and chemical reactivity. When no reactive etching processes are available for a given material, physical etching is always an option. Directional anisotropy remains as long as the dimensions of the surface topographical structures are small compared with the thickness of the sheath between the bulk plasma and the etched surface. However, etch rates are slow, typically a hundred to a few hundred angstroms per minute. The use of a magnetron can help improve the etch rate

and minimize heating of substrates. In both DC and RF diode sputtering, most electrons do not cause ionization events with Ar atoms. They end up being collected by the anode, substrates, and so on, where they cause unwanted heating. A magnetron adjusts this situation by confining the electrons with magnetic fields near the target surface; consequently, current densities at the target may increase from 1 mA/cm^2 to 100 mA/cm^2.

As sputter etching is nonselective, it introduces a masking problem. Another hurdle is the need for rather high gas pressure to obtain sufficiently large ion currents, resulting in a short mean free path, λ_i, of the ions. With a mean free path smaller than the interelectrode spacing, considerable redeposition of sputtered atoms on the etching substrate lying on the cathode can occur. Electrical damage from ion bombardment also must be taken into account when critical electronic components reside on the substrate.

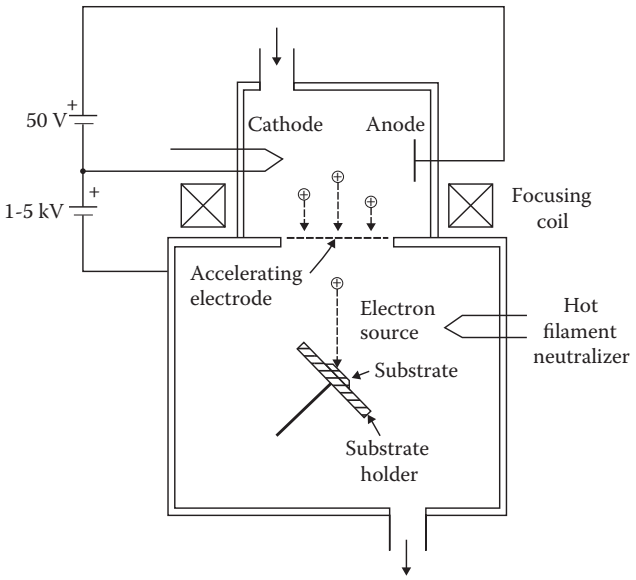

FIGURE 3.13 Ion-beam etching (IBE) apparatus (triode). In an ion-beam apparatus, the beam diameter is approximately 8 cm. Substrates are mounted on a moveable holder allowing etching of large substrates. Coils focus the ion beam and densify the ion flux in magnetically enhanced ion etching (MIE).

Ion-Beam Etching or Ion-Beam Milling

Ion-beam milling (IBM) is a process wherein the plasma source for ion etching is decoupled from the substrate, which is placed on a third electrode. Decoupled plasma is also called *remote* plasma, and the equipment needed is called a *triode* setup. The plasma source can be an RF discharge or a DC source (Penning source). In a typical DC triode setup, as shown in Figure 3.13, control of the energy and flux of ions to the substrate in the substrate chamber happens independently. The sample being etched can be rendered neutral by extracting low-energy electrons from an auxiliary thermionic cathode (i.e., a hot filament neutralizer), thus making this DC equipment usable for sputtering insulators, as well as conductors. In ion-beam milling, as in ion etching, noble gases are generally used as they exhibit higher sputtering yields as a result of heavy ions and avoid chemical reactions. The argon pressure in the upper portion of the chamber can be low (10^{-4} Torr), resulting in a large mean free ion path. Adding a hot wire (Kaufman source) or a hollow cathode can enhance ionization at those low pressures. In a Kaufman source, electrons are emitted by a hot filament (typically tantalum or tungsten) and accelerated by a potential difference between the cathode filament and an anode. A hollow cathode is a metal cylinder with a hole several millimeters in diameter. When the pressure is decreased, the hollow cathode starts to emit extremely strong light (negative glow) when the cathode sheath thickness reaches about the same dimensions as the diameter of the hole. The hollow cathode bounces electrons back and forth within the negative glow, thereby enhancing the plasma density considerably beyond that of a normal discharge.[5]

The discharge voltage in IBE must be larger than the gas ionization potential (15.7 eV for argon) and typically is operated at several times this value, about 40–50 eV, to establish a glow discharge. Ions are extracted from the upper chamber by sieve-like electrodes (extraction grids), formed into a beam, accelerated, and fired into the lower chamber where they strike the substrate. Achievable ion energies range from about 30 eV to several keVs. Beam divergence through collisions with residual gas molecules in the substrate chamber usually limits the lowest practical ion energy to a few hundred electronvolts. Typical etch rates with argon ions of 1 keV of energy and an ion current density of 1.0 mA/cm^2 are in the range of 100–3000 Å/min for most materials such as silicon,

polysilicon, oxides, nitrides, photoresists, and metals. Inert ion-beam etching (IBE) in an ion miller is, in principle, capable of very high resolution (<100 Å), but aspect ratios are usually less than or equal to unity, and selectivity is poor. The use of the extraction grid also increases the potential for contaminating the ion beam with sputtered grid material.

Higher plasma ion densities may be created by using magnetic coils in a magnetron sputtering machine to increase the electron path length. Just as the ionospheric van Allen belts are confined by the Earth's dipole field, plasma remains confined within the magnetic envelope generated by the coils, thus preventing electron loss to plasma-exposed surfaces. This principle is exploited, for example, in magnetically enhanced ion etching (MIE) (see coils in Figure 3.13). A magnetic field is applied so that electrons cannot pass directly from the anode to the cathode, but rather follow helical paths between collisions, greatly increasing their path length and ionization efficiency. To understand this enhancement in ionization efficiency, consider an electron moving with a velocity v_e. This velocity will be affected by both the electric and the magnetic fields, and the force on the electron is given by the Lorentz force (see Volume I, Equation 3.64):

$$F = e\,(V_e \times B) \qquad \text{(Volume I, Equation 3.64)}$$

in which all quantities, except for the electron charge, are vectors. The direction of the force vector on the electron is perpendicular to both the magnetic field and the direction of the velocity; consequently, the electron will spiral around the magnetic field lines (see Figure 3.14).

With an angle ϕ between the momentary electron velocity vector and the magnetic field vector, the radius r of the electron orbit is:

$$r = \frac{m_e v_e}{eB\sin\phi} \tag{3.16}$$

where m_e is the mass of the electron. Equation 3.16 is obtained by equating the magnetic and centripetal forces. When the electron is moving at right angles to the magnetic field, this simplifies to:

$$r = \frac{m_e v_e}{eB} \tag{3.17}$$

The circular motion of electrons in the presence of a magnetic field can also be described in terms of an angular frequency ω_c (also the cyclotron frequency), which can be calculated from the electron velocity v_e and the radius r of the electron helix as described in Equation 3.17:

$$\omega_c = \frac{v_e}{r} \tag{3.18}$$

At an electron energy of 2 eV, the mean electron velocity is 9×10^5 m s^{-1} (see Equation 3.2). According to Equation 3.17, with a magnetic field B of 5×10^{-3} Tesla (T) applied, electrons will be forced into a circular path with a radius of about 1 mm.[21] At a higher electron temperature of 100 eV, the cyclotron radius of an electron in a field of 0.01 T (or 100 Gauss) is 3.2 mm. These cyclotron radii are of the order of the mean free path and smaller than the smallest dimension of the average dry etch reactor. By lengthening the electron path considerably, electrons are prevented from reaching the reactor walls where

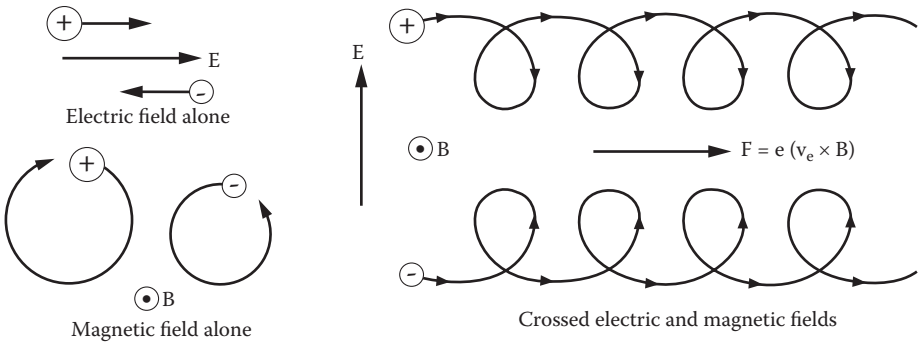

FIGURE 3.14 Electron path with electric field alone and with magnetic field alone and finally with crossed electric and magnetic fields.

they would be lost. Any velocity component of an electron parallel to the magnetic field will change the circular path into a helix. In principle, ions also will move in helical paths; however, the radius r (see Equation 3.17), because of the heavy mass of ions, is so large that the effect can be neglected. Clearly, from the above, a magnetic field can lower wall recombination by confining the electrons, hence making relatively low field strengths adequate for obtaining high plasma densities. When plasma density is increased with magnetic confinement, the degree of ionization is between 10^{-2} and 10^{-4}, compared with 10^{-4}–10^{-6} for simple plate discharges, resulting in an increased etch rate.

The cyclotron resonance frequency of an electron estimated from Equation 3.18 is about 10^8 s^{-1}, which is in the microwave range. If the RF excitation frequency is in the same range, resonance takes effect, causing an additional increase in the RF energy transfer efficiency. Microwave energy may be injected into plasma to energize the ECR ion source as reviewed further below (Figure 3.36b).

When inert argon ions in a triode setup as shown in Figure 3.13 are replaced with reactive ions, reactive ion-beam etching (RIBE) occurs. The ions not only transfer momentum to the surface but they also react directly with the surface, which means a chemical/physical mechanism is involved. Direct reactive ion etching of a substrate is the exception rather than the rule, and it is the radicals generated in the plasma that usually dominate the chemical reactions at the surface.

Systems using a hot filament to produce a plasma have a relatively short lifetime in the presence of reactive gases, as conventional filament materials tend to etch away (e.g., tungsten in the presence of halides forms volatile tungsten halides).[21] The latter type of plasma source problem is avoided by using microwave excitation.

IBE may cover an area of 3–8 cm. This also is referred to as *showered ion etching.* Yet another type of IBE, a maskless technique called *focused ion beam* (FIB), in which the beam is made extremely narrow and used as a direct writing tool, is discussed in more detail in Chapter 6.

Because of its low etch rate and low selectivity, IBE is used more for fundamental mechanistic studies rather than for patterning. For example, in IBE, the substrate can be tilted relative to the direction of ion bombardment, and, as the ion energy at the substrate and the angle of incidence are known, fundamental information, such as sputter yields, can be obtained.[21] The sputter yield S is defined as the mean number of atoms removed from the surface per incident ion. The sputtering yield depends on the incident ion energy, the mass of the incident ion, the mass of the substrate atom to be etched away, the angle of the incident ion with respect to the substrate, the crystallinity and the crystal orientation of the substrate, the temperature of the substrate during etching, and the partial pressure of oxygen in the residual gas. The sputter yield as a function of the incident ion energy is shown in Figure 3.15. The sputtering yield increases with the incident ion energy and reaches a broad maximum at energies between 5 and 50 keV. Beyond 50 keV, the sputtering yield decreases because of the deeper penetration of the ions in the substrate—that is, ion implantation.[22] The angular dependence of the sputtering yield S will be considered below when we discuss etching profiles in physical etching.

In Chapter 7 we will learn more about sputter deposition. In sputter deposition the substrate on the cathode is replaced by a sputter target cathode, and materials sputtered from that target are deposited on the substrate now placed on the anode.

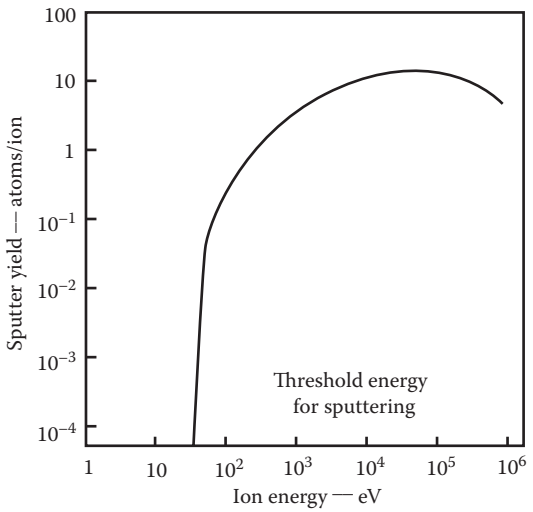

FIGURE 3.15 Sputter yield as a function of the energy of the bombarding ion.

Etching Profiles in Physical Etching

Introduction

The ideal result in dry or wet etching is usually the high-fidelity transfer of the mask pattern onto the substrate, with no distortion of critical dimensions (CDs). Isotropic etching (dry or wet) always enlarges features and thus distorts CDs. Chemical anisotropic wet etching is crystallographic. As a consequence, CDs can be maintained as long as features are strategically aligned along certain lattice planes (see Chapter 4 on wet chemical etching and wet bulk micromachining: pools as tools). With sputtering, the anisotropy is controllable by the plasma conditions.

As can be seen from Figure 3.3a, ion etching and ion milling do not lead to undercutting of the mask, but the walls of an etched cut are not necessarily vertical. A variety of factors contribute to this loss of fidelity in pattern transfer, and they are either caused by involatile sputtering reaction products or by special ion-surface interactions. We shall briefly review these dry physical ion etching problem areas.

Faceting Due to Angle-Dependent Sputter Rate

In Figure 3.15 sputter yield S is shown as a function of the energy E of the bombarding ion. The sputter yield is a complex function of the binding energy U of the material and its atomic number $Z_{material}$ as well as the nature of the sputtering gas (with its own atomic number Z_{gas}). S increases for heavier gases and also depends on the angle of incidence of the ions (θ). The dependence of S on different factors is summarized in Table 3.7. Many different phenomena may occur when an ion hits a substrate/target.

TABLE 3.7 Sputtering Yield S Dependence on Various Factors

Factor		Effect on Sputter Yield S
Target material	Binding energy U	Higher U means lower S
	Atomic number $Z_{material}$	Higher Z means lower S
Sputtering gas	Atomic number Z_{gas}	S increases for heavier gases
	Incident energy E	S increases for higher energy
Geometry		S reaches a maximum 20–30° of glancing

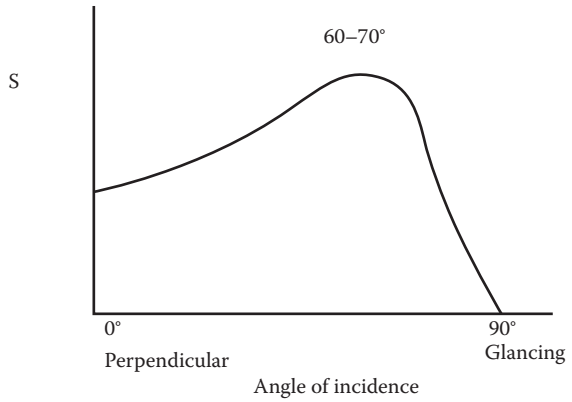

FIGURE 3.16 Sputter yield as a function of angle of incidence of bombarding ions.

The ions may bounce back, implant, absorb on the surface, or reflect by a grazing collision sequence.

In Figure 3.16 we plot the sputter yield S as a function of θ, the angle at which ions are directed at the surface (0° is perpendicular and 90° is glancing). Sputtering is often most efficient at about 20–30° off glancing. In sputtering (at energies <50 keV), the incoming ions may be modeled as hard spheres colliding with the substrate, with 95% of the incident energy going into the substrate (thus making cooling of the target absolutely required) and 5% of the incident energy carried off by substrate/target atoms. The atoms come off with a cosine distribution. It intuitively can be understood that 1) at a glancing angle the incoming ions do not eject atoms from the substrate/target ($S = 0$), 2) hitting the substrate perpendicularly with ions leads to fewer atoms being ejected from the substrate/target, and 3) that in between there are a maximum number of atoms being kicked out.

Even when starting out with a vertical mask sidewall, ion sputtering exhibits a tendency to develop a facet on the mask edge at the angle of maximum etch rate. This corner faceting is detailed in Figure 3.17a. The corner of the mask, always a little rounded even when the mask walls are very vertical, etches faster than the rest and is worn off. Faceting at the mask corner arises because the sputter yield S for materials is a function of the angle at which ions are directed at the surface [$S = f(\theta)$, see Figure 3.16]. The sputter-etch rate of resist, for example, reaches a maximum at an incidence angle of about 60°, more than twice the rate at normal incidence.[22] Sloped mask sidewalls may eventually be followed by sloped etch steps in the

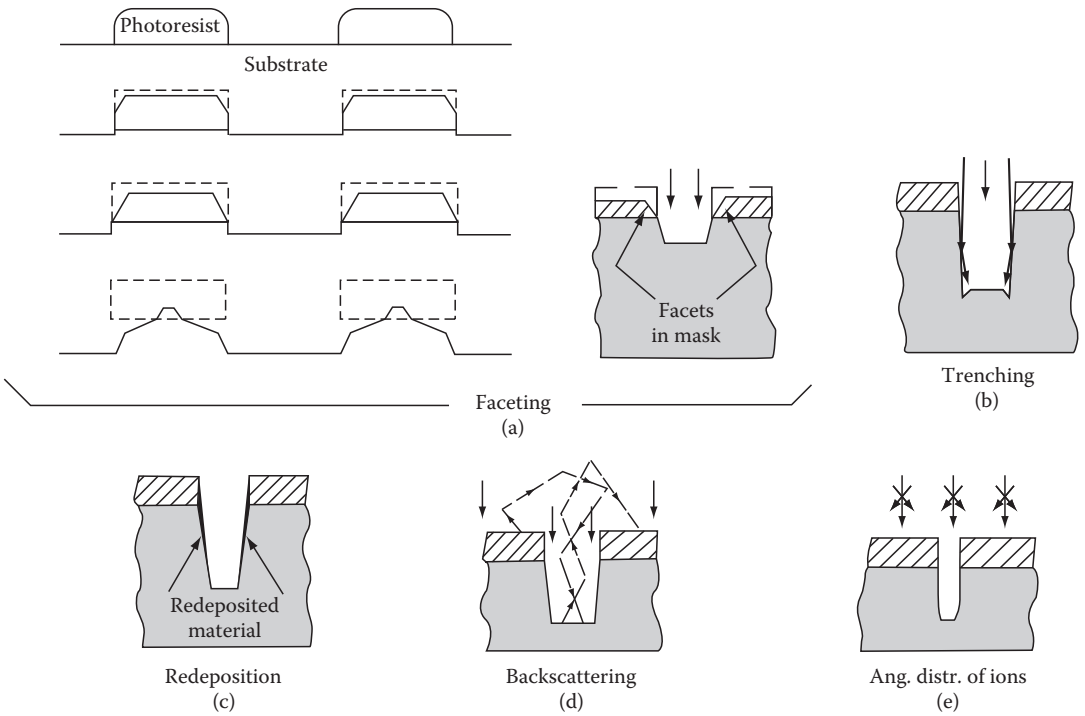

FIGURE 3.17 Limitations of dry physical etching. (a) Faceting. Sputtering creates angled features. An angled facet (~60°) in the resist propagates as the mask is eroded away. Sloped walls may also be created in the underlying substrate. (b) Ditching or trenching as a result of glancing incidence of ions. (c) Redeposition of material sputtered from the bottom of a trench. (d) Backscattering. (e) Angular distribution of incident ions. (Based on Lehmann, H. W. 1991. *Thin film processes II.* Eds. J. L. Vossen, and W. Kern. Boston: Academic Press.[1])

substrate. Faceting of the substrate itself will proceed along its own preferred sputtering direction angle. The faceting is more pronounced with an applied bias as a result of the increased electric field at corners. Usually, faceting affects only the masking pattern, and making the mask sufficiently thick minimizes its influence on the fidelity of the pattern transfer.

It should be noted that some of the disadvantages of physical etching, such as resist corner faceting, can sometimes be exploited. For example, a gently sloping edge is advantageous to facilitate metal coverage or planarization because a tapered sidewall is easier to cover than a vertical wall, especially when using line-of-site deposition methods. The method most often used to obtain such a taper is a controlled resist failure, that is, erodible or sacrificial masks (Figure 3.18). In other words, the "negative effect" of faceting described in connection with Figure 3.17a is put to good use.

Ditching or Trenching

When the slope of the side of the mask is no longer completely vertical, some ions will collide at a glancing angle with the sloping edges before they arrive at the etch surface. This gives a local increase in etch rate, leading to ditches (Figure 3.17b). For this mechanism to be active, there must be a sizable fraction of ions with at least slightly off-vertical trajectories, or the sidewall must have a slight taper as shown in Figure 3.17b.[23] For example, the taper of the sidewall could result from redeposition (see next section) or faceting (see above). Because ditching is a

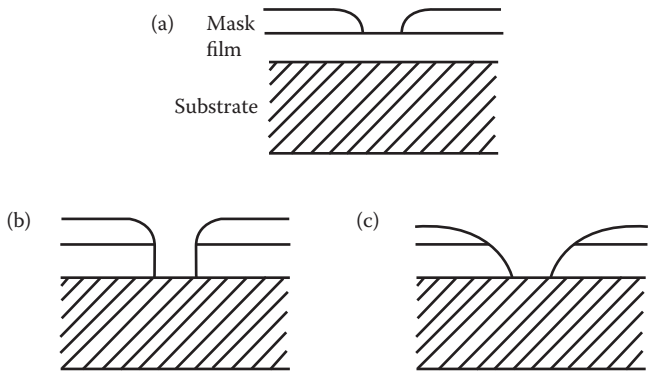

FIGURE 3.18 Erodible or sacrificial masks. (a) Patterned masking structure prior to etching. (b) Nonerodible mask. (c) Partially erodible mask.

small effect (e.g., 5%), it often goes unnoticed unless thick layers are etched.

Redeposition

Another sputtering limitation, already alluded to, is the redeposition of involatile products on step edges (Figure 3.17c). Redeposition involves sputtered involatile species from the bottom of the trench settling on the sidewalls of the mask and etched trench. The phenomenon manifests itself mainly on sloped sidewalls.

By tilting and rotating the substrate during etching (Figure 3.19), etch profiles can be improved. The reasons for tilting and rotating improvements are a combination of shadowing the bottom of the step (to reduce trenching), partially etching the sidewalls of the mask (to reduce redeposition), and gaining more nearly vertical edges on the etched profiles in the substrate. Especially with aspect ratios exceeding unity, redeposition becomes problematic, and reactive gas additives are necessary to generate volatile etch products. With aspect ratios greater than 2:1 or 2.5:1, the etching action at the bottom of too-fine features tends to slow down or stop altogether. Reactive additives bring us into the realm of chemical-physical etching (discussed further below). For micromachining, tilting and rotating of substrates are recurring topics. They are some of the desirable modifications of standard equipment used for micromachining applications (for example, see the fabrication of Spindt field emitters shown in Figure 2.42).

Redeposition may also be used to control sidewall profiles. The material redeposited on the sidewall protects the sidewalls, whereas the material redeposited at the bottom gets removed during the etching process. With the proper control of the redeposition, one can achieve a highly anisotropic profile.

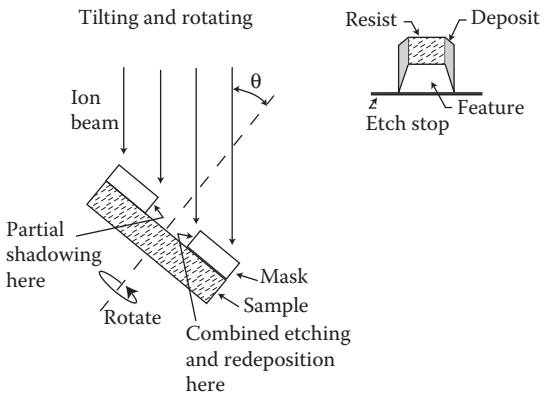

FIGURE 3.19 Left: By tilting and rotating the substrate during etching etch profiles can be improved. Right: Redeposition may be used to control sidewall profiles.

Backscattering

Backscattering, illustrated in Figure 3.17d, is a form of redeposition associated with involatile etch products. A fraction of the sputtered and involatile species from the surface is backscattered onto the substrate after several collisions with gas phase species. This indirect redeposition may involve contaminants from the walls and fixtures in the vacuum chamber. Backscattering fixes the upper pressure limit for ion-enhanced etching. Significant redeposition can take place at pressures as low as 10 mTorr.[1]

Angular Distribution of Incident Ions

Sheath scattering and/or field nonuniformities cause off-vertical ion trajectories. Most ions impinge perpendicularly on the substrate. Scattering of a small fraction of ions in the sheath causes a distribution of impingement angles.[1] This scattering in the sheath is responsible for hourglass-shaped etch profiles that have been observed in trench etching of silicon (see Figure 3.17e). Besides sheath scattering, there is a second mechanism active that may lead to skewing of ion directionality; namely, inhomogeneities in the electrical field at the substrate surface. With etching conductors, the bending of electric field lines caused by surface topography has the effect of enhancing ion flux at feature edges and leads to ditching. On the other hand, with etching insulators, charging effects may cause appreciable ion fluxes to the sidewalls of a trench and contribute to lateral etching. The latter will again lead to hourglass-shaped trenches. The importance of the effect is very much related to the electrical conductivity of the masking and etching surfaces, with the greatest significance for strongly insulating materials.[24]

Temperature Control during Dry Etching

During dry etching, heavy ion bombardment of the substrate generates a lot of heat. To protect photoresist masks, temperature control is required. This could in principle be achieved by water cooling the

wafer-chuck (pedestal or cathode) although the low pressure makes for poor heat transfer between the substrate and the wafer-chuck, so helium backside cooling is required. Alternatively a clamp ring or electrostatic chuck (E-chuck) is used to hold the wafer.

Physical Etching Summary

In physical etching, ion etching or sputtering, and ion-beam milling, argon or other inert ions extracted from the glow discharge region are accelerated in an electrical field toward the substrate, where etching is purely impact controlled. Sputtering is inherently nonselective because large ion energies compared with the differences in surface bond energies and chemical reactivities are involved in ejecting substrate material. The method is slow compared with other dry etching means, with etch rates limited to several hundreds of angstroms per minute compared with thousands of angstroms per minute, and higher for chemical and ion-assisted etching (as high as 6 μm/min with the newest deep RIE equipment). Sputter etching tends to form facets, ditches, and hourglass-shaped trenches and frequently redeposits material in high-aspect-ratio (>2:1) features. Electrical damage to the substrate from ion bombardment and implantation can be problematic. However, some of the reversible plasma damage can be removed by a thermal anneal. With the continuing increase in device complexity, which includes layers of different chemical composition, inert ion etching and ion-beam sputtering will continue to find new applications.

Plasma Etching (Radical Etching)

Introduction

In reactive plasma etching (PE), which corresponds to a high-pressure RIE extreme, reactive neutral chemical species such as chlorine or fluorine atoms and molecular species generated in the plasma diffuse to the substrate where they form volatile products with the layer to be removed. The only role of the plasma is to supply gaseous, reactive etchant species. Consequently, if the feed gas were reactive enough, no plasma would be needed. At pressures of $>10^{-3}$ Torr, the neutrals strike the surface at random angles, leading to isotropic, rounded features. A dry chemical etching regime can be established by operating at low voltages, eliminating impingement of high-energy ions on the sample, and facilitating surface etching almost exclusively by chemically active, neutral species formed in the plasma. The reaction products—volatile gases—are removed by the vacuum system. The volatility of the formed reaction product introduces a major difference with sputtering, where involatile fragments are ejected like a billiard ball and may be redeposited close by.

Reactor Configurations

Reactive plasma etching is one extreme of RIE and basically follows the same process we encountered when discussing dry stripping of resists (Chapter 1, Dry Stripping). Three different popular configurations for plasma etching (barrel reactor, downstream etcher, and parallel-plate system) were shown in Figure 1.36. In resist etching, the process is called *ashing*. Depending on the configuration, high-energy ion bombardment of the substrate can be prevented, more or less, and plasma-induced device damage avoided. For example, in a barrel reactor, the substrates are shielded by a perforated metal shield to reduce substrate exposure to charged high energetic species in the plasma. In a downstream stripper, the geometry of the reactor allows reactant generation and stripping to take place in two physically separated zones (triode-type configuration with a remote plasma). In parallel-plate strippers, the substrates are placed inside the plasma source, which leads to higher ion damage compared with the two previous methods.

Reaction Mechanism

The plasma etching process can be broken down into as many as five primary steps, as illustrated in Figure 3.20. The first step is the production of the reactive species in the gas phase (1). In a glow discharge, a gas such as CF_4 dissociates to some degree by impact with energetic particles in the plasma with an average energy distribution between 1 and 10 eV. In the dissociation, reactive species such as

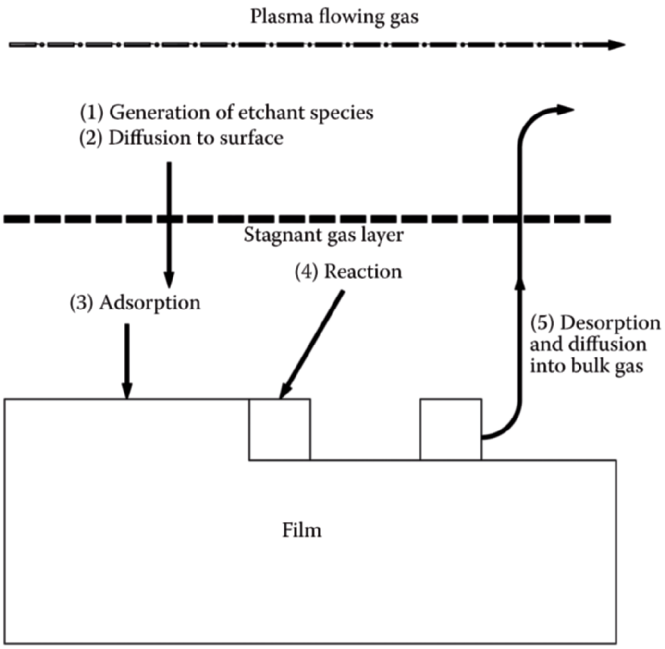

FIGURE 3.20 Primary process steps occurring in a plasma etch process. See text for details.

CF_3^+, CF_3, and F are formed. This step is vital because most of the gases used to etch thin films do not react spontaneously with the film; for example, CF_4 does not etch silicon. In a second step, the reactive species diffuse to the solid (2) where they become adsorbed (3), diffuse over the surface, and react with the surface (4). The etching species must get to the surface to react with a thin film or substrate molecules. The mechanics of getting to the surface can limit aspect ratio and determines undercutting and uniformity. Adsorption also can affect aspect ratio. The reaction is strongly temperature-dependent. Finally, the reaction products leave the surface by desorption and diffusion to the bulk (5). Desorption can stop the etching process if the reacted species are not volatile, and diffusion to the bulk gas phase can lead to nonuniform etching as a result of dilution of unreacted etching species. As in a parallel resistor combination, total resistance is determined by the smallest resistance—the reaction with the smallest rate constant determines the overall reaction rate.

Some of the reaction steps listed above occur in the gas phase and are termed *homogeneous* reactions, whereas others occur at the surface and are called *heterogeneous* reactions. For homogeneous reactions, the plasma only plays the role of creating highly reactive species from the plasma gas. Radicals are more abundant in a glow discharge than ions because they are generated at a lower threshold energy (e.g., <8 eV), which leads to a higher generation rate. Moreover, the uncharged radicals have a longer lifetime. Low-energy ions rarely act as the reactant themselves; instead, neutrals are responsible for most reactive etching (chemical etching) at pressures greater than 0.001–0.005 Torr. Radicals and molecules formed in the plasma are not inherently more chemically reactive than ions, but they are present in significantly higher concentrations. Heterogeneous reactions display even more complexity than homogeneous reactions. In principle, all the species generated in the plasma may influence the reaction rate at the surface; nonreactive species may decrease the reaction rate by blocking surface sites, and adsorption of radicals may enhance the reaction rate. Radicals and other neutrals reach the surface by diffusion, whereas ions are accelerated toward the surface by the negative potential on the substrate electrode. Besides chemically active species and ions, the effect of electron bombardment and irradiation by visible and UV radiation emanating from the plasma requires consideration. Chemical etching occurs at low bias, and because, in principle, no highly energetic ions bombard the surface, sputtering itself is not an important surface-removal mechanism, and radiation damage to the substrate is reduced. Unfortunately, the term *reactive ion etching* is used indiscriminately for all chemical dry etching, even though ions themselves are not the major reactive species. Radicals and molecules also serve as the primary depositing species for all types of films in plasma-enhanced chemical vapor deposition (PECVD) (see Chapter 7). Ions directly participate in chemical etching only in RIBE, where ion reactions at very low pressures can etch at modest rates of less than 400 Å/min. RIBE is an example of physical/chemical dry etching where the same ion has both a physical (ion impact) and a chemical (reactive etching) component. Working with remote plasma in a triode-type system (e.g., a downstream stripper) further reduces ion bombardment of and current flux to the wafer. The steps of reactant generation and etching are separated efficiently because charged species (mainly electrons and positive

O_2^+ ions in the case of pure oxygen plasma used for stripping resist) suffer a much higher loss than reactive neutrals such as atomic oxygen as a result of the presence of plasma excitation.

In the absence of crystallographic effects (typically seen with III–V compounds but not with Si), chemical dry etching leads to isotropic profiles only when ions do not assist the reaction. In the case where ions assist, anisotropy is induced (see below under Energy-Driven Anisotropy or Damage Mechanism). Isotropic etching of the reactive species leads to mask undercutting. In some cases mask undercutting is required—for example, in device fabrication involving lift-off or when layers on sidewalls must be cleared.

Because of the chemical nature of the etching process, a high degree of control over the relative etch rates of different materials (i.e., selectivity) can be obtained by choosing suitable reactive gases. During stripping, oxygen plasma removes photoresists by oxidizing the hydrocarbon material to volatile products. Fluorine compounds are used for silicon etching, and many materials are susceptible to chlorine etching. For example, aluminum is etched in chlorine but not in fluorine because aluminum chlorides are volatile, whereas aluminum fluorides are involatile. Mixtures of gaseous compounds such as CF_4 (fluorocarbon)-O_2 assist in patterning silicon, silicon dioxide, silicon nitride, and so on.

Macro- and Microscopic Loading Effects

Macroscopic Loading Effects

In dry etching, the number of radicals in the plasma is in the same range as the number of atoms to be removed; in wet etching, on the other hand, the number of etchant molecules might be 10^5 times higher than the number of atoms to be removed. A "loading effect" occurs in dry etching as the etchant is depleted by reaction with the substrate material. As a result, the etch rate is inversely proportional to the Si area that is exposed to the plasma.[2] The more purely chemical the etching process, the bigger the loading effect. With lower pressures, the loading effect becomes smaller. Conventional plasmas can sustain enough radicals to etch at rates of 1000 Å/min. With more effective power sources, such as a cyclotron or magnetron, 10^4 Å/min can be achieved.

The loading effect brings an important limitation of dry etching to light: as the etch rate becomes dependent on wafer loading, uniformity is jeopardized. If the supply of reactant limits the etch rate, small variations in flow rate or gas distribution uniformity may lead to nonuniformities in the etch rate. The gas flow F is the most important parameter to control in this regard. Gas flow rates are on the order of 5–200 sccm (standard cubic centimeter per minute), with a maximum flow rate set by the maximum pumping speed and the desired working pressure.[1] The symmetry of the gas flow (i.e., the relative position of gas inlet and pumping port) has to be optimized for a given reactor configuration. Hence a minimum flow rate of the reactant gas prevents the process from being limited by reactant supply. A utilization factor, U (the ratio of rate of formation of etch product to the rate of etch gas flow), may be defined, and $U \geq 0.1$ is suggested for uniform etching. To illustrate: a 500-Å/min etch rate of a 3-in. Si wafer in a CF_4 plasma corresponds to a removal rate of 5×10^{19} Si atoms/min, or a SiF_4 evolution rate of approximately 2 sccm. This means that the CF_4 flow rate should be at least 20 sccm.[1,25]

Closely linked to the utilization factor U is the residence time τ in seconds of the feed gas in the dry etch reactor. The residence time is given by:

$$\tau = \frac{PV}{F} \tag{3.19}$$

where V = reactor volume in liters
P = steady-state pressure in Torr
F = flow rate of the feed gas in Torr-liters per second

(Most gas flow meters are calibrated in standard cubic centimeters per minute and 1.0 Torr-L/s = 79.0 sccm.)

The residence time represents the average length of time a molecule of gas spends in the chamber irrespective of any chemical reaction that might occur.

Etching uniformity is also impacted by the relative reactivity of the wafer surface with respect to the cathode material used. Resulting nonuniformities in this case are referred to as *bull's eyes* because circular interference patterns appear on an etched wafer.

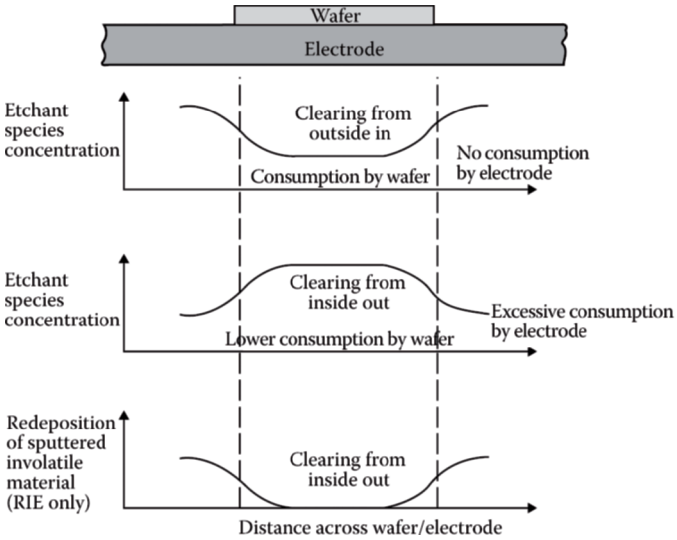

FIGURE 3.21 Chemical and physical effects leading to nonuniform etching across a wafer (bull's eye effect). (From Elwenspoek, M., H. Gardeniers, M. de Boer, and A. Prak. 1994. *Micromechanics*. Report No. 122830, Twente, the Netherlands: University of Twente.[25])

If an aluminum electrode is used for Si or poly-Si etching in SF_6 plasma, a very pronounced bull's eye effect will be evident. The striking nonuniformity in this etching pattern results from a lower consumption of reactant species above the aluminum electrode because aluminum only mildly reacts with reactive species formed by SF_6. By applying an electrode material that consumes the fluorine reactive species as fast as Si itself (e.g., a Si cathode), concentration gradients of reactant species at the edge of the wafer are avoided, resulting in uniform etching (see Figure 3.21).

Microloading Effects during Plasma Etching

The loading effect may also be observed while etching different features on the same wafer. In this case one refers to local loading or microloading effect. For example:

1. Density of the unmasked areas may vary over small distances, resulting in differences in etch rate analogous to macroscopic loading.
2. Etch rates in DRIE show a dependence on the aspect ratio of the feature being etched; the etch rate is diffusion limited and decreases with increasing aspect ratio. In cases where a high-aspect-ratio trench is etched in the vicinity of a wide trench, the latter locally decreases the availability of etching species at the expense of the narrower trench.[26] The effect is also known as "RIE lag" or aspect-ratio-dependent etching (ARDE). Lower etch rate for higher AR trenches (smaller widths) is illustrated in Figure 3.22.

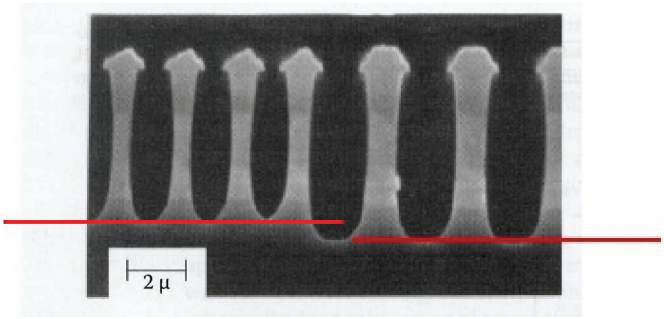

FIGURE 3.22 Illustration of RIE lag. The probability of reactant species reaching the bottom is reduced. (See red lines; wider trenches etch deeper.)

Possible mechanisms for explaining the RIE lag are the depletion or trapping of the reactant species (conductance limitations) as the species travel to the bottom of the trench, thus causing distortion of the ion paths as a result of charging and shadowing effects involving neutrals or ions. In all cases the result is the reduction of the probability of reactant species reaching the bottom.

Silicon Grass or Black Silicon

A common issue of nonuniformity with RIE, especially in the case of deep dry chemical etching (DRIE; see below), is the micrograss or black silicon structures observed, for example, at the bottom of a deep Si trench (Figure 3.23). Jansen et al.[2,27] associated the effect, with all types of micro- and nanomasking from materials deposited or grown on the Si, for example, native oxide or dust (that is, contamination already present on the wafer before etching). Si spikes formed as a result of dirty wafers before etching are easily prevented by a precleaning step, and because the etch is very selective, the native oxide needs to be removed completely. More grass may form during etching because of redeposition of mask material.[2]

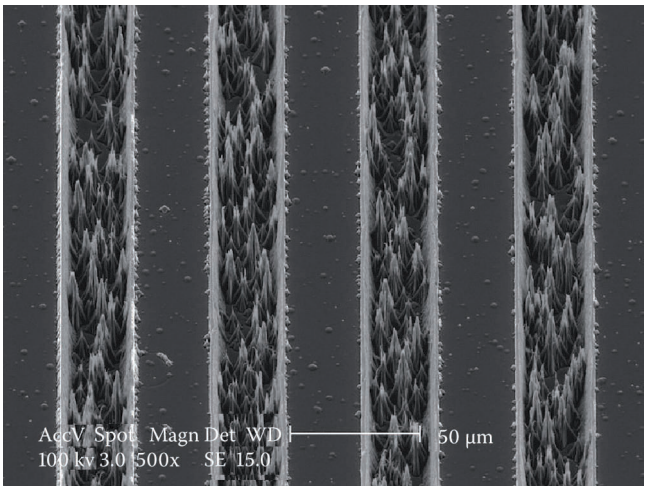

FIGURE 3.23 Silicon "micrograss" structures, which form by plasma etching of silicon in an atmosphere that causes small pieces of silicon dioxide to sputter and then block (mask) etching where they land.

This source of black Si is more pronounced with higher ion energies; therefore, working with a lower self-bias is in general advantageous. Grass formation during RIE was also explained as a consequence of the sharpening of the ion angular distribution with the increasing aspect ratio of a trench during etching.[23] To further minimize the latter types of nonuniformities, wafers should be positioned away from the edges of electrodes to eliminate edge effects caused by changing sheath thicknesses and varying the angles of incidence. A good thermal contact between wafers and cathode is also important. Local temperature variations caused by nonuniform heat-sinking can lead to large etch nonuniformities, particularly in chemically dominated processes.[25]

Atmospheric Plasma Etching

Introduction

Until recently, most plasma science experiments were carried out under vacuum conditions. However, atmospheric-pressure plasmas enjoyed a growth spurt in the 1980s driven by new applications such as high power lasers, MEMS electrostatic switches, novel plasma processing applications and sputtering, EM absorbers and reflectors, remediation of gaseous and other pollutants and waste streams, sterilization, decontamination, and other biomedical applications. Recently, new hardware designs have enabled the stable operation of nonthermal plasmas at atmospheric pressure, and publications on atmospheric-pressure glow discharge plasmas have grown rapidly. We introduce two examples of atmospheric plasmas: one operates in an argon plasma arc, whereas the other is arc free.

The main characteristics of a plasma, such as the breakdown voltage and the voltage current characteristic and structure of the discharge, depend on the geometry of the electrodes and the vessel, the gas used, and the electrode material. In the highly

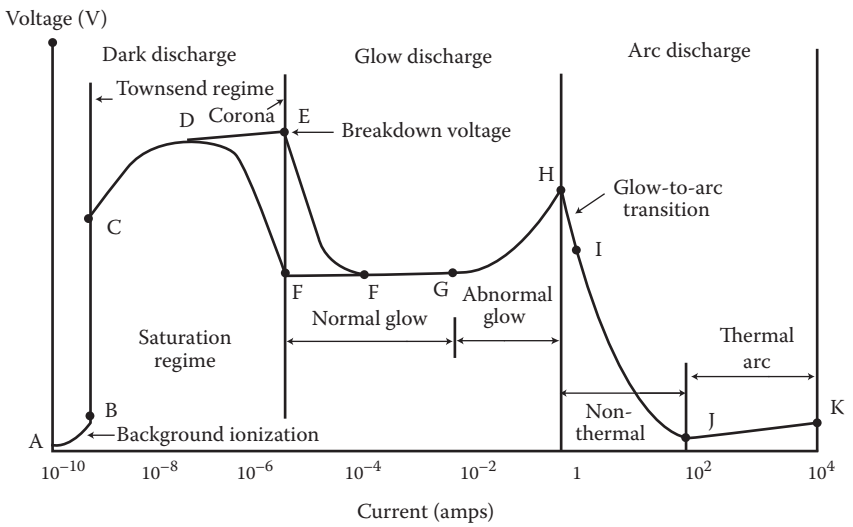

FIGURE 3.24 Voltage current plot of a glow discharge.

nonlinear voltage current plot of plasma, as shown in Figure 3.24, we discern several regimes:

A to B: The applied electrical field E accelerates residual ions and electrons as a result of background radiation in the reactor (e.g., from cosmic rays, radioactive materials in the building). These ions and electrons move toward the electrodes.

B to C: As the applied V increases, eventually all the available residual charges are swept up. This causes the current through the plasma to saturate.

C to E: As the applied V increases beyond C, the E field is now large enough that the remaining electrons can ionize gas. As V increases further, secondary electrons also cause ionization.

D to E: In the so-called Townsend regime, coronal discharges occur at various edges and sharp points of the electrodes in the gas. This is the result of the E field concentration at such sites.

A to E: Electrical breakdown occurs. The voltage is now high enough to cause ionization to occur because of secondary electrons in the gas. Additional secondary electrons are generated at the cathode as a result of ion impact on it. There is a sudden increase of the current by several orders of magnitude, causing an avalanche.

F to G: After breakdown from E to F, the gas enters the normal glow where the voltage V is almost independent of the current over several orders of magnitude. As the current increases, the fraction of the cathode occupied by plasma increases until the plasma covers the entire cathode surface at G.

G to H: In the abnormal glow regime, further increases in the applied voltage cause increases in the current. This is the region of operation for most sputtering and other plasma systems.

H to K: At H, the electrodes have become sufficiently hot that the cathode can now emit electrons thermionically, and a second avalanche can happen in the arc region (this is the regime used in spectrochemistry). If the DC power supply is capable (low internal R), a transition from glow to arc happens in the region from H to I. In this arc regime from I to K, the discharge V decreases as I increases. The point J marks the transition from a nonthermal to a thermal arc (electrons have the same temperature as the gas).

At atmospheric pressures, plasmas are weakly ionized, and the mean-free path for electron-molecule collisions is very short (<1 μm). These plasmas are typically thermal with electrons and gas at the same temperature. At atmospheric pressure a small perturbation can easily cause a glow-to-arc transition. The transition time is very short, and this makes it hard to stabilize an atmospheric glow discharge. Some tricks to prevent an arc include the use of inert gas to lower breakdown voltage, high-frequency power sources and operation in the dielectric barrier discharge mode, and a structured cathode (e.g., a pin cathode). Stabilization of high-pressure (atmospheric-pressure) plasmas is most easily achieved if the plasma is confined to "small" spaces. Interesting pattern formation and self-organization has been observed in these microplasmas.

Atmospheric Downstream Plasma

In atmospheric plasma jet etching, reactive chemical species are generated in a DC arc between two electrodes in a noble gas (such as argon) at atmospheric pressure. A stream of reactant gas (the gas jet) such as CF_4 then flows into the arc and onto the wafer, which is located up to 12 in. away to avoid damage, as shown in Figure 3.25.[28] Although atmospheric plasma sources have been used previously for industrial powder spray and plasma cutting (see Chapters 5 and 9), they have not been used in microelectronic processing for fear of damaging and contaminating the silicon wafer surface. Among the concerns were possible overheating as a result of high power density, contamination from chemical erosion of electrodes, and nonuniform etching.

Atmospheric downstream plasma (ADP) processing overcomes these problems by using a magnetically controlled, inert gas, DC arc-plasma discharge.

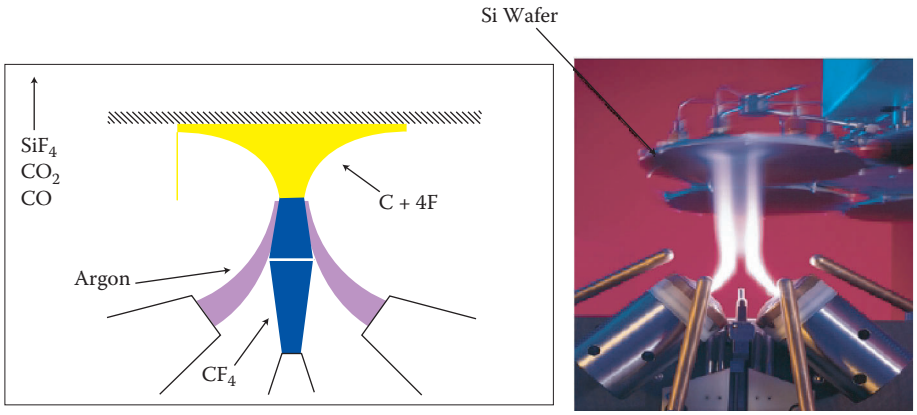

FIGURE 3.25 Atmospheric downstream plasma processing of a Si wafer. (From Tru-Silicon Technologies, http://www.trusi.com/frames.asp?.)

Plasma jet etching is an atmospheric variant of plasma etching capable of producing very high etch rates without substrate damage. By deploying the plasma in a downstream configuration, ADP prevents ion impact damage while keeping wafer temperatures low. This technology may improve the performance and reduce the cost of bulk material removal operations, such as mechanical grinding, lapping, and wet chemical etching [especially chemomechanical polishing (CMP); see Chapter 1, Figure 1.66]. ADP etching for back-side damage removal after grinding and wafer thinning is a potential major application. Other applications include damage-free dicing and via etching (for the latter two applications, an aluminum mask is used). The trend to thinner wafers and thinner chips will not stop with the current 200–250-μm thickness, but is forecast to continue reducing to 100–150 μm and even thinner (see Figure 3.26), driven by the demand for portable electronic devices, smart cards, multichip modules, PC Card (originally PCMCIA Card for People Can't Memorize Computer Industry Acronyms or more seriously for Personal Computer Memory Card Interface Association), and so on. Wafer strength requirements of large-diameter wafers limit back-grinding to thickness of 200–250 μm; therefore, new technology is essential. Tru-Silicon Technologies is one of the companies providing this type of equipment (for a tutorial on applications of ADP, see http://www.trusi.com/frames.asp?).

Atmospheric Arc-Free Plasma Etching

A picture of an atmospheric, arc-free (!), plasma jet invented at the University of California, Los Angeles is shown in Figure 3.27.[29] The "cold flame" (T ~ 75°C) shown here is impinging on a finger (http://www.seas.ucla.edu/prosurf). This jet was developed for

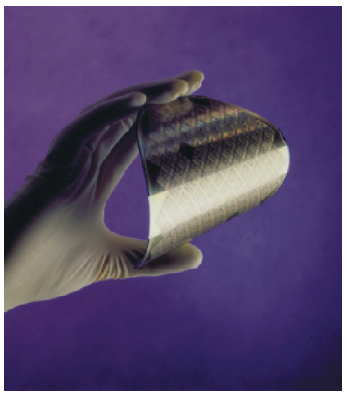

FIGURE 3.26 A 50-μm thin silicon wafer produced using atmospheric downstream plasma (ADP). (From Tru-Silicon Technologies.)

FIGURE 3.27 A picture of an atmospheric, arc-free (!), plasma jet invented at University of California, Los Angeles. The "cold flame" (T ~ 75°C) shown here is impinging on a finger (http://www.seas.ucla.edu/prosurf).

etching materials and depositing materials at atmospheric pressure and temperatures between 100 and 275°C. Gas mixtures containing helium, oxygen, and carbon tetrafluoride are passed between an outer, grounded electrode and a center electrode, driven by 13.56-MHz RF power at 50–500 W. At a flow rate of 51 L/min, a stable, arc-free discharge was produced. The discharge extends out through a nozzle at the end of the electrodes, forming a plasma jet. Materials placed 0.5 cm downstream from the nozzle are etched at high rates: 8.0μm/min for Kapton (O_2 and He only), 1.5 μm/min for silicon dioxide, 2.0 μm/min for tantalum, and 1.0 μm/min for tungsten.[29] The plasma jet produces a large flux of atoms and/or radicals, depending on the gas fed to the device. The setup may also be used for deposition. For example, tetraethoxysilane was used to deposit high-quality silicate glass films. It should be noted that like ADP this is a downstream plasma source. The ions and electrons are rapidly consumed by collisions before impinging on the substrate.

Physical/Chemical Etching

Introduction

The most useful plasma etching is neither entirely chemical nor physical. By adding a physical component to a purely chemical etching mechanism, the shortcomings of both sputter-based and purely chemical dry etching processes can be surmounted.

In physical/chemical techniques, ion-surface interactions promote dry etching. A first type is found in reactive ion beam etching (RIBE). RIBE constitutes a rather exceptional case of energy-driven anisotropy where ions are reactive and etch the surface directly. More common in energy-driven etching is *chemically assisted ion-beam etching* (CAIBE). In this case, ion bombardment induces a reaction by making the surface more reactive for the neutral plasma species, for example, by creating surface damage. In inhibitor-driven anisotropy, ions clear the surface of film-forming reaction products, allowing etching with reactive neutrals to proceed on the cleared areas. We will also learn that silicon dry etch anisotropy may be influenced by local dopant concentrations and that a wide variety of existing gas compositions crucially influences the etch profile. To help the reader summarize matters, a list of simplifying rules is provided at the end of this section.

Energy-Driven Anisotropy or Damage Mechanism

During energy-driven anisotropy, bombardment by ions (<1000 eV) disrupts an unreactive substrate and causes damage, such as dangling bonds and dislocations, resulting in exposed surface atoms, which are more reactive toward etchant species (electrons or photons also can induce surface activation). Ion bombardment is mainly in the vertical direction so that the etch rate in the vertical direction is much higher than in the lateral direction (anisotropy!). Besides "energy-driven anisotropy," the process is also referred to as the *damage mechanism*. In Figure 3.3c, a typical resulting etch profile was shown. Vacuum pumping removes the volatile reaction products. This type of etching is referred to as *reactive ion etching* (RIE) when it involves reactive chemicals in a diode-type reactor, and as *chemically assisted ion-beam etching* (CAIBE) when it involves chemical reactants (e.g., Cl_2) introduced over the substrate surface in a triode-type setup. Figure 3.11 shows a parallel-plate setup for RIE, and a hexode reactor is shown in Figure 3.28. The hexode reactor is designed for batch processing. In this design, the cathode has the shape of a hexagon surrounded by the cylindrical chamber walls forming the anode. As many as 24 100-mm-diameter or 18 150-mm-diameter wafers

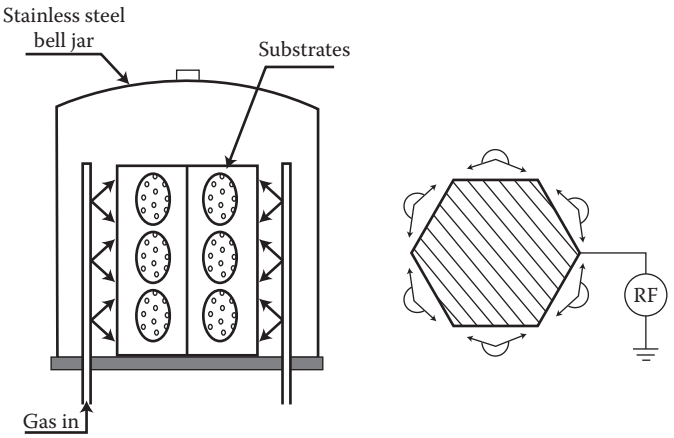

FIGURE 3.28 Schematic diagram of a multiwafer RIE etcher, the so-called hexode reactor.

can be mounted on the slightly tilted sidewalls of the hexagonal cathode. The latter is slowly rotated during operation to increase uniformity.[1]

The etch rate reached by RIE is substantially higher than in ion etching. For example, the etch rate of Si in Ar sputtering hovers around 100 Å/min compared with 2000 Å/min for a reactive gas such as CCl_2F_2. Chemically assisted ion etching can lead to accurate transfers of the mask pattern to the substrate and to a fair selectivity in etching different materials. The directional anisotropy ensues from operating at low pressures and high voltages. Under these conditions, the mean free path of reacting molecules typically grows larger than the depth to be etched, resulting in the horizontal surfaces being hit and etched by reactive neutrals more frequently than the sidewalls. The need for energetic impinging ions, as in the case of physical etching, is reduced as the complex on the surface activates more easily. In Figure 3.29 we illustrate the energy-driven anisotropy process or damage mechanism.

Reactive ion-beam etching (RIBE), like CAIBE, involves chemical reactants in a triode setup. There is an important difference, however. In the case of RIBE, the reactive ions are introduced through the ion source itself; in CAIBE, the reactive gas is fed over the substrate to be etched, and unreactive ions are generated in the ion source. At very low pressures in RIBE systems, reactive ions, substituting Ar ions, can sustain a modest etch rate of less than 400 Å/min. In CAIBE, ion bombardment of a substrate in the presence of a reactive etchant species leads to a synergism where fast directional material removal rates greatly exceed the separate sum of chemical attack and sputtering rates. At one point, this type of etching was thought to be caused by direct chemical reactions between the ions and the surface material (as with RIBE). However, in most practical situations for etch rates ranging from 1,000–10,000 Å/min that is impossible because the ion flux is much lower than the surface removal rates. The synergistic effect of chemical attack and sputtering rates is illustrated in Figure 3.30; the etch rate of Ar^+ ion bombardment alone or the chemical etch rate of XeF_2 alone does not add up to the combined effect.

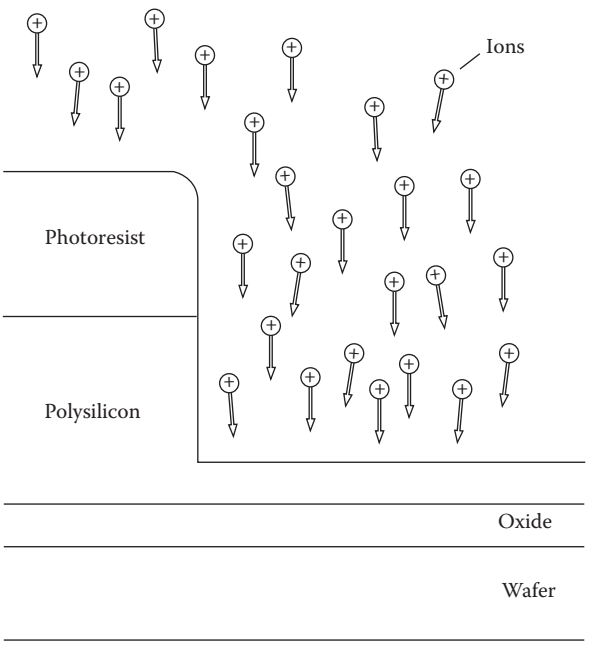

FIGURE 3.29 Energy-driven anisotropy or damage mechanism. (Drawing by Genis Turon.)

CAIBE is particularly effective in achieving highly anisotropic etch profiles because of the independent control of the physical and chemical etching components. To get an idea of how smooth a sidewall can be achieved by CAIBE, consider the work on vertical mirror facets in an InGaN/AlGaN laser diode structure. Atomic force microscope (AFM) measurements show that the laser diode vertical sidewalls etched in a CAIBE system (using Cl_2 and BCl_3 as the reactive species) exhibit a root mean squared roughness of only 40–60 Å, and the inclination angle is within ±2° of vertical.[30] Using $N_2/H_2/CH_4$ chemistry, extremely smooth sidewalls were also observed in CAIBE etching of InP.[31] To reduce surface damage, the aim is to increase the chemical component, decrease the ion acceleration energy, and work with a high ion flux. In CAIBE, as in other ion-beam techniques, the ion acceleration energy and the ion density can be independently controlled. With an ICP or ECR, a highly dense and uniform ion beam (e.g., Ar^+) is generated. ICP and ECR plasmas are discussed below.

The distinction between RIBE and CAIBE is not absolute because the presence of a reactive gas in CAIBE will produce some beam ions from species that back-diffuse into the broad-beam ion source. In a magnetically enhanced RIE (MERIE) system, a higher ion flux is obtained at lower energy through

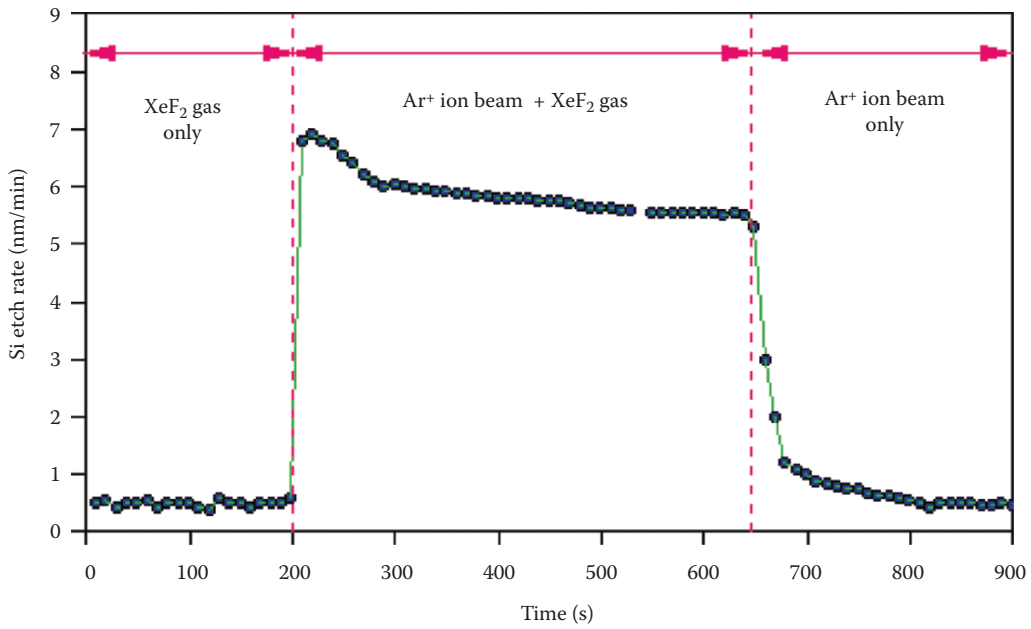

FIGURE 3.30 Etch rate experiment in RIE. Etch rate of Ar^+ bombardment alone or chemical etch of XeF_2 alone does not add up to their combined synergistic effect.

magnetic confinement of the plasma. For typical RIBE and CAIBE performance characteristics also visit http://www.oxfordplasma.de/technols/ibe.htm.

A hypothetical etch profile for Si and SiO_2 etching with a reactive gas and positive ion bombardment is shown in Figure 3.31a. In the absence of ionic bombardment, the etch rate is assumed to be zero for SiO_2; consequently, the SiO_2 film etches with perfect anisotropy (vertical sidewalls). The silicon etch rate in the absence of ionic bombardment, on the other hand, is assumed to be finite but small; consequently, the etched feature ends up having a profile with slanted sidewalls. Mathematically, the above can be expressed in terms of etch depth Z, undercut X, the etch rate under bias V_Z, and the etch rate without bias V_X, as:

$$\frac{V_x}{V_z} = \frac{X}{Z} \tag{3.20}$$

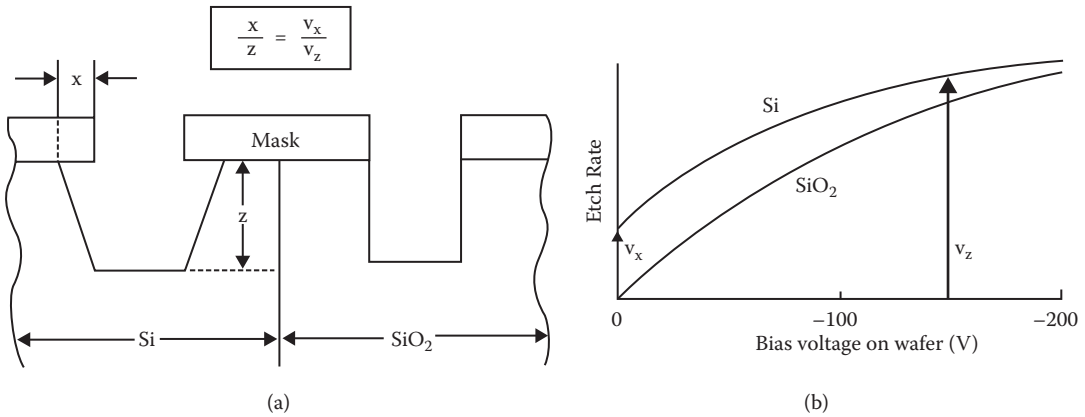

FIGURE 3.31 Relationship between the shape of the etched wall profile and the dependence of the etch rate on the wafer potential. (a) Etch profiles. (b) Etch rate bias dependence. The etch rate of SiO_2 in the z-direction, V_z, increases with increasing wafer bias. Assuming no chemical etching component is present in the SiO_2 reaction, that is, $V_X = 0$ (the etch rate equals 0 at bias = 0), an ideal vertical profile results. The etch rate of Si also is bias-dependent, but some reaction occurs at $V_X = 0$. In other words, a chemical component to the reaction does not need ion bombardment resulting in nonvertical walls (see text). (From Manos, D. M., and D. L. Flamm, eds. 1989. *Plasma etching: An introduction.* Boston: Academic Press.[76])

(See Figure 3.31b.) The anisotropy of RIE can further be enhanced by the use of helium back-side cooling (as low as –120°C might be required). The low-temperature suppression of chemical attack of silicon by fluorine atoms exemplifies how lower temperatures further improve anisotropy and critical dimension control. Although suppressing the isotropic fluorine reaction, the same low temperature influences ion-assisted reactions only slightly and hence improves the anisotropy of profiles; the etch rate at $V_X = 0$ decreases or becomes zero.

Inhibitor-Driven Anisotropy or Blocking Mechanism

Inhibitor-driven anisotropy embodies another example of a physical/chemical etching technique (Figure 3.3d). In this case, etching leads to the production of a surface-covering agent in a so-called blocking mechanism. Ion bombardment clears the "passivation" from horizontal surfaces; reaction with neutrals proceeds on these cleared surfaces only, and the etch proceeds again mainly in the vertical direction as shown in Figure 3.32. The protective film may originate from involatile etching products or from film-forming precursors that adsorb during the etching process. Passivating gases, such as BCl_3 and some halocarbons (Freons™ such as CCl_4 and CF_2Cl_2), are sources of inhibitor-forming species. In the latter case, the reactive gas component appears to be adsorbed on the surface (for example, a polymer is formed), where it is subsequently dissociated by electron, ion, or photon bombardment, clearing the surface for reaction with the reactive neutrals.

An example of etch profile manipulation with inhibitor-driven chemistry using an idealized Si sample is illustrated in Figure 3.33. At the top of this figure, we show the silicon etch rate as a function of percentage of H_2 in CF_4 for a biased and an unbiased wafer. We remember from earlier in this chapter that the silicon etch rate increases as the wafer bias is increased; thus, the etch rate curve for the biased wafer lies above the one for the unbiased wafer. If H_2 is added to a CF_4 feed gas, the Si etch rate decreases, and at some value of H_2 concentration, the nonbombarded surface etch rate decreases to zero ($V_X = 0$ at 10% H_2 in Figure 3.33), whereas the bombarded surface continues to etch. The decrease in etch rate stems from an increase in the amount of passivating polymerization. Aggressive fluorine reacts with the hydrogen so that carbon compounds polymerize more readily. As before, Equation 3.20 can be used to calculate the ratio of underetch X to etch depth Z. At $V_X = 0$, that ratio, of course, is zero.

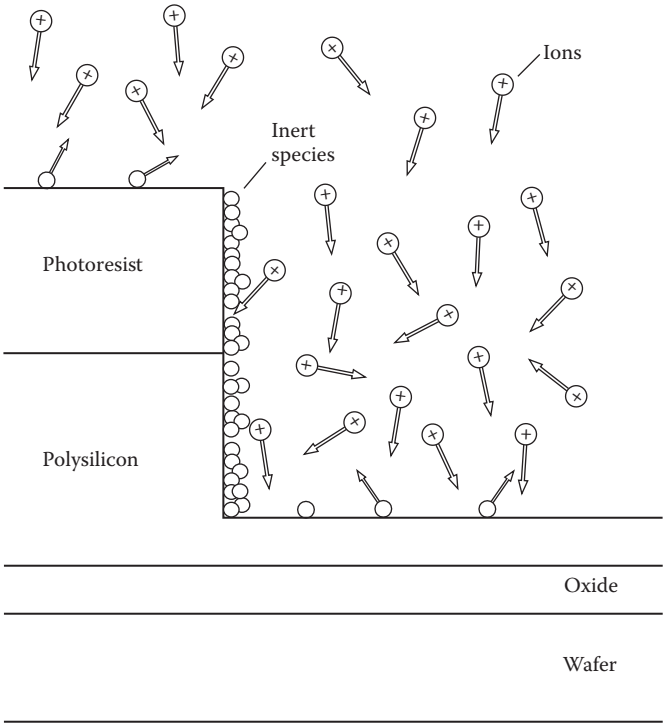

FIGURE 3.32 Inhibitor-driven anisotropy or blocking mechanism. (Drawing by Genis Turon.)

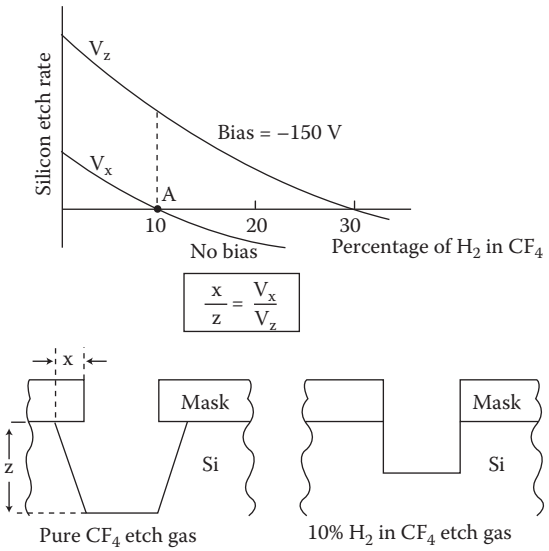

FIGURE 3.33 Trench profile manipulation by decreasing the fluorine-to-carbon ratio (through hydrogen introduction). (From Manos, D. M., and D. L. Flamm, eds. 1989. *Plasma etching: An introduction.* Boston: Academic Press.[76])

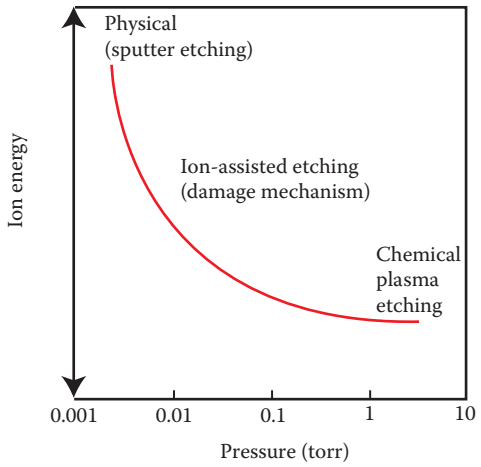

FIGURE 3.34 Ion energy versus pressure for a plasma. (Redrawn by Genis Turon from Flamm, D. L. 1992. Dry plasma resist stripping part I: overview of equipment. *Solid State Technol* 35:37–39. With permission.[36])

Similarly, aluminum etching in $CCl_4 + Cl_2$ or $CHCl_3 + Cl_2$ plasmas presents a good example of an inhibitor system. Even though Cl_2 gas and chlorine atoms formed in these plasmas are rapid chemical etchants for clean aluminum, aluminum in these plasma mixtures can afford near-vertical profiles with excellent line-width control.

Another typical example of a sidewall mechanism is the etching of phosphorus-doped Si, which etches isotropically in Cl_2 plasma but etches anisotropically when C_2F_6 is added to the source gas. Qualitatively the effect is accounted for by assuming that the two gases dissociated in the plasma are:

$$C_2F_3 + e \rightarrow 2CF_3 + e \qquad \text{Reaction 3.1}$$

$$Cl_2 + e \rightarrow 2Cl + e \qquad \text{Reaction 3.2}$$

and the possible surface reactions are:

$$xCl + Si \rightarrow SiCl_x \text{ (etching)} \qquad \text{Reaction 3.3}$$

$$CF_3 + Cl \rightarrow CF_3Cl \text{ (recombination)} \qquad \text{Reaction 3.4}$$

Reaction 3.3 results in etching of the silicon surface, and Reaction 3.4 results in recombination without material removal. Ion bombardment enhances Reaction 3.3, and Reaction 3.4 is assumed to be dominant on the sidewalls. The recombination reaction acts as a sidewall passivant.

In practice, the anisotropy brought about by the directed ion flux in plasma allows the final etched feature to be within 10% of its dimensions on the mask, and submicron resolutions become feasible. A desire to move away from sidewall passivating chemistries to avoid CD loss is prominent, especially in the IC industry. Thick sidewall coatings not only reduce CD control, but they also prove difficult to strip. Processes involving little or no sidewall thickness increase are sought for tight CD control in submicron devices. In this respect, wafer cooling (to as low as –120°C) presents an attractive way of obtaining sidewall protection without the need for additional chemistries. At low substrate temperatures, reaction products are involatile and can serve as very thin sidewall inhibitors. Generally, at lower temperatures, lateral etch rate can be suppressed while using simpler chemistries. In micromachining applications where feature size is in general larger than in ICs and aspect ratios are more extreme, applying passivating chemistries is almost a necessity, but wafer cooling can help the process.

Dopant-Driven Anisotropy

Although not commonly acknowledged, silicon plasma etch anisotropy may be influenced by local dopant concentrations. For example, Li et al.[32] have demonstrated that Cl-based plasma etch can be used to etch lightly doped p- or n-type silicon anisotropically and heavily doped n-type silicon isotropically. These authors, by forming buried n^+ layers beneath a lightly doped epitaxial layer, were able to selectively undercut structures above the n^+ regions.[32] Schwartz and Schaible[33] also described the dopant dependence of dry plasma etching.

It is more commonly known that the Si etch rate depends on the electronic properties of the Si substrate.[34] The n-type silicon (e.g., doped with P, As, and so on) etches faster than intrinsic silicon, which etches faster than p-silicon (e.g., doped with B, Ga, and so on). Dopant concentration effects on etch rates only become apparent at concentrations greater than 10^{19} cm^{-3}. The doping effect is not chemical in nature because it is absent if the dopants are not electrically activated. The effect depends on the electronic structure of the surface, and band-bending effects at the semiconductor surface have explained it. Using ECR etching, Juan et al.[35] demonstrated

that the n^{++} Si etch increases, but the p^{++} Si etch rate decreases with respect to lightly doped silicon. Thus, it was established that, with a high microwave power or high RF power, as well as an increased temperature, a large difference in etch rates of p^{++} and n^{++} Si results.

Ion Energy versus Pressure Relationship in a Plasma: Comparison of Different Dry Etch Technologies

In the preceding sections, we described two extreme cases of dry etching—ion etching (purely physical) and plasma etching (purely chemical)—and the intermediate case of chemical/physical etching. In general, three factors control the etch rate in a plasma reactor: 1) neutral atom and free radical concentration, 2) ion concentration, and 3) ion energy. Ion and radical concentrations control the reaction rate, whereas ion energy provides the necessary activation and controls the degree of anisotropy. The respective contribution to chemical and physical action of plasma can be manipulated by varying voltage and gas pressure. For good CD control, anisotropy is required, and positive ions need to be formed at low pressures ($<10^{-2}$ Torr) to strike the surface at normal incidence. Etching at low pressures, with a long mean free path length of the ions, λ_i, is inherently more anisotropic (i.e., directional) and less contaminating because etch reaction byproducts are more volatile at lower pressures and are easier to remove. At these lower pressures, ion density drops off quickly, causing a lower etch rate and lower wafer throughput. Increasing the power or wafer bias increases the etch rate, as the remaining ions become more energetic. Higher ion energies can cause additional problems in terms of device damage. What is needed is a plasma source operating at low pressure with very high ion density. Operating at low pressures also reduces the effects of chemically induced macro- and microloading (see above). With high pressure, short λ_i, and low voltage, one gets isotropic chemical etching. The pressure/voltage relationship for a plasma is schematically represented in Figure 3.34.[36] Thus, sputtering and dry chemical etching represent the two extremes of a continuous dry etching spectrum (Table 3.8) with physical etching by sputtering with inert argon ions at one end and chemical etching with reactive neutral species at the other.

In Tables 3.9 and 3.10 we contrast the features of different etching techniques, highlight the underlying mechanism, and give a typical application. Entries concerning endpoint detection will be clarified further below.

Gas Compositions in Dry Etching

Most dry bulk etching of silicon is accomplished using fluorine free radicals, generated from fluorine-containing gases and by forming volatile SiF_4 during the etch (the byproducts in dry etching should always have the highest possible vapor pressure). As opposed to chlorine- and bromine-based processes, fluorine plasma reactions with silicon usually proceed spontaneously, not requiring ion bombardment. This method results in high etch rates, and by themselves fluorine radicals produce profiles that are nearly isotropic. Often, chlorofluorocarbons (CFCs) are used to produce polymer deposition in parallel with the etching process. Oxidizing additives increase etchant concentration and suppress excessive polymerization. The addition of oxygen to CF_4 in Si etching typifies the procedure.[37] Oxygen, at concentrations less than 16%, reacts with CF_X radicals to enhance F atom formation [increase of fluorine-to-carbon ratio (F/C)] and eliminate polymerization. At yet higher concentrations, adsorbed oxygen on

Table 3.8 Dry Etching Spectrum

Types of Etching	Methods	Geometry	Selectivity	Excitation Energy	Pressure
Gas/vapor etching	Chemical	Isotropic	Very high ↓	None ↓	High (760–1 Torr) ↑
Plasma etching	Chemical	Isotropic	High ↓	10–100s of watts ↓	Medium (>100 mTorr) ↑
Reactive ion etching	Chemical and physical	Directional	Fair ↓	100s of watts ↓	Low (10–100 mTorr) ↑
Sputtering etching	Physical	Directional	Low ↓	100–1000s of watts ↓	Low (~10 mTorr) ↑

1 Torr = 1 mmHg.

TABLE 3.9 Comparison of Different Dry Etch Technologies

	Chemical Etch	RIE	Physical Etch
Examples	Stripping	Plasma patterned etches	Argon sputtering
Etch rate	High to low	High, controllable	Low
Selectivity	Very good	Reasonable, controllable	Very poor
Etch profile	Isotropic	Anisotropic, controllable	Anisotropic
Endpoint	By time or visual	Optical	By time

the surface depresses the etch rate.[37] Radical scavengers, such as hydrogen, increase the concentration of inhibitor former and reduce etchant concentration of fluorine in the etchant (decrease of F/C) (see also example in Figure 3.33). Heinecke[38] realized that the etch ratio of SiO_2/Si could be increased either by adding H_2 to the CF_4 feed gas or by using CHF_3 or, in general, fluorocarbons displaying a smaller F/C ratio than CF_4. Adding hydrogen to fluorocarbon gases helps promote CF_X film growth (such as CF_2, C_2F_4) for selective SiO_2 etching. Carbon accumulates less on oxide surfaces than on Si surfaces, as SiO_2 surfaces directly react with hydrogen. By adding hydrogen, carbon blocking increases (especially on the Si) because hydrogen scavenges fluorine, forming HF and preventing reaction with carbonaceous species on the surface.

The same approach helps to optimize the selectivity on other oxide/nonoxide systems (e.g., SiO_2/resist, SiO_2/Si_3N_4, and Ta_2O_5/Ta). The F/C ratio should not be made smaller than 2, or contamination of the whole system with C_xF_y polymer sets in. Factors that tend to control polymerization and selectivity are temperature, hydrogen concentration, pressure, and ion bombardment. Some etchants, such as Cl atoms, do not readily etch through thin native oxide films on Si, Nb, and Al, for example. These native oxides prevent the onset of etching unless small amounts of native oxide etchants, such as BCl_3, are added. Inert gases such as argon or helium help stabilize the plasma, enhance anisotropy, improve uniformity, or reduce the etching rate by dilution. Because helium has a high thermal conductivity, it also improves heat transfer between wafers and the supporting electrodes.[25]

From the above, the F/C ratio in dry etching is a key parameter to control. With an F/C ratio >3, etching is dominant, and with an F/C <2, polymerization takes over. In Figure 3.35 we show the F/C ratio for a number of different etchant gases (for CF_4, the F/C ratio is obviously 4 and for C_2F_4 it is 2) and different applied voltages. A negative bias on a surface exposed to the plasma increases, at a constant F/C ratio, the etching behavior over

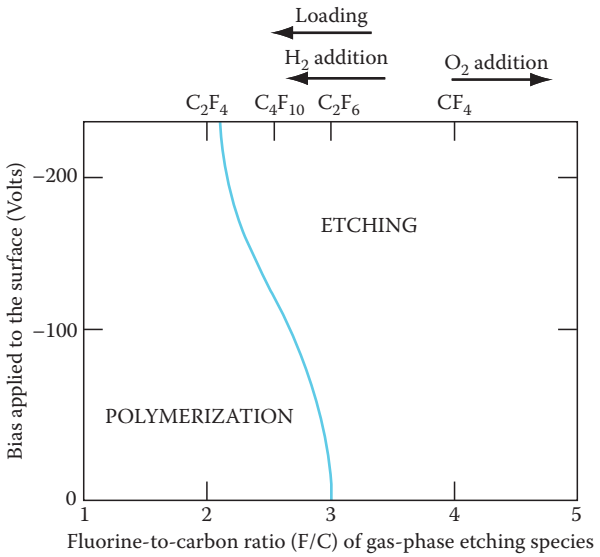

FIGURE 3.35 F/C ratio, DC bias, and polymerization. (Drawing by Genis Turon.)

TABLE 3.10 Dry Etch Mechanism and Their Application

Pure Chemical Etch	Reactive Ion Etch (RIE)		Pure Physical Etch
	Blocking mechanism	Damaging mechanism	
No ion bombardment	Light ion bombardment	Heavy ion bombardment	Only ion bombardment
Photoresist strip	Single crystal Si etch		
Ti strip	Polysilicon etch	Oxide etch	Sputtering etch
Nitride strip	Metal etch	Nitride etch	

polymerization tendency. This effect is caused by the enhanced energy of the ions striking the surface, resulting in polymer sputtering. In an etch of an oxide film, the oxygen byproducts react with C to release more F, and the F/C ratio increases shifting to a more aggressive etching regime. When etching Si or a silicide, no oxygen is released, and F is consumed, lowering the F/C ratio and thus favoring polymerization. For selectivity, etching in the etch-dominant region but near the polymerization region is preferred.

Table 3.11 lists frequently used reactive gases and typical applications.

The Environmental Protection Agency mandate to eliminate the use of CFCs changed the type of gases used for dry etching purposes. This evolution in gas mixtures is captured in Table 3.12.[39]

The primary new etchant gases are SF_6, NF_3, and SiF_4 (fluorine-based etch); Cl_2, BCl_3, and $SiCl_4$ (chlorine-based etch); and Br_2 (bromine-based etch). For very aggressive etch chemistry at low pressures (e.g., to etch deep trenches in Si), HBr has also gained popularity. Other new etchant gases include $SiBr_4$, HI, I_2, and even nonhalogenated gases such as CH_4 and H_2. Table 3.13 lists etchants appropriate for etching some common electronic materials.

Table 3.14 presents an overview of the etch rates or etch ratios for a variety of important microfabrication materials in some popular reactive gases and gas mixtures.[40] Examples include etching of photoresist on Si, SiO_2, aluminum, and so on in O_2 plasma and etching of silicon with a metal mask (e.g., Al) in CF_4 plasma. Metal masks influence the etch rate of silicon or even SiO_2 by catalytic action of fluorinated metal surfaces, leading to excess production of free radicals.

Finally, Table 3.15 reviews mask materials listing their suitability for a number of gases.[25] A plus sign in this table corresponds with a low etch rate and high selectivity; a minus sign stands for high etch rate and low selectivity.

For further reading on gas composition for dry etching and stripping, see Flamm,[42–44] Jansen et al.,[2] Peters,[39] and Moreau.[40]

Simplifying Rules

Some simple rules help interpret Tables 3.11–3.15 when specifying a choice of dry etchant and mask for a specific application. These rules are a set of semiempirical observations; they should not be looked on independently, and some state the same phenomenon in slightly different ways.[41]

Table 3.11 Frequently Used Reactive Plasma Gases

Etchant Purpose	Composition (Additive-Etchant): Application
Oxide etchant: etches through oxide to initiate etching	C_2F_6–Cl_2:SiO_2 BCl_3–Cl_2:Al_2O_3 CCl_4–Cl_2:Al_2O_3
Oxidant: increases etchant concentration and suppresses polymerization	O_2–CF4:Si N_2O–CHF_3:SiO_2 O_2–CCl_4:GaAs, InP
Inert gas: stabilizes plasma, dilutes etchant, improves heat transfer	Ar–O_2: organic material removal He–CF_3Br:Ti, Nb
Inhibitor former: improves selectivity, induces anisotropy	C_2F_6–Cl_2:Si BCl_3–Cl_2:GaAs, Al H_2–CF_4:SiO_2 CHF_3–SF_6:Si O_2 (50%)–SF_6:Si
Water and oxygen scavenger: prevents inhibition, improves selectivity	BCl_3–Cl_2:Al H_2–CF_4:SiO_2
Radical scavenger: increases film formation and improves selectivity	H_2–CF_4:SiO_2 CHF_3–SF_6:Si CF_3Br–SF_6:Si CF_2Cl_2–SF_6:Si

1. **F/C ratio**: During etching, polymerization occurs simultaneously. Etching stems from the fluorine, and polymerization from the hydrocarbons. The dominant process will depend on the gas stoichiometry, reactive-gas additions, the amount of material to be etched, and the electrode potential. Adding hydrogen causes HF to form and the F/C ratio to decrease, leading to more polymerization and less etching (see example in Figure 3.33). A decrease in the fluorine concentration can also occur by overloading the reactor, leading to overconsumption of fluorine and favoring of polymerization. Adding oxygen to a fluorine carbon mixture leads to formation of CO and CO_2 reaction products, increasing F/C, and thus the etch rate, while decreasing the polymerization tendency. In other words, the addition of oxygen to a gas mixture reduces the tendency of Freons™ to polymerize and increases the concentration

Table 3.13 Plasma Etchants for Microelectronic Materials

Material	Common Etch Gases*	Dominant Reactive Species	Product	Comment	Vapor Pressure in Torr at 25°C
Aluminum	Chlorine-based	Cl, Cl_2	$AlCl_3$	Toxic gas and corrosive gases	7×10^{-5}
Copper	Chlorine forms low pressure compounds	Cl, Cl_2	$CuCl_2$	Toxic gas and corrosive gases	5×10^{-2}
Molybdenum	Fluorine-based	F	MoF_6		530
Polymers of carbon, photoresists (PMMA and polystyrene)	Oxygen	O	H_2O, CO, CO_2	Explosive hazard	H_2O = 26 CO, CO_2 > 1 atm
III-V and II-VI compounds	Alkanes			Flammable gas	
Silicon	Fluorine- or chlorine-based	F, Cl, Cl_2	SiF_4, $SiCl_4$	Toxic gas	SiF_4 > 1 atm $SiCl_4$ = 240
SiO_2	CF_4, CHF_3, C_2F_6, C_3F_6	CF_X	SiF_4, CO, CO_2		SiF_4 > 1 atm CO, CO_2 > 1 atm
Tantalum	Fluorine-based	F	TaF_3		3
Titanium	Fluorine- or chlorine-based	F, Cl, Cl_2	TiF_4 TiF_3 $TiCl_4$		$TiF_4 = 2.10^4$ $TiCl_4$ = 16
Tungsten	Fluorine-containing	F	WF_6		1000

of halogen etchants ensuing from these gases. Adding oxygen to improve the F/C ratio leads to aggressive resist etching. Gases such as NF_3 and ClF_3 allow high fluorine concentrations (for aggressive Si etching) without the addition of oxygen, thus avoiding resist attack.

2. **Selective versus unselective dry etching**: The polymerizing point of the gas (i.e., the composition of the gas where polymerization takes over) primarily determines selectivity. The closer one works to the polymerization point, the better the selectivity. Factors that

have a tendency to increase the polymerization rate increase selectivity. Decreased temperature, high hydrogen concentration, low power, high pressure, and high monomer concentration all increase polymerization and thus selectivity. Typical unselective etchants for Si and polysilicon, used for noncritical etching, are CF_4 and CF_4-O_2. Less toxic gases such as CF_4 and SF_6 have preference over fluorine and are more selective, leading to polymerization. The most commonly used gases for selective Si etching are Cl_2, CCl_4, CF_2Cl_2, CF_3Cl, Br_2, and CF_3Br, along with mixtures such as Cl_2-C_2F_6. Small additions of halogens significantly increase the selectivity of fluorine-based etchants, especially the selectivity of silicon over silicon dioxide. For pure chlorine, the etch rate of SiO_2 is so low that even a native oxide can prevent the Si from etching. The high selectivity of SiO_2/Si is a major objective of many plasma processes trying to mimic the wet HF etch efficiency in this regard.

3. **Substrate bias**: A negative bias on a surface exposed to the plasma increases, at a constant F/C ratio, the etching behavior over polymerization tendency. This effect is caused by the enhanced energy of the ions striking the surface, resulting in polymer sputtering.
4. and 5. **Dry etching of III–V compounds**: Group III halides, particularly fluorides, tend to be involatile. As a result, F plasmas are usually substituted for chlorine-containing plasmas, and elevated substrate temperatures are used to further help volatilize the chlorides (fourth rule). The chemical composition (Ga/As ratio) of the different atomic planes in GaAs varies, and crystallographic etch patterns are observed under etch conditions in which chemical processes dominate (fifth rule). The latter establishes a major difference with dry Si etching, whereas crystallography does not play a role at all.
6. **Metal etching**: Chlorocarbons and fluorocarbons are typically used to etch metal films because they can reduce native metal oxides chemically. Oxygen and water vapor must be rigorously excluded during etching because of the high stability of the metal-oxide bond. Also, because of the stability of such bond, ion bombardment is essential. Because AlF_3 is not volatile, chlorine-containing gases are preferred for Al etching, whereas tungsten can be etched in fluorine (SF_6 or NF_3/chlorine).
7. **Organic films**: To retain an organic mask while etching away materials such as SiO_2 and Si_3N_4, one must work in etching conditions close to the polymerization point so that some loss of resist is compensated by condensation of reaction product, for example, CF_4-C_2H_4 and CF_4-H_2. We have already discussed that CF_4-O_2 plasmas severely degrade resist materials.
8. **Carbon-containing additives**: Carbon-containing additives generally degrade the selectivity of Cl- and Br-based inorganic chemistries for polysilicon etching over SiO_2. The Br atom attack on SiO_2 is thermodynamically unfavorable, whereas reactions between carbon halogen-bonded species and SiO_2 are exothermic. With HBr, a selectivity of 300:1 of polysilicon

over silicon dioxide can be achieved when completely avoiding carbon-containing gases or photoresists; the presence of resists or carbon traces in gases severely diminishes this ratio.

Leading suppliers of plasma etching equipment are Applied Materials, Inc. (Santa Clara, CA; http://www.appliedmaterials.com) and Lam Research Corporation (Fremont, CA; http://www.lamrc.com).

Deep Reactive Ion Etching

Introduction—Need for High-Density Plasmas

For building high-aspect-ratio micromachines and nanomachines with dry etching, until the mid-1990s, one had to battle three major problems. The first was the low etch rates with which to contend; typical Si dry etch rates of 1 µm/min required more than 5 hours to etch 300 µm deep! A second impediment was the inability to maintain high-aspect ratios over etch depths of a few tens of microns. Third, masking layers performed poorly and could not protect during a long etch.[45] New, high-density plasma sources provide an answer to each of these problems. As a result, for many applications, deep reactive ion etching (DRIE) presents an attractive MEMS solution today. An important example is the fabrication of high-aspect-ratio micromolds, which may be made much less expensive with deep DRIE than fabricating them with LIGA—an alternate high-aspect-ratio technique (see Chapter 10).

Ideally, dry etching stations generate high plasma densities (>10^{11}/cm^3) to achieve a high etch rate while operating at low pressure (1–20 mTorr). Low pressure increases ion directionality and discourages microloading. Normally low pressure also means less ionization and low plasma density. However, as we saw earlier, the use of magnetic fields forces electrons to spin with a very small gyroradius. This makes for a longer travel distance and thus more chance for electrons to collide with atoms, making a higher plasma density at low pressure possible. The source also needs to produce ions uniformly in energy and distribution while keeping the energy of the ions low to prevent damaging active electronics. The magnetic field reduces the charge difference in the sheath region, lowering the DC bias and therefore reducing the ion energy.

The two high-density plasma sources discussed here are inductively coupled plasma (ICP) stations [also called transformer coupled plasma (TCP)] and electron cyclotron resonance (ECR) machines. Both systems work at low pressures (a few mTorr) and can independently control ion flux and ion energy. In Figure 3.36 we show a schematic of an ICP and an ECR station.

Inductively Coupled Plasma

In inductively coupled plasmas, a coil, operating at the standard 13.56 MHz, drives the

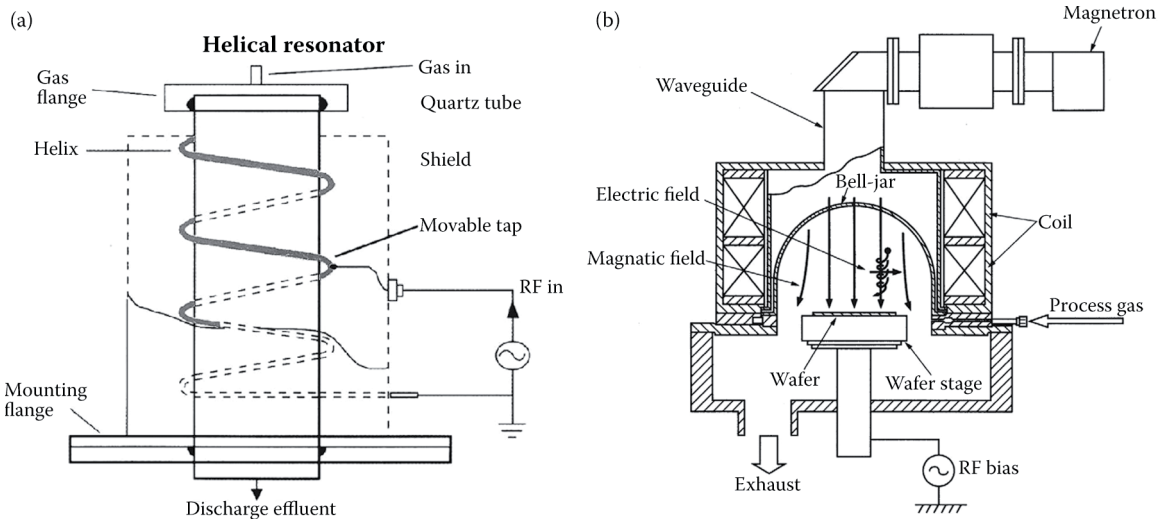

FIGURE 3.36 (a) ICP station. (b) ECR station.

plasma inductively (Figure 3.36a). Such an ICP source creates high-density, low-pressure, low-energy plasmas by coupling ion-producing electrons to the magnetic field arising from the rf voltage. Electrons travel a long way without collisions with the chamber walls or electrodes. The upper part of the ICP chamber, where the plasma is generated, is either ceramic or quartz. The RF source in the upper chamber generates the plasma and controls the ion density, whereas the RF bias in the lower chamber controls the ion bombardment energy. Thus, the ion energy and ion density are effectively controlled independently. By cooling the wafer chuck to liquid nitrogen temperatures (77 K) and using a helium gas flow under the wafer for efficient heat transfer, wafer temperature can be maintained at cryogenic temperatures during etching.[46] The cryogenic cooling of the chuck results in condensation of reactant gases and protects the sidewalls from etching, which renders a more anisotropic process.

The Alcatel RF ICP source is one of the systems advanced as an ideal source for deep anisotropic Si etching. The electron density in this plasma source reaches $>10^{12}/cm^3$, and using fluorine-based gases, silicon etches at rates of up to 6 µm/min with etch uniformity better than ±5% while maintaining a Si/SiO_2 selectivity of more than 150:1. Etch depths greater than 250 µm and profile angles of ±1° were demonstrated while maintaining aspect ratios of 9:1.

Using an ICP etching station from Surface Technology Systems (STS), Klaassen et al.[45] were able to etch 300 µm deep in Si at 5 µm/min using a photoresist layer as mask of a 6-µm thickness only. Polymerization of the photoresist mask on the sidewalls of the etched trenches slows the lateral etch rate and results in high anisotropy. The Si to photoresist selectivity was determined at about 50:1. However, cryogenic cooling (e.g., –100°C) may introduce undesirable thermal stresses, and an important, much-touted alternative is the "Bosch process" patented by Robert Bosch GmbH (Stuttgart, Germany).[47]

The Bosch advanced silicon etch (ASE) typically achieves high-aspect ratios of 20–30:1, and etch rates of ~3 µm/min are standard.[47] In this process carried out, for example, in an STS or PlasmaTherm high-density plasma system, one switches (pulses) between sequential passivation (85 sccm C_4F_8, 8 s, 0 W platen, 600 W coil, 16 mTorr) and etching (80 sccm SF_6, 6 s, 8 W platen, 600 W coil, 33 mTorr) (see Table 3.16). In the passivation step, a ~10-nm-thick fluorocarbon deposits and energetic SF_x^+ ions remove this layer at the bottom of a trench, as sketched in Figure 3.37.

TABLE 3.16 Characteristics of the DRIE Process Used in the STS and PlasmaTherm Systems

SF_6 flow	30–150 sccm
C_4F_8 flow	20–100 sccm
Etch cycle	5–15 s
Deposition cycle	5–12 s
Pressure	0.25–10 Pa
Temperature	20–80°C
Etch rate	1.5–4 µm/min
Sidewall angle	90° ± 2°
Selectivity to photoresist	~100 to 1
Selectivity to SiO_2	~200 to 1

Source: Maluf, N. 2000. *An introduction to microelectromechanical systems engineering.* Boston: Artech House.[48]

The repetitive alternation of etch and passivation steps results in a very directional etch. Some scalloping near the top of the trench is observed, but in general the sidewalls exhibit good surface planarity with roughness less than 50 nm.[48] The scalloping effect is illustrated in Figure 3.38. The experiment depicted in this figure also demonstrates that changing the length of the sequential passivation and etching cycles can control scalloping.

Using the Bosch process, Chow et al.[49] fabricated through-wafer electrical interconnects by dry etching 20-µm holes through a 400-µm wafer (see Example 3.1). By etching from both sides, the required aspect ratio is reduced by two, from 40:1 to 20:1. Each etch takes 180 minutes.

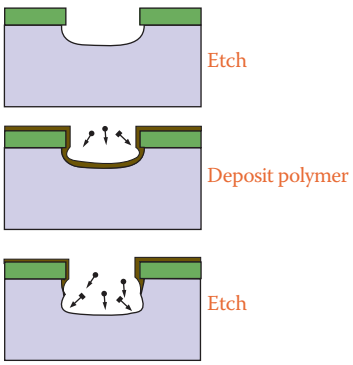

FIGURE 3.37 Illustration of the Bosch process.

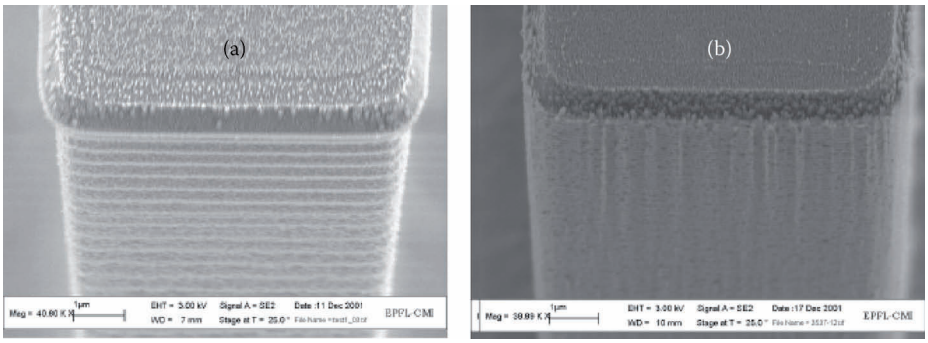

FIGURE 3.38 Sidewall roughness at the top of a deep anisotropic etching of Si (Bosch process) as a function of pulse duration: SF_6/C_4F_8 = 7s/2s (a) and SF_6/C_4F_8 = 3s/1s (b).

Ayon et al.[26] tackled the issue of microloading in the Bosch process by increasing the ion flux through control of the applied source coil power. Ions reaching the wafer surface during the etch cycle promote more efficient removal of the protective polymer coating at the bottom of the trench, obviating the microloading effect. To etch ultradeep anisotropic silicon trenches in the range of 300–500 µm, Ayon et al.[26] compensate the reduction of neutral species flux reaching the feature bottom by increasing the SF_6 flow rates during the etching cycle (thus replenishing the etching species while the higher pressure also facilitates the removal of etching byproducts). This method results in a net improvement in passivation and etch rates and is known as the MIT 59 method (Figure 3.39). The method has already been applied in processes like the fabrication of accelerometers, gyros, microdisk-drive armatures, SCALPEL mask membranes, microgas turbines, tethered motors, power MEMS, and, in general, for etching through wafers.[26,50] A deep silicon back-side Bosch etch also allows fabrication of high-aspect-ratio and MEMS devices integrated with complementary metal oxide semiconductor (CMOS) circuitry (see Example 3.3).[51]

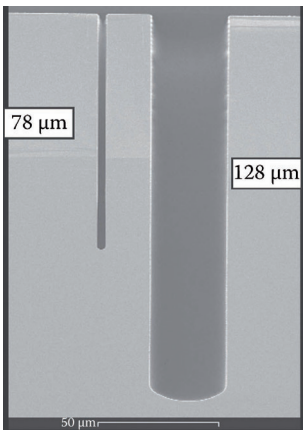

FIGURE 3.39 MIT 59 method. See text.

An extensive database for the Bosch process conditions required to achieve prescribed profiles, as well as targeted silicon etch rates and uniformity, was presented in the *Journal of the Electrochemical Society* by Ayon et al.[52,53]

Electron Cyclotron Resonance

New, high-density plasma sources may also be based on microwave discharges (Figure 3.36b). An RF source controls the ion energy, and a microwave power source controls the ion flux. Microwaves are electromagnetic waves in the 1–100-GHz (corresponding to wavelengths from 30 to 0.3 cm) range. Waves in this frequency range are transmitted by the use of waveguides, which are typically made of metal tubes of rectangular or circular cross-section. Cavities with metallic conducting walls resonate at specific frequencies and harmonics that are easy to calculate. The energy dissipated within the cavity dictates the frequency range above and below the resonant frequency that the cavity will accept and is characterized by the quality factor Q:

$$Q = \frac{f_0}{2\Delta f} \tag{3.21}$$

where $\pm\Delta f$ are the frequencies at which the amplitude is one-half that at the resonant frequency, f_0, for the same input power. In the case of an empty waveguide, the dissipation of energy inside the cavity is determined by the skin depth, δ, of the electrical

field into the metal walls, which is given by (see also Volume I, Chapter 5, Equation 5.215):

$$\delta = \sqrt{\frac{\rho}{\pi \mu f}} \tag{3.22}$$

where ρ is the resistivity in Ωm, μ the permittivity of free space ($4\pi \times 10^{-7}$ Henry/m), and *f* the frequency in hertz. For the generation of microwave plasmas, a cavity in the form of a cylinder with radius *a* and length *l* is generally used operating in $TM_{0,1}$ mode, that is, with the electric field parallel to the axis of the cylinder. In this case:

$$\lambda_0 = 2.61a \tag{3.23}$$

where λ_0 is the microwave wavelength. The resonant frequency of the cavity changes as a result of the change in the dielectric constant of the ionized gas, and *Q* decreases because of the increased power loss in generating the plasma.

In a quartz chamber filled with a gas at low pressure (0.1–10 Torr), the microwave power will cause breakdown when free electrons within the quartz chamber gain sufficient energy to ionize the gas. A static magnetic field generated by solenoid coils is also applied to the quartz chamber, and electrons move in a circular motion at the ECR frequency for that magnetic field (see Equation 3.18). In an ECR etching station, the ECR discharge creates a region, or surface layer, within the quartz chamber where the electron cyclotron frequency and the microwave frequency are equal and the electric field component is perpendicular to the static magnetic field. Under these conditions, the electrons within the ECR region are accelerated until they lose energy by an ionization or excitation collision with a neutral gas molecule. Varying the input microwave power and the gas pressure controls the plasma density. The maximum plasma density is reached if the microwave input power is such that the plasma frequency is equal to the microwave frequency, which is itself equal to the ECR frequency. The interaction of the magnetic field and the microwaves results in an intense, high-density plasma maintainable at low pressure. In operation, a 2.45-GHz microwave frequency is generated by a magnetron and injected into an etching chamber, enclosed by a quartz bell jar, through a waveguide. The maximum number of electrons (and ions) that can be formed within the quartz chamber at 2.45 GHz is about 7.5×10^{10} electrons/cm^3.

In many ECR systems, the wafers are placed downstream of the plasma to further limit their exposure to this intense discharge. Wafers can also be biased to control ion bombardment energy. Like MERIE, ECR and ICP produce higher plasma densities with low-energy density, reducing charge-up damage.

Juan et al.[54] used ECR to etch polyimide molds for the fabrication of electroplated microstructures in one of several reported "pseudo-LIGA" processes (see also Chapter 10). A fast polyimide etch rate of 0.91 μm/min and a high selectivity over a Ti etch mask of 3150:1 were reached in an oxygen plasma. Polyimide (Dupont Pyralin® PI-2611) was spun on in multiple coatings and cured at 380°C for 1 hour. According to the authors, etching with an ECR source is 10 times faster and six times more selective than conventional RIE. The combination of magnetic confinement and microwave power, leading to an order of magnitude greater dissociation efficiency at much lower pressures than RIE, reduces scattering of reactive species and promotes vertical profiles and smooth surface morphology. Cooling down to –130°C helps maintain a vertical etch profile by suppressing spontaneous chemical reactions. This way, lateral resonator elements 32-μm thick with a 1-μm gap have been fabricated in polyimide, and electroplated Ni accelerometers with an aspect ratio of 11:1 were formed from these polyimide molds. Compared with LIGA, where the average wall roughness is <50 nm, the walls produced by this process still appear rough, but for many applications they might be adequate.

For a review on etching high-aspect-ratio trenches in silicon by DRIE, we refer to Jansen et al.[2] This article features an excellent review of possible trench shapes. Equipment for DRIE is available from STS (Abercarn, Wales, UK; http://www.stsystems.com), Plasma Therm Inc. (St. Petersburg, FL; http://www.plasmatherm.com/index.html), and Alcatel, S.A. (Paris, France; http://www.alcatel.com).

Vapor-Phase Etching without Plasma (XeF_2)

As far back as 1983, it was demonstrated that etching of Si with XeF_2 in a CAIBE reactor enabled

sidewall tailoring by changing the partial pressure of XeF_2, the ion energy, and the current density.[55] At the higher partial pressures of XeF_2, isotropic etching and undercutting became predominant. Isotropic etching of Si with xenon difluoride (XeF_2) actually does not require a plasma to generate the etching species. XeF_2 is a white solid with a room temperature vapor pressure of about 4 Torr, which reacts readily with Si. The Si etch occurs in the vapor phase at room temperature and at pressures between 1 and 4 Torr, established by a vacuum pump throttled to the right pressure. The etch rate is very dependent on the feature size in Si to be etched (see microloading). Hoffman et al.[56] observed silicon etch rates as high as 10 µm/min but worked at more typical rates of 1–3 µm. The extreme selectivity of XeF_2 to silicon over silicon dioxide and silicon nitride are well documented, and Hoffman et al.[56] have shown that XeF_2 also displays extreme etching selectivity over aluminum and photoresist. One important problem is that XeF_2 reacts with water to form water and HF. The latter may unintentionally react with Si to form SiO_2. The exothermic etch reaction, according to Chang et al., is given by:

$$2XeF_2 + Si \rightarrow 2Xe + SiF_4 \qquad \text{Reaction 3.5}$$

with only Si in the solid phase.

A 50-nm Al mask or a single layer of hard-baked photoresist suffices as deep etch masks. The simplicity of the process, the fast etch rate, as well as the resistance of even very thin layers of oxide, nitride, and Al metal make this etching process a possible choice for etching micromachined structures in the presence of CMOS electronics (in a "post-CMOS procedure"). The etched surfaces have a granular structure (10 µm and smaller feature size), and this etchant is not suited when polished mirror surfaces are required. In Figure 3.40a, an Al hinge 5 µm wide and 1.1 µm thick, holding an oxide

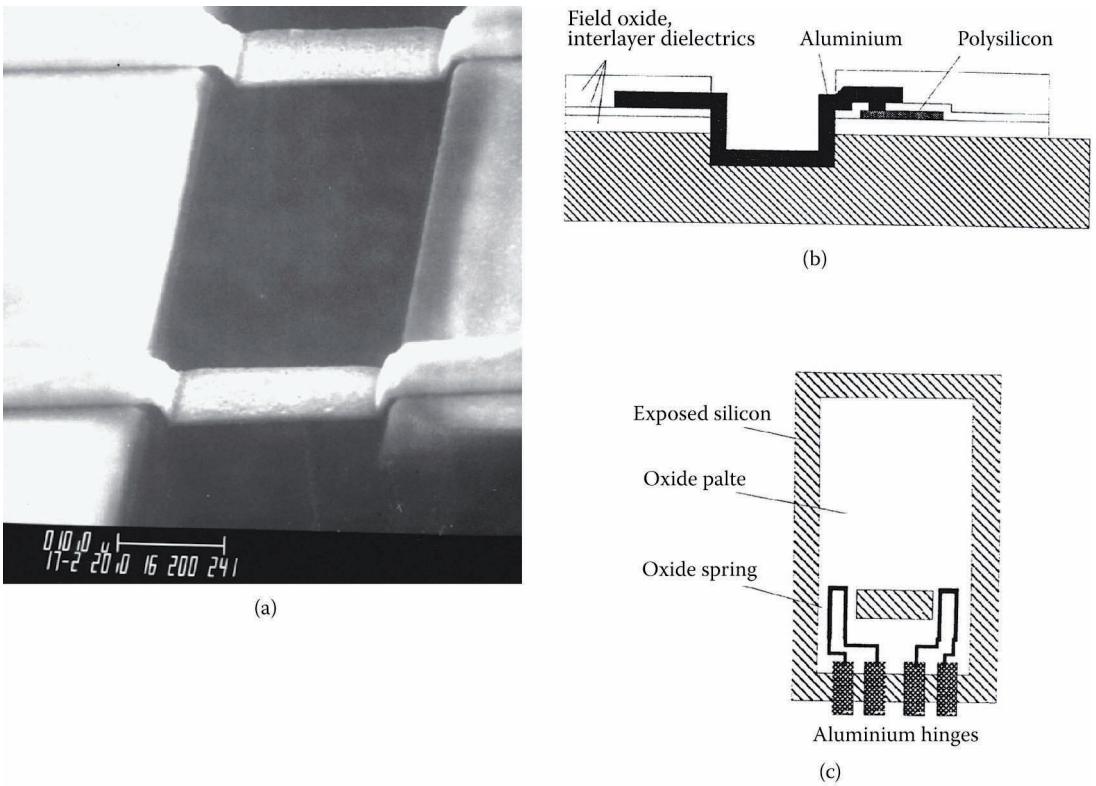

FIGURE 3.40 (a) Al hinge (5 µm wide and 1.1 µm thick) holding a suspended oxide plate (plate is on the right side of the photograph). The Si is etched from underneath the Al hinge and oxide plate by XeF_2. The suspended oxide plate is a 200-µm square. (Courtesy of Dr. Kris Pister.) (b) Al hinge contacts a poly-Si piezoresistor embedded in the oxide plate to protect it from the XeF_2 etchant. (c) The piezoresistive accelerometer design shown enables rotation of the oxide plate out of the plane to detect orthogonal acceleration. (From Hoffman, E., B. Warneke, E. Kruglick, J. Weigold, and K. S. J. Pister. 1995. *Proceedings: IEEE micro electro mechanical systems (MEMS '95).* Amsterdam, the Netherlands: IEEE. With permission.[56])

plate 200-μm square suspended over a Si etch pit, is shown. The etch pit underneath the suspended plate is nearly isotropic and exhibits a surface roughness of several microns. The conductivity of the Al metal was unaffected by the XeF_2 etch. The hinge contacts a polysilicon strain gauge, sandwiched between oxide layers, to protect it from the XeF_2 etchant (see Figure 3.40b). The flexible hinge enables rotation of the oxide plate out of the plane of the wafer. Hoffman et al.[56] suggest that this contraption might function as a piezoresistive accelerometer, with hinges providing mechanical support and electrical connectivity between strain gauges embedded in the oxide plate proof mass and the wafer (see Figure 3.40c).

The rough Si surfaces of a XeF_2 etch in principle may be avoided by using interhalogen gases such as BrF_3 and ClF_3 with xenon gas as diluent.[57] The interhalogens are formed from single-element feed gases (e.g., bromine and fluorine) and result in perfectly isotropic etches and smooth silicon surfaces. Wang et al.[58] measured etch rate ratios for thin films with respect to Si in BrF_3 for several materials:

1. Si:LPCVD silicon dioxide = 3000:1
2. Si:silicon nitride = 400–800:1 (depending on the Si concentration)
3. Si:hard-baked AZ4400 and AZ1518 photoresist = 1000:1
4. Si:Al, Cu, Au, and Ni ≥ 1000:1

A first commercial instrument developed for XeF_2 etching is the Xetch™ from Xactix (http://www.xac tix.com).

Dry Etching Models—In Situ Monitoring

A serious impediment to more effective use of dry etching is the large number of parameters that affect the process.[59] Just consider pressure and temperature. Pressure influences the ion-to-neutral ratio and fluxes of these particles, the sheath potentials and energy of the ions bombarding surfaces, electron energy, and the relative rate of chemical kinetics. Temperatures, both of gas and surface, have a profound influence on discharge chemistry as well. Only the surface temperature is controllable and influences selectivity, etch rates, degradation of resist masks, and surface roughness (higher temperature leads to a rougher surface).

Also, electrode area ratio, RF frequency, and power will alter plasma and electrode potentials, thereby changing ion energies. At lower frequencies, where ions can respond directly to the oscillating field, ions can attain the maximum energy corresponding to the maximum field across the sheath. As a result, for a constant sheath potential, ion bombardment energies are higher at frequencies less than 50 kHz. Nonuniformity can be caused by gradients in etchant concentration. Such gradients are responsible for the dreaded bull's eye etching pattern, where the etch rate decreases monotonically from the wafer periphery to its center (see above). Pressure, power, and gas flow must be adapted until the specified uniformity is obtained.

Predicting the exact relation between the flux and the energy of particles striking a wafer surface and the etch rate still is not state of the art, largely because no equilibrium is attained in these dry etching reactors, and for most reactions the kinetics are not known. Consequently, in situ monitoring of the plasma to improve etching uniformity is an important area for further research.[60,61] Besides measuring these controlling parameters, techniques such as optical emission spectroscopy (OES) to map in situ etchant concentration are coming to the foreground as sensitive and effective endpoint detectors. It is well known that the color of a plasma changes when etching different materials. Emissions can emanate from etchants, etch products, or their fragments. An optical spectrometer is set to the line of a reaction product of interest, and one follows its intensity during an etch cycle. Some etch endpoint wavelengths are summarized in Table 3.17.

Mass spectrometry allows one to monitor the concentration of a wide variety of species; it is limited, however, in that the results are obtained downstream from the real process in the reactor.[62] Laser-induced fluorescence (LIF) has been used to measure ground–state ion and radical concentrations. LIF is more powerful than OES, but it is expensive and requires a lot of experimental expertise; consequently, it is used more in the research lab than on a production line.[63] In imaging

Table 3.17 Etch Endpoint Wavelength

Film	Etchant	Wavelength (Å)	Emitter
Al	Cl_2, BCl_3	2614 3962	AlCl Al
Poly-Si	Cl_2	2882 6156	Si O
Si_3N_4	CF_4/O_2	3370 3862 7037 6740	N_2 CN F N
SiO_2	CF_4 and CHF_3	7037 4835 6156	F CO O
PSG, BPSG	CF_4 and CHF_3	2535	P
W	SF_6	7037	F

of radicals interacting with a surface (IRIS), light from a dye laser optically excites specific radicals in the incident and reflected molecular beam striking a surface. The light emission of radicals in incident and reflected beam is measured and used to extract information on their density. By taking the difference of the emission data, it is possible to determine the intensity of scattered radicals and the reactivity of specific radicals with particular surfaces.[3] Laser interferometry (for thin transparent films such as polysilicon, silicon dioxide, and silicon nitride) and laser spot reflectance (for opaque, highly reflecting metal films) are used to monitor film thickness and film disappearance, respectively. Also, the temperature of the wafer during reactive ion etching affects process quality in terms of photoresist integrity, selectivity, etch rate, and etch residues. An in situ temperature monitor enables one to improve the performance during the plasma etch.[64] With Langmuir probes, one can, in principle, determine the complete electron energy distribution of a plasma. In such an experiment, a small wire probe is inserted into the plasma and biased with respect to some other electrode. By recording the current-voltage plot of the probe, charged particle densities and energies can be deduced. In practice, Langmuir and other electrostatic probes are difficult to apply, invasive, and perturb the plasma.

Bosch-Charpenay et al.[50] integrated an FTIR sensor in an STS Multiplex ICP deep reactive ion etcher. This enabled in situ, real-time measurements of DRIE etch depth and eroding photoresist thickness measurements of MEMS devices using infrared reflectance analysis. Typical capabilities of the system are summarized in Table 3.18.

Examples

Several examples of dry-etched micromachines are presented below. They include deep dry etching to fabricate interconnects through single crystal Si, an example of single crystal reactive etching and metallization (SCREAM), which relies on a combination of anisotropic and isotropic dry etching, a variant on the SCREAM process from the Carnegie Mellon University, dry etching of polymeric materials, and a cantilever micromachining process combining wet and dry etching.

Table 3.18 Summary of FTIR Sensor Capabilities

MEMS structures that can be measured	Pillars, holes, trenches, trench grids, honeycombs of etched width less than ~100 μm
Etch depth precision (reproducibility)	0.05–0.5 μm depending on the structure
Etch depth accuracy (as compared with SEM)	~1–2 μm (estimated)
Maximum measurable etch depth	>200 μm
Current spot size*	~800 μm diameter
Measurement time	~1 s
Measurement spot range†	±5 mm in both *x*- and *y*-direction
Probing IR wavelength	2–10 μm (1000–5000 cm^{-1})

*Optical diffraction limits preclude spot sizes smaller than ~400 μm. MEMS devices smaller than this minimum spot size can, however, still be measured, provided they are geometrically isolated from other DRIE etched features.
†Translation range of infrared spot over sample is strictly related to equipment geometry at the etch chamber—in this case a small overhead view port into the STS Multiplex ICP system.

Example 3.1: Via Etching in Si

Fabrication of high-density electrical, through-wafer interconnects on silicon substrates remains a challenging proposition. In MEMS, through-wafer interconnects greatly facilitate their integration with active electronics (see Making Vias through Silicon in Volume III, Chapter 4). Different approaches to fabricating those 3D contact lines are compared in Volume III, Chapter 4 on packaging. Chow et al.[49] use the Bosch process to etch a high-aspect-ratio through-wafer via and subsequently coat an insulator and then fill in a signal-conducting layer.[49] Etching the via is the first and most critical step. A 10-μm-thick photoresist (Shipley SPR220-7) is coated on both sides of the Si wafer, and a double-sided aligner is used to expose 20-μm circles on both sides (±1 μm accuracy). The authors let the wafers then sit for 8 hours to absorb water. The moisture, they claim, helps ensure a shorter development time (90 s in Shipley LDD26W), resulting in straighter resist walls. Using a high-density plasma etcher from STS, a Bosch etch procedure (such as shown in Table 3.16) is performed for 120 minutes from the front side of the wafer. Resist is then coated and baked again, and another 180-minute etch from the back is used to punch through the vias (Figure 3.41). The diameter of the resulting vias varies from 24 μm (top and bottom) to 18 μm in the middle. By etching from both sides of the wafer, the required aspect ratio is reduced from 40:1 to 20:1, and it is possible to etch a 20-μm circle through a 400-μm-thick wafer. For electrical isolation of the via, thermal silicon dioxide (2 μm) is grown at 1100°C. For signal conduction, low-pressure chemical vapor deposition (LPCVD) polysilicon is deposited into the via and doped by phosphorous diffusion. The resistance of the resulting via is 14 Ω, and its low capacitance (<1 pF) makes it attractive for high-speed applications.

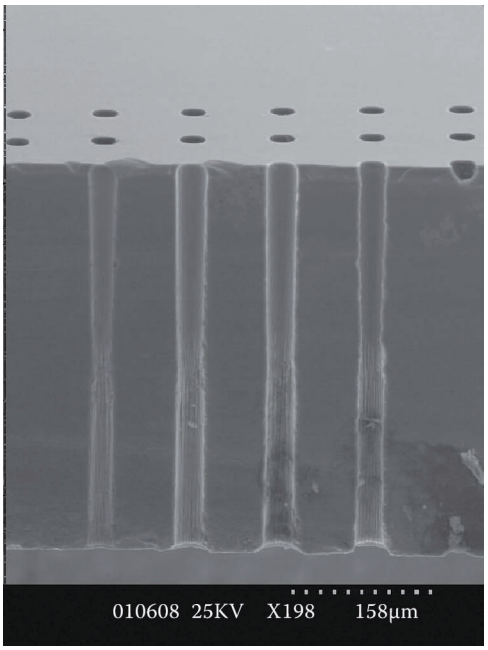

FIGURE 3.41 SEM cross-section after plasma etching vias through the wafer. (From Arnold, J. C., and H. H. Sawin. 1991. Charging of pattern features during plasma etching. *J Appl Phys* 70:5314.[24])

Example 3.2: Single Crystal Reactive Etching and Metallization

As a second example of dry etching in micromachining, we follow some of the work by the Cornell Nanofabrication Laboratory making laterally driven micromachines.[65,66] In laterally driven micromachines, as illustrated in Figure 3.42a, beams and structures of various shapes should preferably be of a narrow and thick construction and able to move freely and in parallel to the supporting substrate while being held rigidly above it. Increased thickness of beams permits greater driving power for a given voltage and increases stiffness of the device perpendicular to the plane of motion. Thin, suspended beams (e.g., 2 μm wide) are fabricated with a combination of dry and wet etching in polysilicon (surface micromachining, Chapter 7). However, thick single crystal beams greater than 20 μm in materials such as quartz, Si, and GaAs can best be made with dry etching, especially because thick lateral moving microstructures of arbitrary shape, given crystallographic limitations, are very difficult to realize using wet bulk micromachining (Chapter 4). The monitoring of the resonant frequency variation of small resonator devices made this way (see Figure 3.42a) can be used to measure monolayer mass changes, as well as pressure, temperature, acceleration, and so on. In the measurement of mass, for example, the sensitivity of the device is a function of resonant frequency and mass of the resonating structure:

$$\text{Sensitivity} \sim \frac{\text{Resonant frequency}}{\text{Mass}} \qquad (3.24)$$

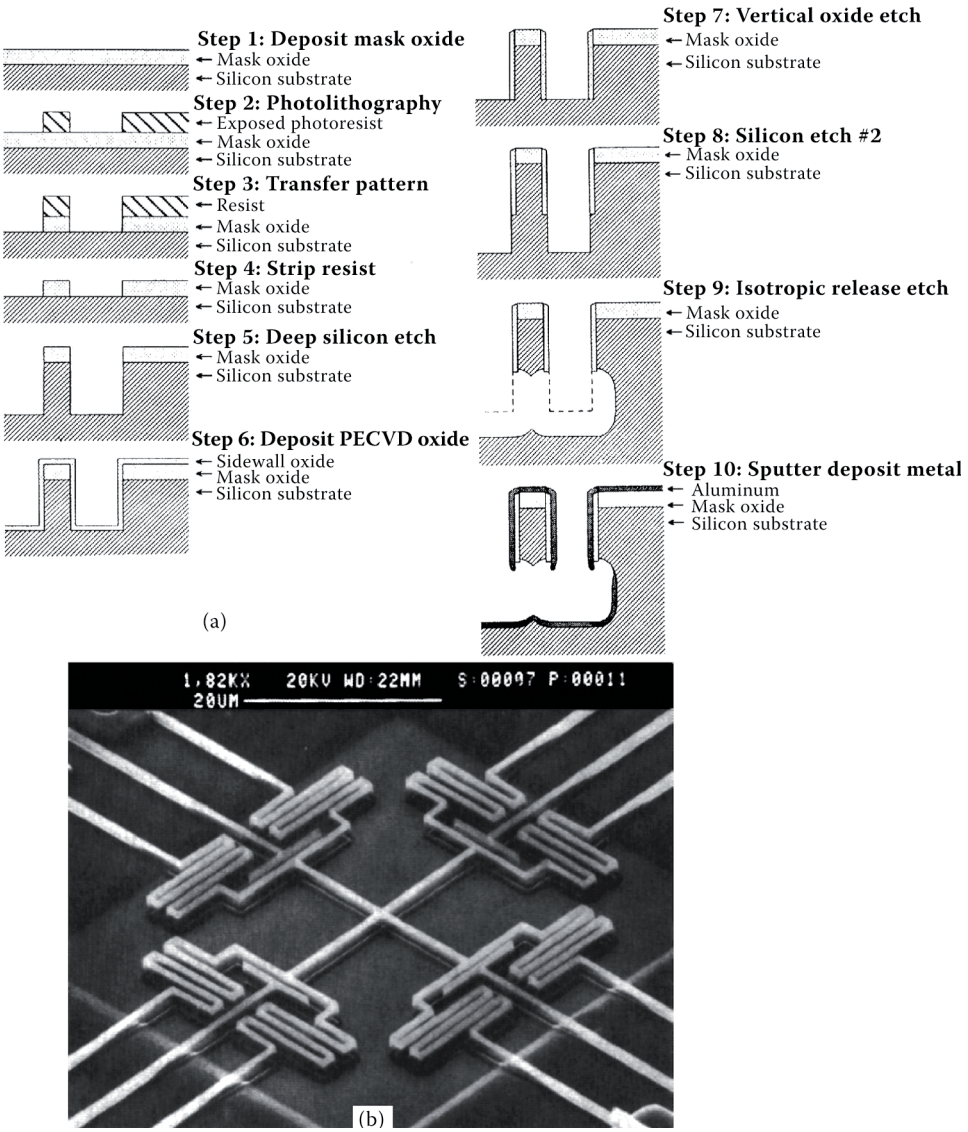

FIGURE 3.42 (a) Si-SCREAM process (see text). The cross-section of a typical beam made using the SCREAM process is illustrated in step 10. This drawing shows a suspended beam and its associated parallel-plate capacitor. The released beam is free to move, whereas the plate on the right is static and can be used to measure the motion of the beam. (From K. A. Shaw et al., *Sensors Actuators A*, 40:63–70 (1994). With permission.) (b) A representative SCREAM structure. SEM micrograph of a Si *x,y* stage with parallel-plate capacitive drives and springs. (From Yao, J. J., S. C. Arney, and N. C. MacDonald. 1992. Fabrication of high-frequency two-dimensional nanoactuators for scanned probe devices. *J Microelectromech Syst* 1:14–22. With permission.[67])

To build the most sensitive detector, the mass must be minimized and the resonant frequency maximized. The mechanical resonant frequency of an ideal resonator is given by:

$$f_0 = \left(\frac{k}{m}\right)^{\frac{1}{2}} \tag{3.25}$$

with k the spring constant and m its mass; in other words, the resonant frequency is proportional to (stiffness/mass)$^{1/2}$. A large spring stiffness must be designed and m minimized to make f_0 as high as possible. For some of the very stiff, low mass structures made at Cornell, f_0 was 5 MHz, with k = 55 N/m and m = 2.0×10^{-13} kg. The above simple considerations illustrate the power of micromachining in enabling more sensitive detectors. For more details on building MEMS resonant beams, see Volume III, Chapter 8 on actuators.

Lateral resonant structures as shown in Figure 3.42a are used to make sets of comb electrodes,

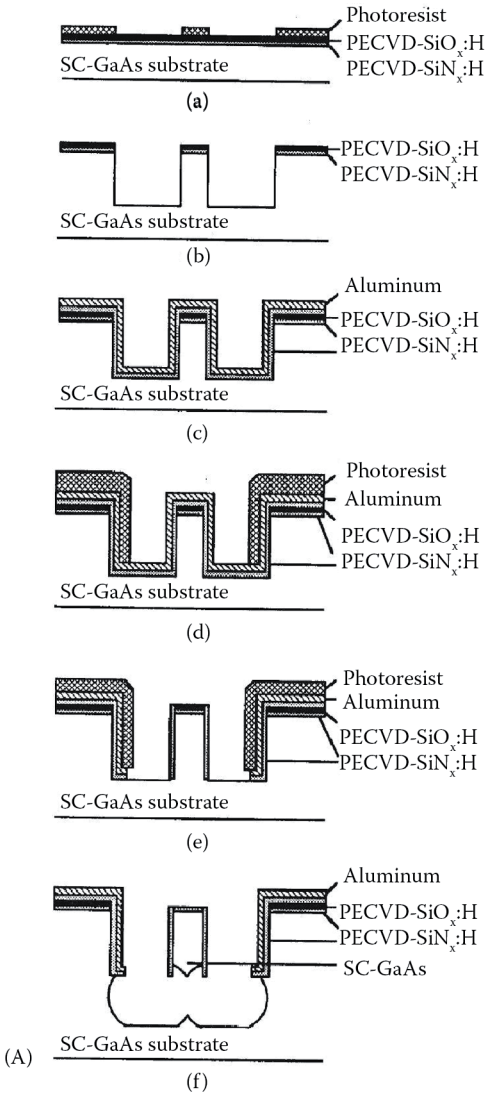
for example, to drive precision *x-y* microstages for accurate positioning or as comb drives in accelerometers. Scanning tunneling microscopes (STMs), 40 × 40 μm in size, have been manufactured using SCREAM technology.[67] In the latter case, field emitter tips were integrated on an *x-y* stage with moving beams with nominal cross-sectional dimensions of 250 nm in width and 1000 nm in height. Displacements in the *x-y* directions through parallel-plate capacitive drives measured ±200 nm for an applied voltage in the 50-V range.

An elegant Cornell dry etching process that obtains such laterally driven, single crystal micromachines is called *SCREAM*. This technology uses reactive ion etching to both define and release structures. SCREAM portrays an important technique from several points of view. It is a self-aligned, single-mask process, run at temperatures lower than 300°C, completed in less than 8 hours, and can be carried out in the presence of active circuitry integrated on the same chip. The example given here is the fabrication of single crystal silicon-released beam structures (see Figure 3.42).[67]

The steps of the SCREAM process are illustrated in Figure 3.42b. As a starting substrate, an arsenic-doped, 0.005-Ωcm, n-type (100) silicon wafer is used. A masking layer of PECVD silicon dioxide, 1–2 μm thick, is coated with resist (step 1). Photolithography on the photoresist layer creates the desired pattern (step 2) to be transferred onto the silicon dioxide using CHF_3-based, magneton reactive ion etching (MERIE) (step 3). The photoresist is then stripped in an oxygen barrel etcher (step 4). The silicon dioxide mask pattern is subsequently transferred to the silicon substrate using a Cl_2/BCl_3 anisotropic etch. The etch depth, depending on the intended micromachine, ranges between 4 and 20 μm (step 5). Following the silicon etch, silicon dioxide is conformably deposited using PECVD. This oxide, at a thickness of 0.3 μm, will serve as a protection for the sidewalls during release (step 6). The next step is interesting and crucial to the process. The objective is to remove the oxide from the bottom and the top of the structure without removing the oxide from the sidewalls. This selective clearing of oxide is carried out in an anisotropic CF_4/O_2 etch at 10 mTorr. It removes 0.3 μm of oxide from the mesas and the trench bottoms while leaving the sidewall oxide intact (step 7). In the next step, a second deep Si etch (BCl_3/Cl_2) deepens the trench further (3–5 μm deeper) to expose some Si sidewall underneath the oxide-covered part (step 8). The release is accomplished with an SF_6 isotropic etch at 90 mTorr. The RIE step etches the Si out from underneath the beams, releasing them in the process (step 9). An etchant such as SF_6 hardly etches the oxide at all and gives good selectivity to the process. A layer of aluminum is then sputter-deposited using DC magnetron sputter deposition (see Chapter 9) (step 10). The Al can be contacted and used as a drive electrode in micromechanical resonator structures. Resonator elements with beam elements 0.5–5 μm wide and aspect ratios >10 have been achieved using this Si SCREAM process.

A variation of the CMOS-compatible Si SCREAM process is used at EG&G's IC Sensors (Milpitas, CA; http://www.meas-spec.com/myMeas/sensors) for the manufacture of accelerometers.

The SCREAM process can also be used to fabricate GaAs micro- and nanomachines. Figure 3.43a outlines the SCREAM process steps in the case of a GaAs-based device.[66] Specifically, the process sequence for the fabrication of a cantilever beam structure identical to the Si one in Figure 3.42a is shown.[68] Considering two identical structures enables us to better compare the degree of complexity of micromachining in those two materials. Single crystal GaAs, in some respects, is an attractive material for micromechanics because of its optoelectronic properties. With GaAs, one can envision the possibility of vertically etched mirrors, lenses, detectors, waveguides, and semiconductor lasers, all adding up to the possibility of a totally integrated optical bench. On the other hand, compared with silicon, GaAs possesses a low fracture strength (its yield strength is considerably lower: 2 vs. 7 GPa) and is more difficult to passivate than Si, as its own oxides are either leaky or chemically unstable. The process example illustrates the difficulty in passivating GaAs versus passivating Si (a dual-layer dielectric is required to passivate GaAs). A more complete comparison of silicon versus GaAs in micromachining is presented in Volume III, Chapter 5 on selected materials for MEMS and NEMS.



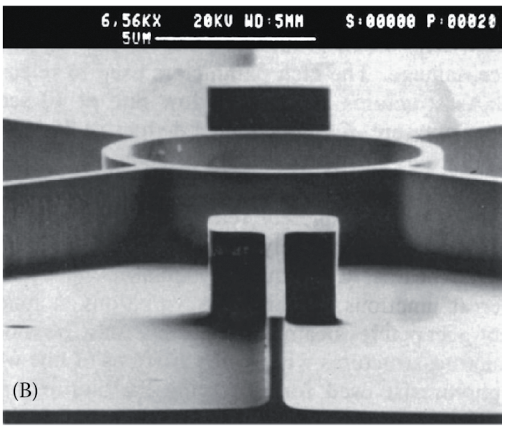


FIGURE 3.43 (A) Formation of an SC-GaAs cantilever beam with aluminum electrodes adjacent to each side of the beam using PECVD-SIN$_x$:H for insulation and for the top and sidewall etch mask. (From Zhang, Z. L., G. A. Porkolab, and N. C. MacDonald. 1992. *Proceedings: IEEE micro electro mechanical systems (MEMS '92).* Travemunde, Germany: IEEE. With permission.[68]) (B) SEM micrograph showing SC-GaAs circular and angled straight-line features after the CAIBE step. (From Zhang, Z. L., and N. C. MacDonald. 1993. Fabrication of submicron high-aspect-ratio GaAs actuators. *J Microelectromech Syst* 2:66–73. With permission.[66])

For creating a simple movable beam, CAIBE produces deep vertical trenches, and RIE laterally undercuts and releases the vertically etched structures from the GaAs substrate.[68] This process produces aspect ratios of 25:1 with trenches of 20 μm vertical depth to 400 nm lateral width. PECVD-SiN$_X$:H (200 nm) and a second layer of SiO$_X$:H (150 nm) are used to mask the GaAs substrate (Figure 3.43Aa). PECVD-SiN$_X$:H on GaAs easily results in structural buckling and layer cracking, but nevertheless is preferred as a conformable layer because the surface of PECVD-SiO$_X$:H on GaAs is too rough as a result of the diffusion of gallium into PECVD-SiO$_X$:H. The PECVD-SiN$_X$:H deposition temperature of 100°C is selected to obtain simultaneously good dielectric properties and low residual stress in the film. To further protect the GaAs during etching, an additional sacrificial PECVD-SiO$_X$:H is deposited. The thermal expansion mismatch between the two dielectrics is less than between either of the dielectrics and the GaAs. The pattern-producing freestanding beams in GaAs are then printed in a photoresist layer on top of the bilayer dielectric. Plasma etching with CHF_3/O_2 transfers this image into the dielectric layer. The pattern in the dielectric stack subsequently is transferred to

the single crystal GaAs by CAIBE (Figure 3.43Ab) using a 500-eV, 0.1-mA/cm^2 Ar ion beam and a Cl_2 flow of 10 ml/min. After the CAIBE process, the remaining photoresist is stripped in oxygen plasma, and a 300-nm PECVD layer of SiN_X:H is conformably deposited. Subsequently, using DC magnetron sputtering, a 400-nm layer of aluminum is deposited (Figure 3.43Ac). Photoresist is spun on the Al layer, and the aluminum side-electrode pattern is printed in the resist, developed (Figure 3.43Ad), and then transferred to the Al by a Cl_2/BCl_3 etch. The latter step removes the aluminum from the areas that have been cleared of resist. Before the Al deposition, contact windows are formed to allow electrical contact with both the GaAs substrate and the movable GaAs beams. To clear the PECVD-SiN_X:H (from the second deposition of this compound) from the bottom of the trenches and to retain the dielectric elsewhere, a highly anisotropic CHF_3/O_2 is applied (Figure 3.43Ae). Finally, the GaAs structures are released from the substrate using a chlorine-based RIE (Figure 3.43Af; the top and sidewalls of the GaAs structure remain protected by the PECVD-SiN_X:H and PECVD-SiO_X:H mask. At the end of the beam-releasing etch, the PECVD-SiO_X:H is consumed, that is, it acts as a sacrificial mask. Finally, the photoresist for the Al patterning is stripped in oxygen. In a simplification of the process described in Figure 3.43A, Zhang et al.[66] later discovered an improved PECVD-SiN_xH_y conformal coating enabling a single dielectric mask for the GaAs SCREAM process. Figure 3.43B demonstrates circular and angled straight-line features in single crystal-GaAs produced with the simplified process.

Example 3.3: Post-CMOS Processing for High-Aspect-Ratio Integrated Silicon Microstructures

Fedder et al.[69] demonstrated the use of a maskless SCREAM-like approach of combined anisotropic and isotropic dry etching to fabricate thin laminated aluminum/silicon dioxide (or dielectrics in general) mechanical structures using the top-level aluminum layer in standard CMOS as an etch mask for the underlying Si.[69] In this process, an anisotropic silicon dioxide etch (CHF_3/O_2) is followed by an anisotropic Si etch (SF_6/O_2), and finally an undercutting isotropic Si etch is used to release the movable mechanical elements. This post-CMOS process is illustrated in Figure 3.44. The etching masks are the interconnect metals from preceding CMOS processing, so no post-CMOS lithography is required, hence the name "maskless post-CMOS micromachining." An aspect ratio of 4:1 can be achieved. The microstructures consist of up to three metal layers that are electrically isolated by dielectrics. Both lateral and vertical CMOS accelerometers with fully differential full-bridge capacitive interface circuits have been fabricated using this post-CMOS micromachining process, and a triaxial microstage has also been realized.[51] A major drawback with this type of CMOS-MEMS is that the residual stress and thermal expansion coefficient in the thin metal/dielectric layers cause curling or bending.

More recently, with the improvements in deep RIE, the same Carnegie Mellon University-based research group has revisited their SCREAM-like

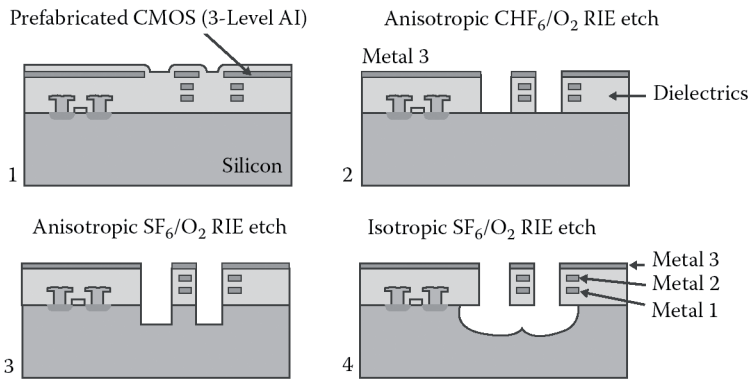

FIGURE 3.44 Cross-sectioned view of thin-film post-CMOS micromachining. Illustration of the process flow showing use of the uppermost metallization level as mask for silicon etching, first with an anisotropic etch and then an isotropic etch to free movable structures.

approach by incorporating a front and a back-side anisotropic Bosch etch. The process flow is illustrated in Figure 3.45A. In step 1, a deep anisotropic etch leaves a 10–100-μm thick single-crystal Si membrane underneath the CMOS microstructural layer. The central idea is to leave a thick layer of single crystal backing the thin CMOS multilayer such that the mechanical properties are dominated by the underlying single-crystal Si, and electrical connections continue to be provided by the CMOS microstructure layer. In step 2, a front-side anisotropic etch is carried out to etch through the thin CMOS dielectric layers. In step 3, the microstructure is released by an anisotropic Si etch instead of the isotropic etch typically used in the SCREAM process. The resulting thick Si, which remains underneath the CMOS layer, results in a totally flat released microstructure (no curling). Moreover, the proof mass and comb-finger capacitance for CMOS-based inertial sensors are significantly increased because of the higher *z*-dimensions. A close-up of one corner of a comb-drive actuator fabricated using the new process is shown in Figure 3.45B.

Example 3.4: Dry Etching of Polymeric Materials

As we learned so far, to obtain the optimum anisotropy in high-aspect-ratio devices, one cools the substrate, uses high RF power density, works at the lowest possible pressure, uses high gas flow rate, relies on sidewall-passivating additives, or, as in the Bosch process, one switches back and forth between etching and passivation. We give examples here of the anisotropic power of MERIE by Furuya et al.[70]

Furuya et al.,[70] at NTT, made a fluorinated polyimide microgrid (Figure 3.46) by using MERIE in oxygen plasma. The grid elements consist of 18 pole-shaped, gold-covered electrodes connected at the base by a common electrode. Individual poles measure 15 μm in diameter and are 100 μm high. The microgrid is formed by pairs of grid elements facing each other. A voltage can be applied between opposing electrodes of the grid-element pairs. A microgrid like this, the authors suggest, can be used in an electrostatic ion drag micropump and in microelectrophoresis devices. The fluorinated polyimide used in this study etches rapidly (3–5 μm/min) and with high selectivity (2600 over a Ti mask) because MERIE produces a high-density, low-energy plasma and because the fluorine in the polyimide produces a high concentration of oxygen radicals in the plasma. From the F/C rule presented above, we predict that a fluorocarbon/oxygen atmosphere leads to a more aggressive and less selective etch. In the current case, by adding the fluorine to the polyimide instead of to the etchant gas, a faster etch rate occurs without losing the high selectivity.

The morphology of the fluorinated polyimide surface, as revealed by atomic force microscopy

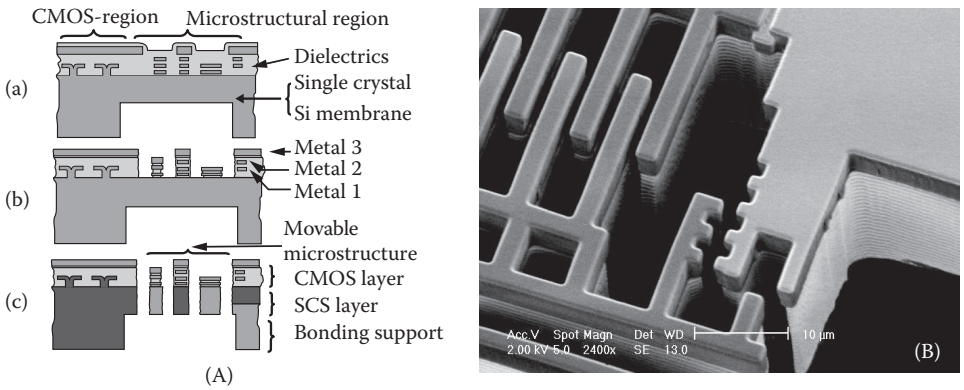

FIGURE 3.45 (A) The process flow for the modified CMOS-MEMS micromachining process; in step (a) the CMOS chip with back-side etch is shown; in step (b) the anisotropic dielectric etch is illustrated; and in step (c) the anisotropic silicon etch for the release is demonstrated. (B) SEM of a corner of a comb-drive actuator fabricated in Hewlett-Packard 0.5-μm CMOS followed by post-CMOS Si DRIE micromachining. The upper 5-μm-thick composite layer is the CMOS three-metal interconnect stack. The underlying Si is 25-μm thick and illustrates the sidewall scalloping caused by the Si DRIE. (Courtesy of Dr. G. Fedder, CMU.)

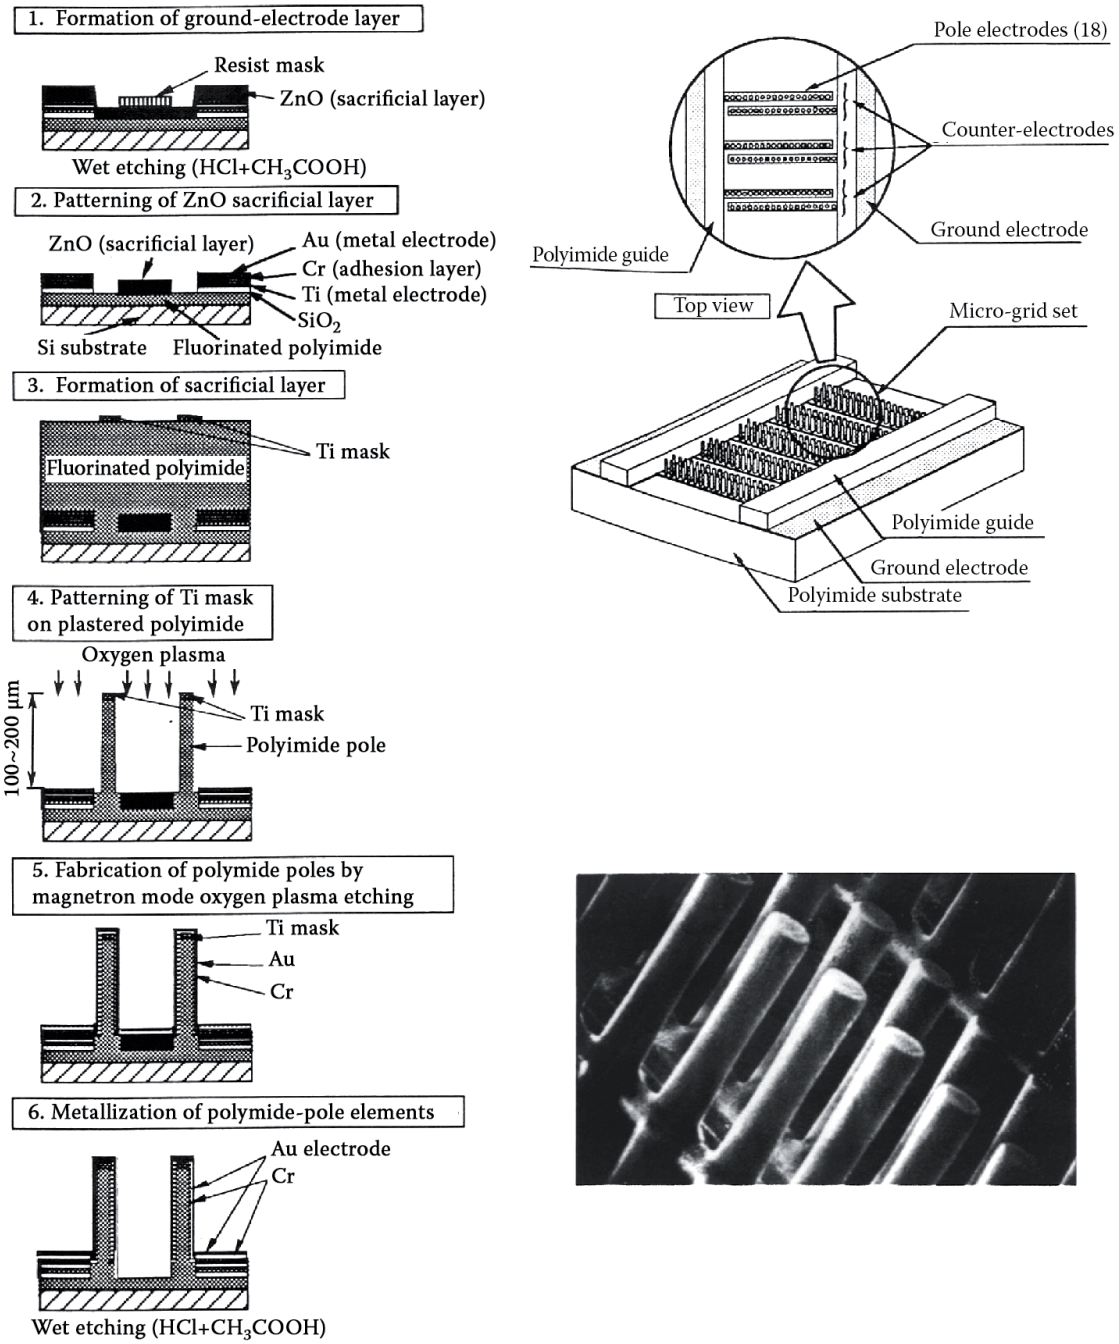

FIGURE 3.46 An array of polyimide posts made by cryogenic MERIE. (Furuya, A., F. Shimokawa, T. Matsuura, and R. Sawada. 1993. *Proceedings: IEEE micro electro mechanical systems (MEMS '93).* Fort Lauderdale, FL: IEEE. With permission.[70])

is smooth at a high etching rate, that is, at high magnetic fields. The NTT fluorinated polyimide is chemically stable, and the fluorine content makes the material extremely transparent, so it can be used to make optical components such as optical waveguides and lenses. The optical quality (and the high-aspect ratio of the produced polyimide structures) could make this fabrication technology competitive for many x-ray lithography-based LIGA structures (see Chapter 10).

Example 3.5: Combination Wet and Dry Etching

Brugger et al.[71] developed a micromachining process, combining wet and dry etching, to fabricate a meander-type cantilever with an

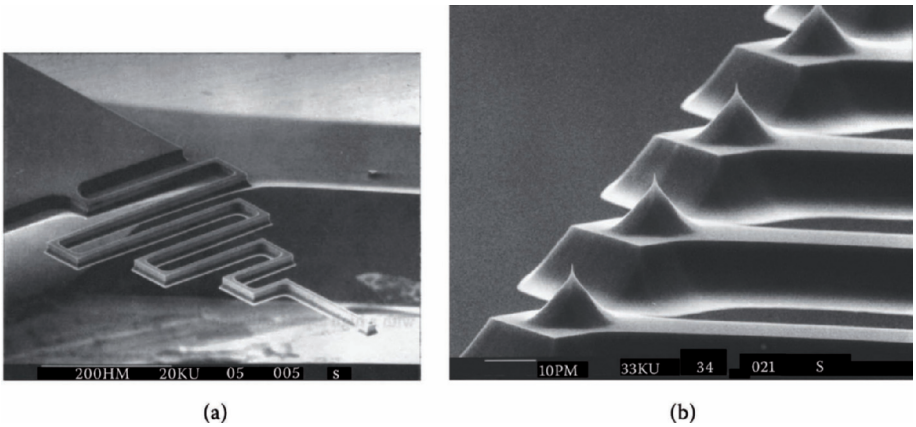

FIGURE 3.47 Si cantilever with square cross-section, designed as a meander shape. (a) Meander cantilever with tip. (b) Close-up view of tips. (From Brugger, J., R. A. Buser, and N. F. de Rooij. 1992. Silicon cantilevers and tips for scanning force microscopy. *Sensors Actuators A* A34:193–200. With permission.[71])

integrated high-aspect-ratio tip for microprobe applications. The crucial part of an atomic force microscope (AFM) or scanning tunneling microscope (STM) microprobe is the tip, which for some applications (e.g., IC trench probing) should have a curvature radius ideally in the range of 50 Å or less, an angle of aperture of about 5°, and a height of 10 µm. The meander structure and integrated tip are presented in Figure 3.47, and the process sequence is in Figure 3.48.

First, a 30-µm thin Si membrane is anisotropically etched in a double-sided polished 280-µm-thick Si wafer (Figure 3.48a). The etching occurs at the back with 40% KOH at 60°C through an opening etched with buffered HF in a 1.5-µm thermal oxide. During the KOH etch, the front side is protected by a mechanical chuck. The front-side oxide is patterned into a two-step profile using two lithographic and two buffered HF etching steps. The 0.75 µm-thick oxide in the two-step profile acts as the mask for the cantilever, and a 1.5-µm-thick oxide serves as the mask for the tip (Figure 3.48a). The topside is etched with 15-µm- deep RIE using chlorine/fluorine gas mixtures (C_2ClF_5/SF_6) to preshape the cantilevers (Figure 3.48b). By adjusting the RIE parameters, vertical sidewalls of the cantilever can be obtained. The 0.75-µm-thick oxide that covered the cantilever is completely removed afterward, and the remaining oxide cap, formerly 1.5 µm and now 0.75 µm thick, serves as a mask for the tip etching. Then a C_2ClF_5/SF_6 gas mixture is applied again to RIE the tip (Figure 3.48c). In the final step (Figure 3.48d), an isotropic

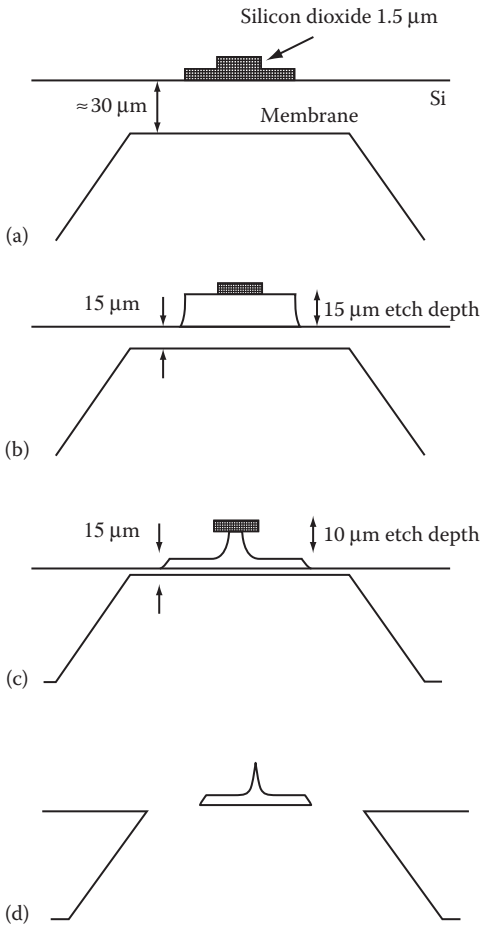

FIGURE 3.48 Fabrication process for a silicon meander beam with integrated tip. (a) Patterning of oxide mask onto preprocessed 30-µm thin membrane. (b) Dry etching of rough cantilever shape. (c) Dry etching of the tip. (d) Final wet etching step releasing the cantilever, forming the tip and smoothing the surface. (From Brugger, J., R. A. Buser, and N. F. de Rooij. 1992. Silicon cantilevers and tips for scanning force microscopy. *Sensors Actuators A* A34:193–200. With permission.[71])

HNO_3:HF:CH_3COOH etch lasting 2 minutes forms the tips (using the oxide cap as mask), releases the cantilever by etching through the remaining Si membrane, smoothes the dry-etched rough surface, and cleans the remaining organic photoresist. Mixtures of HNO_3, HF, with CH_3COOH and/or water etch the silicon isotropically and exhibit high etch rates (10–300 μm/min). The SiO_2 mask withstands the three successive etch steps: cantilever RIE etching, tip RIE etching, and 1–2-min wet etching with HF:HNO_3:CH_3COOH sharpening the tip. Tip heights up to 20 μm with opening angles of approximately 5–10° and tip radii estimated to be 40 nm can be obtained this way.

A postoxidation process yielding Si tips with curvature radii of less than 10 nm by several consecutive oxidation and HF etching steps, exploiting an anomaly of the oxidation behavior at regions with high geometric curvature, has been demonstrated by Marcus et al.[72,73] and by our own group[74] (see also Volume I, Chapter 4, on the dependence of oxidation rate of Si on geometry). By applying this oxidation-sharpening technique to the tips produced in the current example, further sharpening would result. A rigid cantilever structure rather than a meander structure as shown in Figure 3.48a would also be of more use in a practical STM.[74]

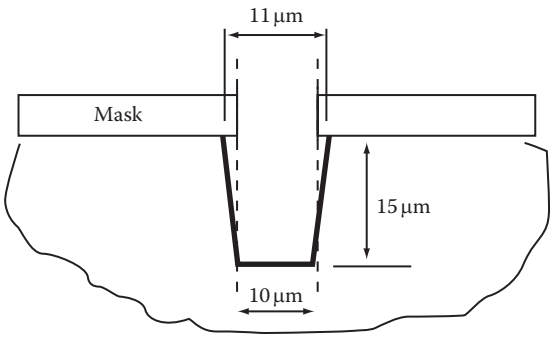
Questions

3.1: How is a DC plasma created, and how does an RF plasma differ? Why is a plasma always positive with respect to the reactor vessel walls? In which etching setup would you prefer to etch an insulator?

3.2: Detail the different dry etching profiles available and explain how they are obtained.

3.3: Consider a single electron in an electric field between two parallel plates located 10 centimeters apart (d = 10 cm). Assume the potential varies sinusoidally between 1000 V and –1000 V at a frequency of 13.5 MHz. Calculate the maximum kinetic energy of the electrons.

3.4: Using the figure below as a model, assume that the silicon wafer has a bias of –150 V. A reactive ion etch is used to etch 10 μm wide grooves.



After 1 hour, the shape of the grooves is measured and found to have the following topology:

(a) If the bias were increased to –200 V and the depth of the groove was maintained at 15 μm, would the width at the top of the groove be less than or greater than 11 μm?
Explain.

(b) If the same etch procedure was used to etch SiO_2, qualitatively describe the shape of the grooves in the SiO_2 if a –150 V bias is applied.

3.5: Explain the DC breakdown voltage vs. electrode distance curve (Paschen's law) and how it is relevant to dry etching. How is miniaturization of an electrode set equivalent to creating a local vacuum?

3.6: Use SCREAM to fabricate a capacitive accelerometer. You may rely on the newest deep dry etching technology.

3.7: Why is reactive ion etching (RIE) somewhat of a misleading name? In physical-chemical etching, there are at least three types of ion-surface interactions which may promote dry etching. Detail each of them.

3.8: Develop a process sequence to fabricate a capacitive pressure sensor using both wet and dry etching techniques.

3.9: Explain loading effects in wet and dry etching. How do you avoid the loading effect? What is the bull's-eye effect? What is the difference between loading and micro-loading?

3.10: Discuss the etch profiles in physical etching (ion sputtering). Also draw profiles exhibiting faceting, ditching, and redepositioning.

3.11: Explain the F/C ratio effect in dry etching and present a couple of means to influence it. How can cryogenic cooling lead to similar etching behavior as inhibitor-driven chemistry?

3.12: Explain the ion energy versus pressure curve for a plasma and how different etching mechanisms are enabled by it. Describe the differences between high-pressure plasmas and reactive ion etching systems. Explain for what applications each is the preferred process.

3.13: You have only a high-pressure plasma etch and an ion mill at your disposal. Select which one to use in the following applications. Justify your answer.

(a) Etching a 5000 Å polysilicon layer that serves as the upper electrode of a large square capacitor. The capacitor dielectric is 50 Å of SiO_2.

(b) Anisotropic patterning of a thin layer of $YBa_2Cu_3O_7$ on a thick insulating film.

(c) Recessing the channel of a GaAs FET. For this application the residual etch damage must be minimized.

3.15: Sketch the voltage distribution for an RF plasma discharge in equilibrium and contrast it with the voltage distribution in a DC plasma.

3.16: How would you monitor a dry etching process? Why does endpoint detection of a reactant species require a loading effect?

3.17: Why is the grounded electrode (anode) in an AC sputtering station made as large as possible? Use equations to illustrate your answer.

3.18: Explain how magnetic coils enable higher ion density plasmas. Use equations to explain.

3.19: Compare dry versus wet etching techniques.

3.20: How would you make the structure below with the least expensive equipment, the highest selectivity, and the fastest process?

Ignorance more frequently begets confidence than does knowledge: it is those who know little, and not those who know much, who so positively assert that this or that problem will never be solved by science.

Charles Darwin
The Descent of Man (1871)

The human mind treats a new idea the way the body treats a strange protein; it rejects it.

P.B. Medawar

Introduction

Chapter 4 is split in two parts: one part deals with *wet chemical etching* and the other with *wet bulk micromachining*. Both these subtractive manufacturing techniques cover purely chemical etching, photochemical etching, electrochemical etching, and combinations thereof. Wet bulk micromachining is derived from chemical etching, but wet etching and bulk micromachining are typically used in very different industrial settings. In chemical etching, one carves isotropic features, large (milling) and small (blanking), out of metals, glasses, polymers, and ceramics. The technique is mostly used in more traditional industrial manufacturing settings such as aerospace, electronics, automotive, medical, computer, instrument manufacturing, and decorating. Wet bulk micromachining, on the other hand, is used to sculpt isotropic and anisotropic microstructures principally in semiconductors substrates. It is a technique championed in the integrated circuit (IC) industry and in micro- and nanomachining.

We start with a historical note covering both chemical etching and wet bulk micromachining.

Historical Note

The ancient Egyptians etched copper jewelry with citric acid as long ago as 2500 BC. The Hohokam people, of what is now Arizona, etched snail-shell jewelry with fermented cactus juice around 1000 BC. The earliest use of wet etching of a substrate, using a mask (wax) and etchants (acid-base), appears in the late fifteenth or early sixteenth century for decorating armor (Figure 4.1).[1,2] Engraving hand tools were not hard enough to work the armor, and more powerful acid-based processes took over. By the early seventeenth century, chemical etching to decorate arms and armor was a well-established process. Some pieces stemming from that period have been found with designs as small as 0.5 mm. This is remarkable as masking involved cutting the maskant (linseed oil paint) with a scribing tool and peeling the maskant off where etching (with vinegar) was desired. This purely chemical-driven etching process is today also called chemical milling (larger pieces) or chemical blanking (smaller pieces).

FIGURE 4.1 Armor pieces have been found where the chemical milling led to designs as small as 0.5 mm. A maskant (wax) is cut with a scribing tool and peeled off where etching is desired. Elements of a Light-Cavalry Armor, ca. 1510 Italian (Milan). Steel, etched, and gilded; weight 19 lb., 13 oz. (9 kg). Gift of William H. Riggs, 1913. The Metropolitan Museum of Art. http://www.metmuseum.org/TOAH/hd/rarm/ho_14.25.716.htm.

Harris[1] describes in detail the improvements that, by the mid-1960s, made chemical milling a valuable and reliable method of manufacturing, especially popular in the aerospace industry (M. Sanz of North American Aviation patented chemical milling in 1953 for use on aerospace parts, and in 1956, Turco Inc. purchased the patent rights). The method enabled many parts to be produced more easily and cheaply than by other means and, in many cases, provided design and production configurations not previously possible.

Through the introduction of photosensitive masks by Niépce in 1822 (see Chapter 1), chemical milling in combination with lithography became a reality, and yet smaller feature sizes were within reach. This type of chemical etching is called photochemical milling (PCM). In PCM, photomasks are used to mask parts typically smaller and thinner than those used in chemical milling. The inventor of the printed circuit board (PCB) is generally assumed to be the Austrian engineer Paul Eisler (1907–1995), who, working in England, made a printed circuit board in 1936 as part of a radio set (Eisler is sometimes referred to as the "father of the PCB"). In about 1943 the United States began to use the

technology on a large scale to make rugged radios for use in World War II. After the war, in 1948, the United States released the invention for commercial use. Printed circuits did not become commonplace in consumer electronics until the mid-1950s. A PCB basically consists of a planar (flat) substrate that has electronic components mounted on it that are interconnected by conductive tracks. The high volumes required for this product provided strong impetus for the development of more sophisticated PCM methods, particularly in the design of better etching equipment. Today the two most important applications of lithography-based chemical milling remain the manufacture of PCBs and, by 1961, the fabrication of Si-integrated circuitry. The latter application of chemical milling became better known as *wet bulk micromachining*. In this case, the substrates are typically smaller yet (Si wafer size) than in PCM, and the etch profile can be isotropic or anisotropic. The method used to produce a "cut" when etching silicon integrated circuits (ICs) is the same as that used for photochemical milling of metals in the aerospace industry, but the IC and microelectromechanical system (MEMS)/nanoelectromechanical system (NEMS) industries have refined the technique to reach minimum feature sizes orders of magnitudes smaller and to obtain much higher aspect ratios (height-to-width ratio of the features as high as 400 in anisotropic etching of Si). Whereas the device sizes in microfabrication are often much larger than in IC processing, the aspect ratios in MEMS/NEMS are generally much greater than in IC fabrication (see Figure 4.2).

Isotropic etching in silicon semiconductor processing has been used since its introduction in the early 1950s. One finds representative work from that period in an impressive series of papers by Robbins and Schwartz[3–6] on chemical isotropic etching and in Uhlir's early work on electrochemical isotropic etching.[7] The usual chemical isotropic etchant used for silicon was HF in combination with HNO_3, with or without acetic acid or water as diluent. The early work on isotropic etching in an electrochemical cell (i.e., *electropolishing*) was carried out mostly in nonaqueous solutions to avoid black or red deposits that formed on the silicon surface in aqueous solutions.[8] Turner[9] showed that, if a critical current density is exceeded, silicon can be electropolished in aqueous HF solutions without the formation of those deposits.

In the mid-1960s, Bell Telephone Laboratories started work on anisotropic Si etching in mixtures of, at first, KOH, water, and alcohol and later in KOH and water. The need for high-aspect-ratio cuts in silicon arose in the fabrication of dielectrically isolated structures in integrated circuits, such as those for beam leads. Both chemical and electrochemical anisotropic etching methods were pursued.[10–20] In the mid-1970s, a new surge of activity in anisotropic etching was associated with the work on V-groove and U-groove transistors.[21–23]

In Volume I, Chapter 1, we mentioned that the first use of Si as a micromechanical element can be traced back to a discovery and an idea from the mid-1950s and early 1960s, respectively. The discovery was the large piezoresistance in Si and Ge by Smith in 1954.[24] The idea stemmed from Pfann et al.,[25] who in 1961 proposed a diffusion technique for the fabrication of Si piezoresistive sensors for stress, strain, and pressure. This led eventually to

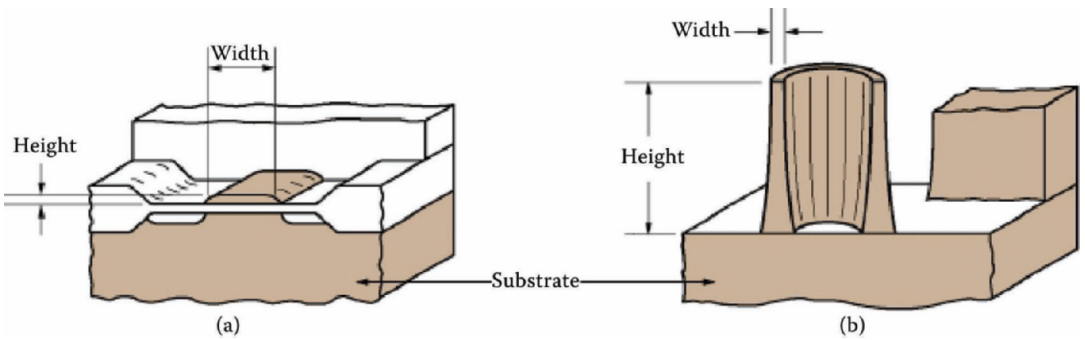

FIGURE 4.2 Aspect ratio (height-to-width ratio) typical in fabrication of integrated circuits (a) and microfabricated components (b).

the development of commercial Si micromechanical pressure sensors, accelerometers, and gyros made by wet bulk micromachining.

Chemical Etching

Introduction

Under chemical etching we review a number of different processes where material removal through etching of preferentially exposed (masked) surfaces produces stress-free parts in many types of substrates. The energy source at the work piece in this subtractive process is purely chemical (chemical milling or CM), photochemical (photochemical milling or PCM and photofabrication), or electrochemical (all types of electrochemical removal processes).

In the simplest embodiment of chemical etching, i.e., chemical milling or chemical machining, the method relies on nonlithographic masking, in which a masking layer is physically carved out to open up a pattern. A scribing tool, of the surgical knife type, is used to cut through the maskant along the line defined by the edge of a template.

In PCM, photomasks are used to mask parts typically much smaller and thinner than those used in chemical milling. The process uses photolithography just as in the etching of Si and other semiconductors, in which case one refers to wet bulk micromachining (see below). Photofabrication is a type of photochemical milling where ultraviolet exposure through a mask results in a strong modification of the solubility in an optically clear solid layer. This permits the direct photochemical production of thick three-dimensional (3D) glass, plastic, or ceramic structures without the need for a separate pattern transfer to an underlying substrate.

Electrochemical removal techniques use an electrical field in an electrolyte that destroys the atomic bonds of the material.[26] Under electrochemical removal techniques, we will review electrochemical machining (ECM), including microelectrochemical machining (μ-ECM), electrochemical jet etching, laser-assisted electrochemical jet micromachining, scanning electrochemical microscope (SECM), and through-mask electrochemical micromachining and electrochemical grinding (ECG).

Chemical Milling

Chemical milling or chemical machining involves material removal through chemical etching of preferentially exposed (masked) surfaces, producing stress-free parts in many metals. It is the oldest among nontraditional machining processes and has been used to engrave metals and hard stones. The method is also referred to as immersion chemical blanking/milling, and it is a purely chemical process that dissolves material from the unmasked (unprotected) areas of metallic parts immersed in a tank filled with heated and agitated chemical reagents. The term "blanking" denotes small, thin work pieces, and "milling" indicates relatively large work pieces. The method produces clean, sharp, well-defined edges with no burrs (often a source of fatigue failure in highly stressed parts). The work piece does not require finishing of the surface, and no electric current to remove material is involved. Although most common with aluminum and titanium, several other metals have been successfully chemically milled, with different metals etched in different etch solutions. The method relies on nonlithographic masking, in which a masking layer is physically carved out to open up a pattern as illustrated in Figure 4.3.[1] The mask, an organic layer—usually a tape or chemically resistant paint—covers a large area substrate that may be up to 2 cm thick. The etch factor, A/R, or eat-back ratio, is identified in Figure 4.3a, with R the etch depth and A the overhang of the maskant. A scribing tool, of the surgical knife type, is used to cut through the maskant along the line defined by the edge of a template (Figure 4.3b). Lateral tolerances of ±0.25–0.5 mm are typical for chemical milling, an accuracy mainly determined by the manual scribing process. For the IC industry and micromachining, this lateral tolerance would be very poor performance, but for many industrial applications, this tolerance is adequate. Chemical machining of metals is isotropic in nature, and aspect ratios are low. Creating high-aspect-ratio structures (>1), e.g., to make deep channels in stainless steel sheets, would necessitate laminating several of these sheets. Obviously, this type of technology is better suited for etching shallow features in large, single-substrate devices. Chemical milling has at least two key

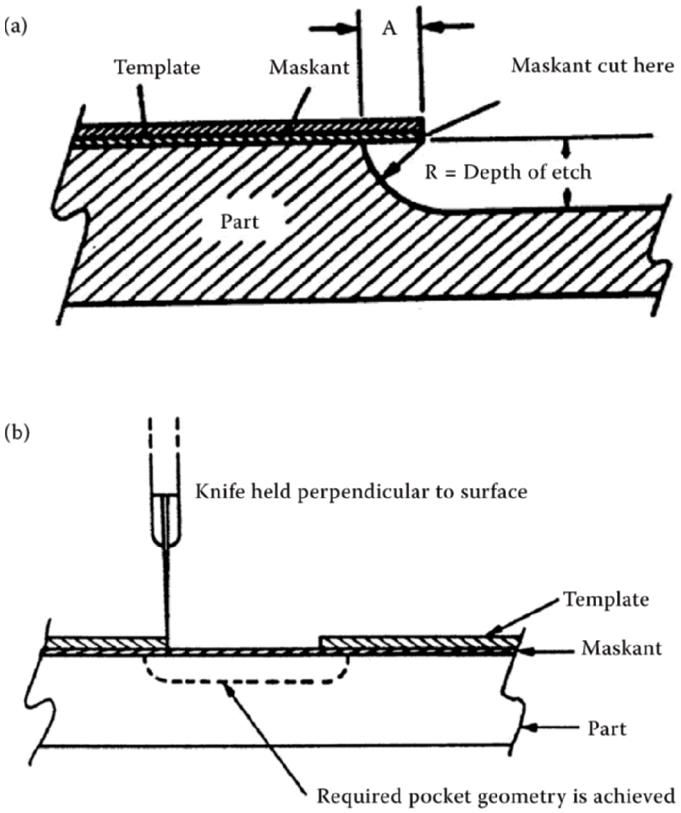

FIGURE 4.3 Chemical milling showing the effect on the work piece. (a) Undercut caused by chemical milling. (b) Scribing of the maskant. (From Harris, T. W. 1976. *Chemical milling.* Oxford: Clarendon Press. With permission.[1])

advantages over traditional mechanical milling. First, mechanical milling is difficult on thin metal sheets because the tool tends to pull the thin metal foil, severely damaging the work piece. Second, chemical milling can produce complexly shaped parts, such as the inside leading edge of an airplane wing, which a milling machine could not reach.

Chemical milling of metals is widely applicable, simple, and requires little operator skill. Practical cutting (etching) depths are generally limited to less than 2 cm because the etchant process is relatively

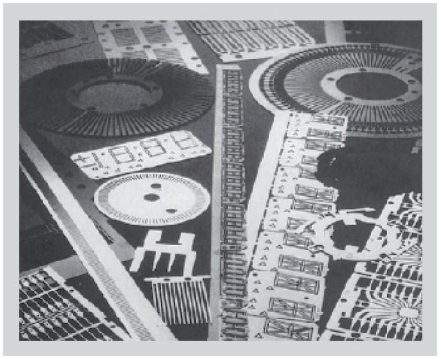

FIGURE 4.5 Various parts made by chemical blanking. Note the fine detail. (Courtesy of Buckabee-Mears St. Paul.)

slow, and undercutting occurs behind the edges of the protective mask. Industrial applications are mainly in the shaping of thin metal foils and large shallow areas. Most modern aerospace designs use chemical milling to remove about half the weight of their products. It is used extensively on commercial and military airplanes, satellites, and the space shuttle. Large parts can be accommodated; aluminum airplane wing parts, for example, are chemically machined in 50-ft.-long tanks. In Figure 4.4 we show a chemical milling tank and a piece that has been thinned using three consecutive masking steps. Example products made by chemical blanking are shown in Figure 4.5.

A good further review with many relevant details on wet etching as it relates to the IC and electronics industry is presented by Romankiw.[27]

Photochemical Milling

Photochemical milling (PCM) is an engineering production technique for the manufacture of burr-free and stress-free flat metal components by selective chemical etching through a photographically

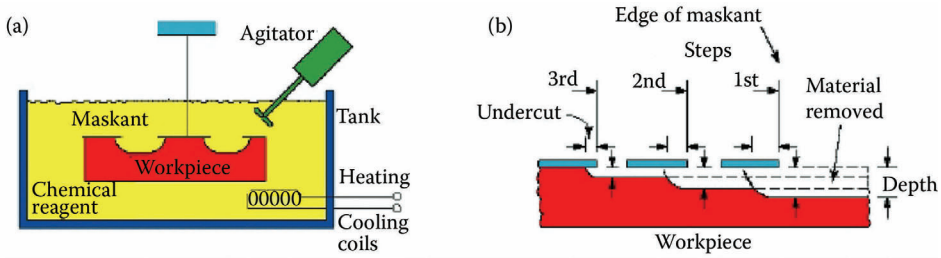

FIGURE 4.4 (a) Schematic illustration of the chemical machining process. Note that no forces or machine tools are involved in this process. (b) Stages in producing a profiled cavity by machining; note the undercut.

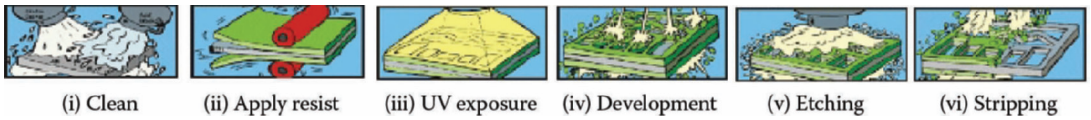

FIGURE 4.6 Photochemical milling (PCM) of metal parts.

produced mask. In PCM of metals, illustrated in Figure 4.6, photomasks are used to mask parts typically much smaller (a maximum of about 60 × 60 cm) and thinner (<0.5 mm) than those used in chemical etching (see above). The process uses photolithography just as in the etching of Si and other semiconductors as discussed in the section below on wet bulk micromachining. To ensure high accuracy, oversized drawings (100×) of a design are reduced photographically to actual size. The photomask is then used to contact print the component image onto a metal sheet covered with a photosensitive coating. The photosensitive layer may be a dry resist layer such as Etertec® 5600 from Eternal (http://www.eternal-group.com) or Riston CM206 from DuPont (http://www2.dupont.com/Imaging_Materials/en_US/tech_info/product_selector.html) (see also Chapter 1). Careful masking is crucial to achieve precise parts in both chemical and photochemical cutting. However, because of the absence of scribing errors in photochemical milling, the photosensitive maskant is extremely accurate and leads to far superior tolerances for small intricate parts. Photochemical milling was designed specifically to alleviate the lateral-accuracy problem of chemical milling, achieving it extraordinarily well; lateral accuracies (e.g., for printed circuit board production) are ±0.013 mm. Another reason why the tolerances in PCM are so much better than in chemical milling is related to the attempted etch depths. For example, the geometry of the cut produced with photoetching printed circuit boards or integrated circuits might be similar to the chemical-milling cut of the aerospace industry, but one must remember the many orders in magnitude difference in the depth of the cut.[1] As the dimensions of the components decrease (i.e., from precision products to printed circuit boards and to integrated circuits), the necessity for chemical cleanliness of the material surfaces increases and requires clean-room manufacture in the case of IC fabrication.

Photoetching of metals is less generic than chemical milling but can be used, for example, with the following metals (in order of increasing difficulty): copper, nickel, carbon steel, stainless steel, aluminum, titanium, and molybdenum.[28,29] Etching rates—with sodium hydroxide for aluminum, hydrochloric and nitric acids for steel, and iron chloride with nitric acid for copper—vary from $1.3–7.6 \times 10^{-3}$ cm/min. Some PCM etchants are listed in Table 4.1.

Photochemical etching of metals, like chemical etching, is isotropic, and aspect ratios are consequently low. Normally, the diameter of a hole or width of a slot needs to be equal to or exceed the metal thickness. A rule of thumb for PCM tolerance is ±10% of the metal substrate thickness. This guideline, however, does not express the ultimate capabilities of the PCM process because variable etch factors and reduced sheet size can enhance dimensional control.

Photoetching of metals requires moderate investments and competence in two fields: metal

TABLE 4.1 Example PCM Etchants and Materials That Are Etched by Them

Aqueous Etchants	Material Etched in the PCM Process
Acidified ferric chloride	Aluminum, Alloy 42, copper and copper alloys, HyMu, Inconels, Invar, Kovar, Permalloy, Monel, Mumetal, nickel, Nimonics, phosphor bronze, stainless steels and other steels, tin
Acidified cupric chloride	Beryllium copper, copper and copper alloys including brass and bronze, lead
Alkaline potassium ferricyanide	Aluminium, molybdenum, and tungsten
Sodium hydroxide	Aluminium, anodized aluminium
Hydrofluoric acid	Beryllium, columbium (niobium), titanium, zirconium, glasses, and ceramics

Source: Allen, D. M. 2004. Photochemical machining: from 'manufacturing's best kept secret' to a $6 billion per annum, rapid manufacturing process. *Annals of the CIRP*, 53: 559–572.

Table 4.2 PCM and Chemical Milling Compared

Fabrication Method or End Product	Typical Material Etched	Thickness of Material Etched	Underlying Material or Support
Photochemical machining (PCM)	Metals, glasses, or ceramics	2 mm (typical maximum)	Not applicable
Printed circuit boards (PCBs)	Electroformed foil (a conductor)	17.5 μm (typical)	Rigid epoxy fiber glass or other insulator such as flexible polyimide
Integrated circuits (ICs)	Silicon dioxide or silicon nitride	0.01–0.1 μm (typical)	Silicon
Chemical milling	Aluminum, titanium, and aerospace alloys	0.1–10 mm (typical)	Not applicable

etching and lithography. PCM is a fast, efficient, cost-competitive, burr- and stress-free method of producing metal components. Applying photochemical etching to large surface areas is a very expensive proposition,[30] and, in that case, chemical milling may be a better approach. Common industries served include aerospace, electronics, automotive, computer, and instrument manufacturing. Major applications are lead frames, PCBs, shadow masks for color televisions, heat sinks, shields, covers, lids, gaskets, springs, encoders, disks, grids, screens connectors, panels, shims, bus bars, and combs.

In Table 4.2 we compare PCM on metals, glasses, and ceramics with PCM on printed circuit boards and ICs and chemical milling in Al, Ti, and aerospace alloys.

A typical foundry for PCM in the United States is PhotoMachining, Inc. (http://www.photomachining.com/apps.html). Good information on Photochemical Milling is available at http://www.pcmi.org. Standard tool production time in these foundries is 2–3 days but can be several hours if necessary. Tooling is produced and stored in an environmentally controlled facility to ensure accuracy and quality. Modern digital photography uses customer-supplied IBM/Mac-based programs, as well as all AutoCAD versions and DXF and GbR files. In Figure 4.7 some typical PCM products are shown.

Photofabrication

Introduction

Photofabrication is a subtractive process in which ultraviolet exposure through a mask results in a strong modification of the solubility in an optically clear solid layer. This permits the direct photochemical production of thick 3D structures without the need for a separate pattern transfer to an underlying substrate. In photofabrication, photosensitive glasses, plastics, and ceramics are patterned into intricate 3D shapes. As opposed to most photolithography processes, where photoresist is a sacrificial layer only, in photofabrication the photosensitive material itself becomes a permanent part of the microdevice under construction. The photosensitive materials in photofabrication are permanent, and in the case of polymers this typically involves negative photoresists (see also Chapter 1). The method offers simple, inexpensive, high-aspect-ratio 3D microstructures for small to medium batch sizes without the need to resort to more expensive methods such as Si wet bulk micromachining or LIGA (see Chapter 10). The industrial application of photofabrication, creating sharp images in ceramics, plastics, and glasses, preceded the Si microfabrication era. Given the current interest in high-aspect-ratio 3D structures, this technique is worth revisiting.

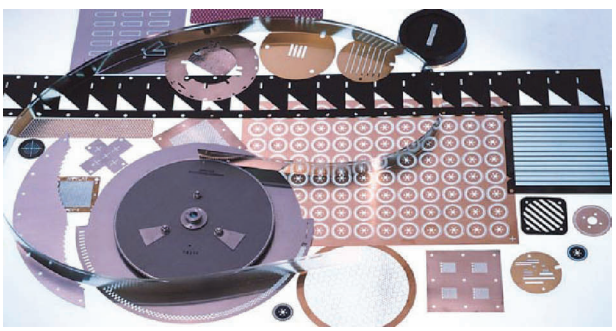

FIGURE 4.7 Mechanical metal parts produced by photochemical milling: leaf springs, connector arrays, masks, free standing grids, laser and IR target apertures, precision pin holes, and encoders.

For most photoplastics, aspect ratios do not exceed 3:1, but, with photosensitive glasses and ceramics, it is possible to make a 0.13-mm-diameter hole through a 2.7-mm-thick plate, with an aspect ratio of ~21:1; this is no small achievement. We will mostly detail photosensitive glasses here. A few words on photosensitive plastic sheets suffice because the topic of dry permanent resists was covered already in Chapter 1.

Note stereolithography, as discussed in Chapter 8, is an additive technique in which plastic shapes are generated by laser writing in a molten plastic mass; the technology is sometimes referred to as *microphotoforming* and should not be confused with the subtractive photofabrication discussed here.

Photosensitive Glasses/Ceramics—Photography in Glass

Electrochromic glasses temporarily change color when exposed to strong light. Photosensitive glasses, on the other hand, develop an invisible, permanent "latent image" after UV illumination through a mask. Subsequent heat treatment can develop the latent image into a permanent structural and/or color change with accompanying differences in solubility. In the mid-1940s, Donald Stookey invented both photosensitive and electrochromic glasses at Corning Glass Works (now Corning, Inc.) To read up on Stookey's career, consult *Profiles in Ceramics* (http://www.ceramicbulletin.org/months/Mar00/StookeyProfile.pdf)[31] and *Explorations in Glass: An Autobiography S. Donald Stookey.*[32] A typical photosensitive glass composition, FotoForm® glass, developed by Corning Glass Works, was SiO_2, 81.5; Li_2O, 12.0; K_2O, 3.5; Al_2O_3, 3.0; CeO_2, 0.03; and Ag, 0.02 (all in weight percent). On exposure to UV light, photoelectrons released by cerium, the photosensitizing ingredient, are trapped at specific sites in the silicate-glass network to form a latent image. By heating the exposed glass to around 500°C, the electrons are released from the traps, and silver ions are reduced to silver atoms, which aggregate into minute colloidal islands. The minute silver clumps serve as nuclei on which crystals, such as lithium metasilicate, sodium bromide, or sodium fluoride, precipitate. If sufficient numbers of fairly large crystals form (~4 μm), an opalescent image results, whereas the masked regions remain glassy and transparent. In HF, opal regions etch 15–30 times faster than the unexposed glass. No masking is required during the etching process. In this way, by exposing a photosensitive glass plate to UV and etching in HF after heat treatment, a wide variety of microstructures can be made. Through-holes in photosensitive glass were experimentally found to have a sidewall taper of only 2–3°; this means that substantially parallel holes may be cut, having a very high depth-to-diameter ratio. The sloping effect can be reduced even further if the HF etching occurs from both sides of the glass simultaneously. Etching from both sides produces a profile with two truncated cones and gives a minimum overall increase of hole diameter. Although etching of holes with diameters appreciably less than one-tenth of the thickness of the glass is not recommended, aspect ratios of 20 are possible. In contrast, in photoetching of metal, as we have seen above, holes cannot be made with a diameter less than the thickness of the sheet. If sidewall taper in photosensitive glass is desired, it can be increased to 20–30°.

Further heat treatment of the finished photosensitive glass pieces, Stookey discovered by accident in 1957, converts the glass to a stronger, partially crystalline material, e.g., Fotoceram®. Stookey left a sample of lithium silicate glass containing silver in an oven at too high a temperature. He expected to find a puddle of glass once he realized his mistake, but instead found a piece of white ceramic because the glass had crystallized with a fine grain size.

The maximum sheet thickness of FotoForm glass available was 0.6 cm, but several pieces can be thermally bonded, forming excellent seals and converting the glass to Fotoceram glass. One disadvantage of the bonding process is that it causes the photoglasses to become dark, which makes the approach less attractive for optical applications.

Corning's photosensitive FotoForm glass found an important application in fluidic logic in the mid-1960s (see for example Figure 4.8), but as that application started fading the production of FotoForm glass and Fotoceram unfortunately was discontinued.[31]

Fluidic components, providing functions such as flip-flops, logic elements such as OR-NOR and AND

gates, proportional amplifiers, and fluid resistors, exemplified the capabilities of photofabrication with FotoForm glass in the mid-1960s. The fluidic-control device in Figure 4.8 shows the individual layers of an AND device after through-etching.[1]

Fusion of stacks of photosensitive glass plates provided a permanently sealed and rugged unit, complete with the necessary input and output vents. Through-etching provides the connection between the different planes. The geometrical accuracy of these fluidic devices was maintained within ±0.025 mm, and the tolerance that may generally be expected on this type of etched glass product was ±0.05 mm on etched edges up to 12.7 mm in length. With hole spacings up to 25 mm apart, accuracy to within 0.025 mm center to center was possible.

Few of the Si and plastic microfluidic structures produced today have reached the degree of complexity achieved with photofabrication methods of almost four decades ago when they were applied to fluidic logic (see Figure 4.8). "Fluidic" elements made in the 1960s could achieve many of the functions of an electronic circuit, and they were robust, simple to fabricate, and suited to operating in a hostile environment. Of course, they were much slower (milliseconds instead of nanoseconds) and much larger than their electronic counterparts. The latter spelled the eventual demise of microfluidic "computing" in the late 1960s. In the 1990s, several micromachined fluidic devices were developed for analytical/biomedical applications, without reference to this earlier sophisticated work in photosensitive glasses. Early in the development of these analytical/biomedical applications, many fluidic devices were attempted in Si. However, the relatively large size of fluidic elements, the need for a robust environment, the relatively low numbers of required devices, and the fact that electronics usually do not need to be integrated render the use of silicon for this application hardly justifiable. The photofabrication machining approach, which is inexpensive and simple, coupled with the chemical inertness of glass, represents a more attractive approach. Fluidic oscillators, fabricated using the more expensive and hardly accessible LIGA technique, are even more difficult to justify when compared with photoformed devices.[33,34] The latter misapplication of miniaturization tools was eventually recognized, and photoformed glass was reintroduced as the best solution for this application by one of the inventors of LIGA technology[35] (see Volume III, Figure 1.2). In July 1996 the commercial entity "Mikroglas" was founded out of the Institute of Microtechnology in Mainz, Germany. Mikroglas obtained the exclusive rights for the use of Foturan™ glass from Glaswerk-Schott (http://www.us.schott.com/english). In 1999, Mikroglas started with the development of microfluidic components for chemical and biotechnological applications. Products include chemical microreactors and whole equipment to use these microreactors (http://www.mikroglas.com/index_e.html).

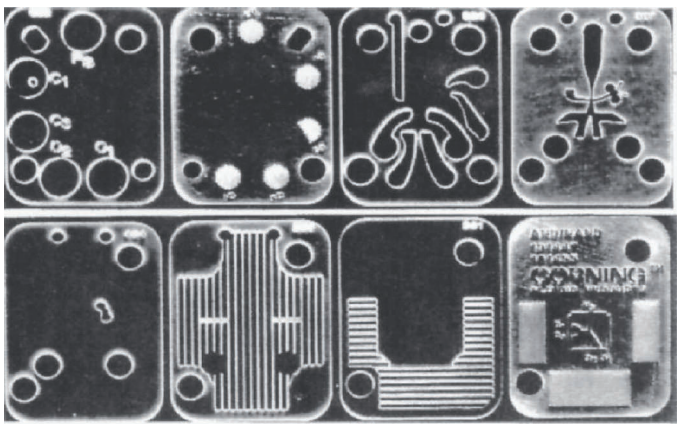

FIGURE 4.8 Fluidic-control device using chemically milled photosensitive glass. The individual layers of an AND device after through-etching with HF. (From Harris, T. W. 1976. *Chemical milling.* Oxford: Clarendon Press. With permission.[1]) See also Volume III, Figure 1.2.

Unlike ceramics, Foturan is pore-free, has higher temperature stability and chemical resistance than plastics, and has a higher breaking strength than silicon. Processing of Foturan consists of exposure to ultraviolet light, crystallization through heat treatment, and etching as illustrated in Figure 4.9a. In Figure 4.9b we show example hole plates made this way. The thermal expansion coefficient of the processed Foturan can be precisely varied between 8 and 16 ppm/°C. Variously shaped recesses can readily be formed on both sides of the "wafer," as well as 40:1 aspect ratio through holes. In addition, the surfaces can be metallized and patterned by conventional techniques. The material can be processed in sheets of up to 250 mm × 200 mm. Besides for making photosensitive glass ornaments,

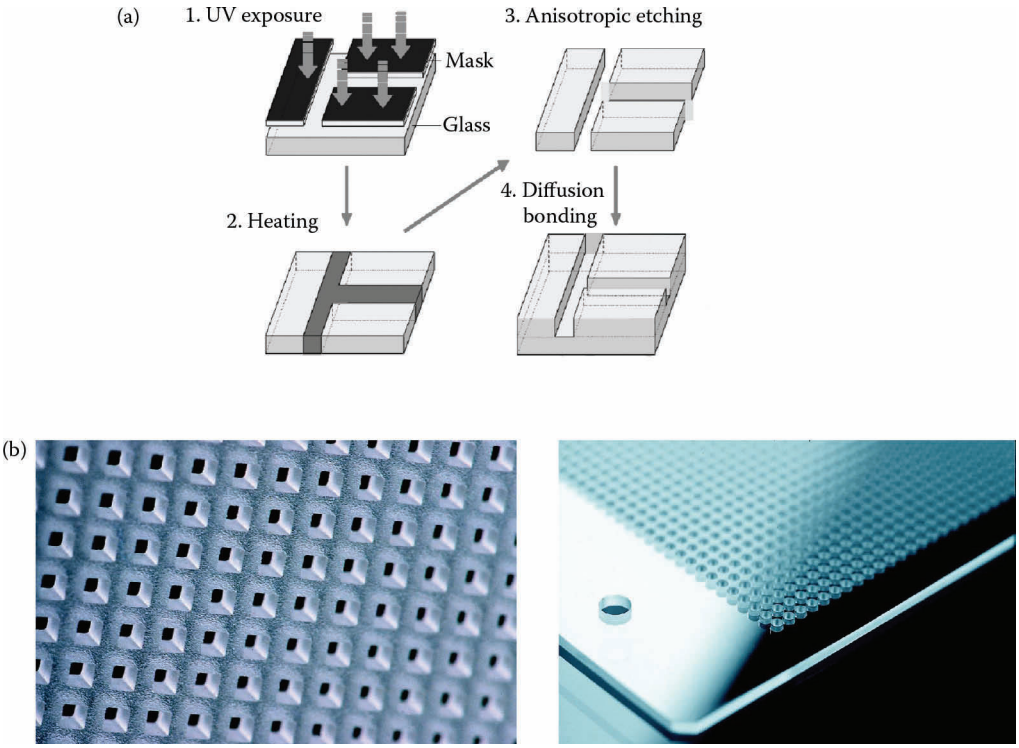

FIGURE 4.9 (a) The photofabrication process in Foturan. (b) Hole plates shapes, round or rectangular; diameter of holes, down to 50 μm; thickness of plates, 0.1 up to 2.5 mm and up to 100 holes/mm^2 (http://www.mikroglas.com).

photosensitive glass has been used to make microlenses (±100 μm in diameter), fluidic elements (see Figure 4.8), spacers in photomultiplier tubes, color filters, integrated optics cell sheets in gas-discharge displays, and charge plates and nozzles in ink-jet printers.

In a very intriguing further development of photosensitive glasses, it was found that the different properties of opal and glass areas on photosensitive glass enable the direct formation of electrical circuitry on glass. Immersing a sample with an opal pattern in a molten salt bath and heating it in a hydrogen atmosphere forms a conducting silver film on the opal regions. The film that forms on the glassy regions remains nonconducting.[31] This discovery could be used in the construction of DC and AC electrokinetic devices with complex patterns of metal electrodes on a glass substrate (see Volume I, Chapter 7).

Suggestion: A most useful new MEMS material would be a Foturan-type photosensitive glass with a thermal expansion coefficient matching that of Si (like Corning 7740 glass used in anodic bonding). Such a product would enable the packaging of all types of Si sensors (see Volume III, Figure 4.9) combining a Si micromachined sensing element with a photofabricated glass package.

Photosensitive Plastics

Although dry photoresists and photosensitive plastics are covered in Chapter 1 and Volume III, Chapter 4, some additional photosensitive plastics are briefly covered here. In the early 1960s, DuPont started developing a photosensitive nylon sold in sheet form, either bonded to a substrate such as carbon steel, aluminum, or a polyester Cronar film, or freestanding. The alcohol-soluble nylon is made photosensitive by adding a cross-linking agent such as methylene bis-acrylamide and an activator such as benzophenone. On exposure to UV, the benzophenone forms free radicals, which react with both of the other compounds, hence insolubilizing the nylon; in other words, the material acts as a negative tone resist. The unexposed areas are then washed away with a dilute aqueous sodium hydroxide spray, forming channels and cavities. By using the benzophenone in a low concentration, about 5% by weight, a layer with a relatively low absorption coefficient results, and thick layers can be insolubilized.

Stencils with 1-mm-high vertical sidewalls with a taper of 2° can be produced this way, and 25-µm-deep, 25-µm-wide channels do not show any undercutting. The aspect ratio did not exceed 3:1, and the operating temperature range is limited to –100 and +200°F. To seal cavities or channels (e.g., for the fabrication of fluidic devices), the first nylon sheet can be laminated with another Cronar film (http://www2.dupont.com/Products/en_RU/Cronar_en.html).[28]

Riston®, Fodel®, and VACREL® photopolyer films are other DuPont dry photoresists (see Figure 1.33). These complex photosensitive systems are designed to polymerize and harden when exposed to ultraviolet light. Fodel can pattern 75-µm vias on a 150-µm pitch, and conductors can be patterned with 50-µm lines on a 100-µm pitch. Fodel extends the density capability of the thick film process to allow densities typically achievable using more costly thin film processes.

Negative-tone photosensitive resins such as SU-8 are particularly suited for high-aspect ratio, high-thickness photofabrication. As we saw in Chapter 1, SU-8 is an epoxy-type, near-UV photoresist based on EPON SU-8 epoxy resin (from Shell Chemical) that was originally developed and patented by IBM. The main advantage of photosensitive resins over glasses and plastics is the fact that they are deposited in liquid form, thus conforming better to existing 2D and 3D structures. Other advantages include exquisite control over the thickness of the layer, higher attainable aspect ratios, higher feature density, and easier alignment to existing features.

Conclusions

Photofabrication is an attractive alternative for microfabrication of all types of high-aspect-ratio, passive elements, especially for intricate shapes that are >1 cm^2 in size and are only produced in modest volumes. The current interest in micromachined fluidic elements for analytical purposes is reviving interest in photosensitive glasses, plastics, and resins. Photosensitive glasses are also being considered for the fabrication of photonic crystals (see Volume I, Chapter 5). It certainly makes more sense to use photofabrication of insulators than to fabricate fluidic elements from Si because the latter, after etching, must be passivated. This passivation may undergo electrical breakdown, especially in an aqueous environment. We expect dry photoresist formulations to continue to improve, with tolerances approaching those of traditional spin-on photoresists (see Chapter 1). Applications such as RF-MEMS and fluidics might also lead to the introduction of novel photoformable ceramics and glasses.

Electrochemical Removal Techniques

Introduction

The term *electrochemical machining* is used to describe electrochemical removing and forming processes with or without masking the substrate. Both processes involve electrochemical energy. Despite performance, speed, and cost advantages, electrochemical milling (ECM) is used little in the IC field when other techniques, especially dry processes, are available. This seems to be connected in part with the overall trend toward dry processing and the disproportionately large number of electrical engineers versus chemical and electrochemical engineers in the IC world. LIGA and other replication techniques described in Chapter 10 have reinvigorated interest in electrodeposition, however. Both electrochemical removing and forming techniques are of extraordinary importance in miniaturization science—without electrochemical removal there would have been, for example, no porous Si (PS) work, and without electroplating of Ni master molds, there would be no plastic micromolding. Here we will review subtractive electrochemical processes only. Additive electrochemical processes are covered in Chapter 8. In electrochemical material removal, an electrical field in an electrolyte destroys the atomic bonds of the material.[26] Under electrochemical removal techniques, we will review electrochemical grinding (ECG), ECM including µ-ECM, electrochemical jet etching, laser-assisted electrochemical jet micromachining, scanning electrochemical microscope (SECM), and through-mask electrochemical micromachining.

Electrochemical Grinding

Introduction Grinding usually constitutes a mechanical machining process that removes small

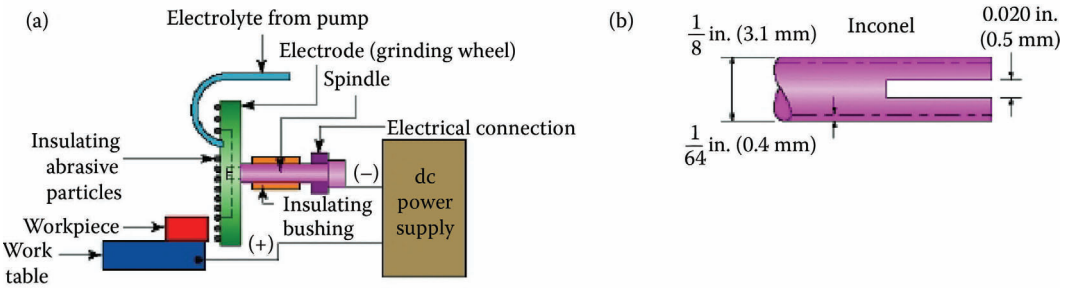

FIGURE 4.10 (a) Schematic illustration of the electrochemical grinding process. (b) Thin slot produced on a round nickel alloy tube by this process.

amounts of material from a metallic work piece in the form of tiny chips through the contact of small, hard, sharp, nonmetallic particles often embedded in a grinding wheel (see Chapter 6). In electrochemical grinding (ECG), the abrasive action of an electrically conductive wheel, the cathode, accounts only for 10% of the metal removal; the remainder is electrochemical. This technique should not be confused with electrolytic in-process dressing or ELID, where the material removal process (any type of material in this case) is purely mechanical but an electrochemical dissolution process of the metal matrix dresses the abrasive wheel continuously (see Chapter 6).

Electrochemical Grinding Operating Principles In ECG, an electrically conductive abrasive wheel, the cathode, and an anode work piece are connected to a low-voltage DC power source (Figure 4.10).[36]

An electrolyte is flushed onto the abrasive wheel, and the abrasive particles in the wheel's surface remove electrochemically dissolved material, always keeping the surface fresh for further electrochemical attack. Very low DC voltages (usually between 3 and 15 V) are used in ECG; therefore, spark discharge is minimized and little or no heat is developed in the cut. All hard conductive materials are candidates for ECG (e.g., sharpening of tungsten-carbide tool bits). The method is also good for fragile parts that would be damaged by conventional mechanical grinding. The method produces parts free of residual stresses and heat damage and surface finishes ranging from 0.1–0.5 μm. The surfaces are also free of scratches and burrs. This process provides not only burr-free machining but also considerably less cutting wheel wear. ECG is similar to electrochemical machining (see below) except that the cathode is a specially constructed grinding wheel instead of a tool shaped like the contour to be machined.

Compositron Corporation is a service company providing an electrochemical grinding homepage (http://www.evercut.com), and Everite Machine Products Co. sells ECG equipment (e.g., Everite Model EG618; http://www.everite.net).

Electrochemical Machining

Electrochemical machining (ECM) historically followed electrochemical grinding (ECG). In ECM one uses a cathode electrode shaped to provide the complementary structure in an anode work piece (Figure 4.11). A highly conductive electrolyte stream separates the cutting tool from the work piece, and metal removal is accomplished by passing a DC current of up to 100 A/cm^2 through the salt solution cell. As the cathode tool approaches the anode work piece it erodes its complementary shape in it. Thus, complex shapes may be made from a material such as

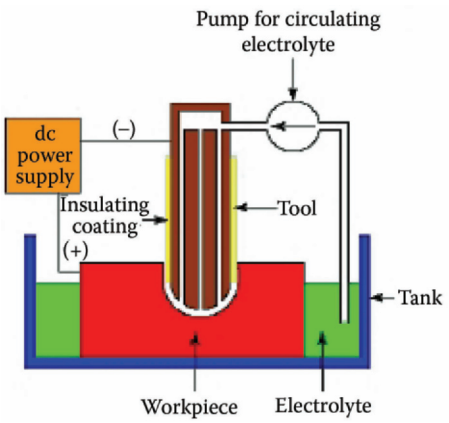

FIGURE 4.11 Schematic illustration of the electrochemical machining process. This process is the reverse of electroplating, described in Chapter 8.

soft copper and used to produce negative duplicates of it. The process is also called electrochemical sinking. Machines having current capacities as high as 40,000 A and as low as 5 A are available. The pressurized electrolyte (concentrated solutions of inorganic salts such as sodium chloride, potassium chloride, and sodium nitrate) passes at high speed (10–60 m/s) through the gap (about 0.1–0.6 mm) between the work piece and the tool to prevent metal ions from plating onto the cathode tool and to remove the heat that is generated as a result of the high current flow. The cathode is advanced into the anode work piece at a rate matching the dissolution rate, which is between 0.5 and 10 mm/min when applying current densities of 10–100 A/cm^2. The supply voltage commonly used in ECM ranges from 5–20 V; the lower values are used for finish machining (creating a final smooth surface), and the higher voltages are used for rough machining. The rate of material removal is the same for hard or soft materials, and surface finishes are between 0.3 and 1 μm. These cutting speeds and surface finishes are comparable with those of electrical discharge machining (EDM; a thermal subtractive technique described in Chapter 5).

The cathode tool must have these four characteristics: be machinable, be rigid (high Young's modulus), be a good conductor, and have good corrosion resistance. The three most common cathode materials used are copper, brass, and stainless steel. The outside of the electrode is insulated to prevent machining actions on the sides. This makes the fabrication of these tools challenging. Because there is no contact between the tool and the work, the tool does not have to be harder than the work, as in traditional machining methods. Hence, this is one of the few ways to machine very hard material; another is spark-discharge machining (see Chapter 5).

The advantages of ECM are that it has relatively low running costs, as there is little scrap, no tool wear, and unskilled labor or automatic machine operation can be used. Because shear is not involved in this process, the surface of the work is, as in chemical milling, free from imperfections and burrs. It is also used in deburring already machined components. A very good surface finish is usually obtained. The disadvantages of ECM are that the machine is initially very expensive—several times the cost of an EDM machine; large systems may cost up to $600,000 (about the same as multiaxis milling machines). The tool is also difficult to make because its sides have to be insulated. The electrolyte has to be well contained, and the most common electrolyte, sodium chloride, corrodes the equipment, tool, and work. Another issue is that the electrochemical erosion reduces sharp surfaces and profiles so the method is not suited for making products with sharp edges. Also, irregular cavities may not be produced to the desired shape with acceptable dimensional accuracy, and designs should make provisions for small taper for holes and cavities to be machined. Overall, the technique is best suited for mass production of high-precision, small, and complex shapes in hard-to-machine materials (accuracy better than 10 μm).[37] To date, ECM has found its widest acceptance in the aircraft, automotive, and business machine industries. In the aircraft industry, ECM is used extensively for shaping turbine blades. In the automotive industry, the technique is used to make connecting rods, pistons, and fuel-injection nozzles. Some example products are shown in Figure 4.12.

The fact that metal removal in ECM is not achieved by mechanical shearing (as in mechanical machining) or by melting and vaporization of the metal (as in EDM or laser machining; see Chapter 5) means that, as with chemical machining, no thermal damage occurs and no residual stresses are produced on the worked surface. For this reason, ECM is often selected for highly stressed or fatigue-sensitive applications in the aerospace industries.

Pulsed electrochemical machining (PECM) is a refinement of ECM, where current pulses are used instead of DC currents. This improves fatigue life and eliminates the recast layer left on die and mold surfaces by EDM (see Chapter 5).

Sometimes, chemical and electrochemical removal machining are in competition. Chemical machining might be preferred when very large work pieces have to be machined because of the large currents involved in ECM, and also for ultrasmall parts, where the electric connection causes problems for ECM.

Typical ECM service providers are Köppern (http://www.koeppern.com/en_ecm_set.htm) and Raycon/AMCHEM (Ann Arbor, MI). A handbook

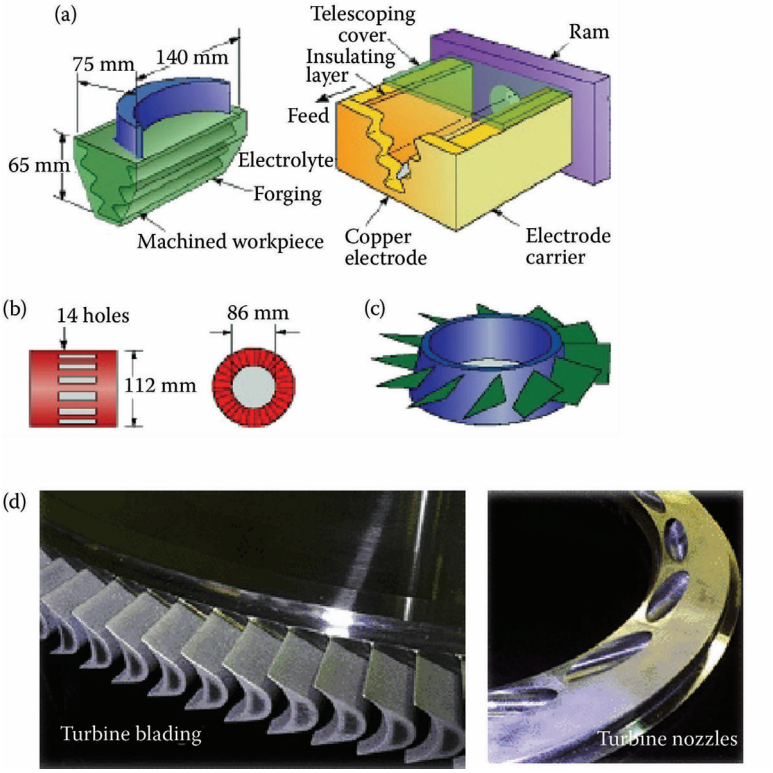

FIGURE 4.12 Typical parts made by electrochemical machining. (a) Turbine blade made of a nickel alloy, 360 HB. (From *Metal handbook,* 9th ed., vol. 3. Materials Park, OH: ASM International, 1980, p. 849). (b) Thin slots on a 4340-steel roller-bearing cage. (c) Integral airfoils on a compressor disk. (d) Because of the low forces on the work piece, ECM can be used to make holes at very large angle to a surface; in the example, we show turbine nozzle holes (http://www.barber-nichols.com).

covering ECM is the *Non-Traditional Machining Handbook* by Carl Sommer.[38]

Electrochemical Micromachining or Microelectrochemical Machining

Introduction The application of ECM in thin film processing and in the fabrication of microstructures is referred to as *electrochemical micromachining* (EMM) or *microelectrochemical machining* (μ-ECM).[39] Different from ECM, the cathode does not necessarily have the shape of the contour desired in the anode work piece. The 3D shaping in EMM may involve maskless or through-mask material removal, and we will examine examples of both approaches. The tool may also be connected to a CNC machine to produce even more complex shapes with a single tool as illustrated in Figure 4.13.

In conventional ECM, the gap between cathode tool and anode work piece is typically about 150 μm; in μ-ECM, the gap is closer to 15–20 μm, and feature sizes change from 150–200 μm to 15–20 μm as we move from the ECM to the μ-ECM domain. The major challenge in moving from the conventional ECM to the μ-ECM domain is to control the size of the reaction region. Methods to accomplish this include:

1. Reduce the size of electrodes—μ-EDM is used.
2. Shield the electrode—for stray currents.
3. Gap control strategies.
4. Use ultrashort-pulsed voltages having time duration in the ranges of nanoseconds.

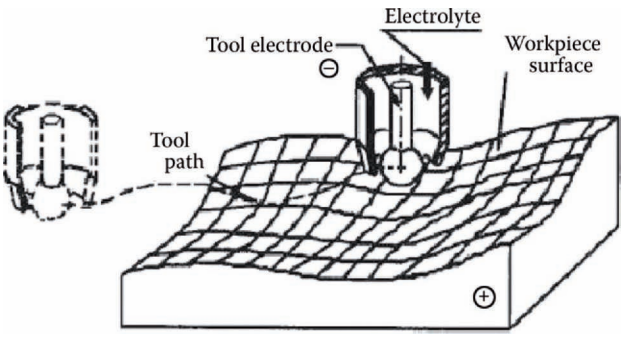

FIGURE 4.13 The ECM microcathode is connected to a CNC machine to produce more complex shapes with a single tool.

With EMM, most metals, alloys, and conducting ceramics of interest in the microelectronics and MEMS/NEMS industry can be anodically dissolved in a variety of neutral salt electrolytes, such as sodium nitrate, sulfate, or chloride. The dissolved metal ions form hydroxide precipitates in these electrolytes and remain suspended in solution so they may easily be filtered out. The latter minimizes safety problems and waste disposal. With hydrogen evolution generally as the main cathodic reaction, metal plating on the cathode is avoided. EMM is currently receiving considerable attention in the electronics and other high-technology industries, particularly as an alternative, "greener" method of processing metallic parts.[39] Compared with chemical etching, the EMM process offers better control, less aggressive chemicals, and thus minimizes safety and environmental concerns.[39]

Electrochemical Jet-Etching and Laser-Assisted Electrochemical Jet-Etching Thin film patterning by maskless EMM may be accomplished by highly localized material removal induced by the impingement of a fine electrolytic jet emanating from a small nozzle.[39] Investigation of jet EMM at IBM demonstrated that neutral salt solutions can be effectively used for high-speed micromachining of many metals and alloys. An example of such an investigation, using a nozzle diameter of 200 µm and a 5 M sodium nitrate solution, is shown in Figure 4.14. Through-slots were micromachined in a 50-µm-thick stainless steel foil to create the IBM logo, which demonstrates the feasibility of using an electrolytic jet for generating complicated patterns in metallic foils and substrates.

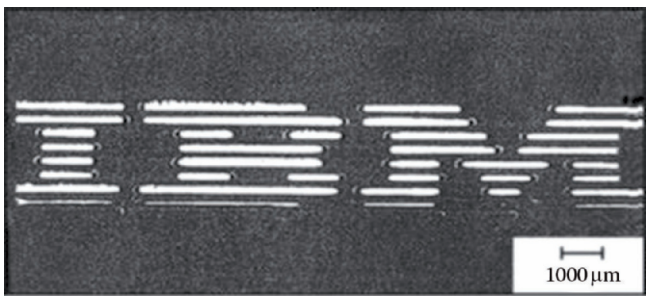

FIGURE 4.14 IBM logo made by jet EMM. Through-slots machined in a 50-µm-thick stainless sheet using a 5 M sodium nitrate electrolyte jet. The jet nozzle diameter is 200 µm. (Courtesy of Datta, M. J., 1995. Fabrication of an array of precision nozzles by through-mask electrochemical micromachining. *Electrochem Soc* 142:3801–05.[44])

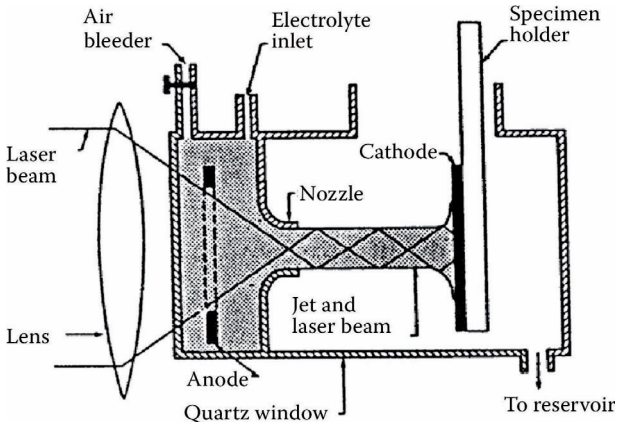

FIGURE 4.15 Schematic representation of laser-enhanced electrochemical jet etching/plating showing the coincident laser beam and solution jet with the jet acting as the waveguide. (From Romankiw, L. T., and T. A. Palumbo. 1987. *Proceedings: symposium on electrodeposition technology, theory and practice*. Pennington, NJ: The Electrochemical Society, Inc. With permission.[27])

An interesting variation on electrochemical jet etching is a combination of a fluid-impinging jet and laser illumination (see Figure 4.15). In laser-enhanced electrochemical jet etching, properly chosen lasers, whose energy is not absorbed by the etching solution but is absorbed by the solid, cause local heating of the substrate (up to 150°C), resulting in highly increased etching. The jet is used as a light pipe for the laser and at the same time as a means for the local high rate of supply of ions. For stainless steel, etch rates of 10 µm/s have been demonstrated using laser-enhanced electrochemical jet machining.

For more background on electrochemical jet etching and laser-enhanced jet etching, refer to Romankiw et al.[27] and references therein and Datta et al.[40] Several of these techniques offer tremendous opportunities for the development of alternative micromachining methods.

Water jet etching is a mechanical process, and as such it is covered in Chapter 6 on mechanical energy-based removing. Water jet-guided laser etching without the electrochemical component is a purely thermal technique and is covered in Chapter 5. In this important method we will see that a fine water-jet again guides the laser beam, provides cooling for the work piece, and expels the molten material.

Scanning Electrochemical Microscope The scanning electrochemical microscope (SECM) is a scanned probe microscope (SPM) related to the familiar scanning tunneling (STM) and atomic force microscopes (AFM) (see Volume III, Chapter 6). All SPMs operate by scanning or "rastering" a small probe tip over the surface to be imaged. In SECM, imaging occurs in an electrolyte solution with an electrochemically active tip. In most cases, the SECM tip is an ultramicroelectrode (UME), and the tip signal is a Faradaic current from an electrochemical reaction at the surface. In some SECM experiments, the tip is an ion-selective electrode (ISE). In Chapter 1, we saw how a scanning tunneling microscope may induce electrochemical anodization reactions (an oxidation) on surfaces such as Si and GaAs. An SECM can also be used for local etching and deposition with high resolution in the x, y, and z dimensions, basically forming a high-resolution ECM setup (Figure 4.16).

Metal and semiconductor surfaces can be etched by the generation of a suitable etchant at the tip, for example Br_2, which will etch holes in GaAs.[41] In many cases, dissolution of semiconductors can be further enhanced by irradiation of the surface, creating holes in the valence band, which react with the lattice of the semiconductor. Besides electrochemical micromachining, SCEM is also used for chemical microscopic imaging and the measurement of physicochemical constants and coefficients.

In 2008, a review on the technology appeared in the *Annual Review of Analytical Chemistry.*[42] For an update on SECM on the Internet, visit http://www.msstate.edu/Dept/Chemistry/dow1/secm/secm.html and http://www2.warwick.ac.uk/fac/sci/chemistry/cim/research/electrochemistry/research/secm.

Through-Mask Electrochemical Micromachining Through-mask electrochemical micromachining (EMM) involves selective metal dissolution from unprotected areas of a one- or two-sided photoresist-patterned work piece that is made the anode in an electrolytic cell.[39,43] The technique is faster than chemical milling and provides better control on a micro- and macroscale of shape and surface texture of anodically dissolved materials. The performance of through-mask EMM depends largely on the successful control of voltage distribution in the cell, hydrodynamics, and surface kinetics.[43] In wet isotropic chemical etching, the material is removed both vertically and laterally at the same rate, and the etch boundary usually recedes at a 45° angle relative to the surface. In EMM, however, the metal-removal rate in the lateral direction may be significantly reduced through proper manipulation of mass transport and current distribution.[39]

Datta[44] described a cost-effective, high-speed process for the fabrication of precision nozzles for ink-jet printer heads using through-mask EMM. The process involves fabrication of a series of rombezoidal nozzles in a metal foil and is applicable to a variety of materials, including high-strength, corrosion-resistant materials such as conducting ceramics. For the

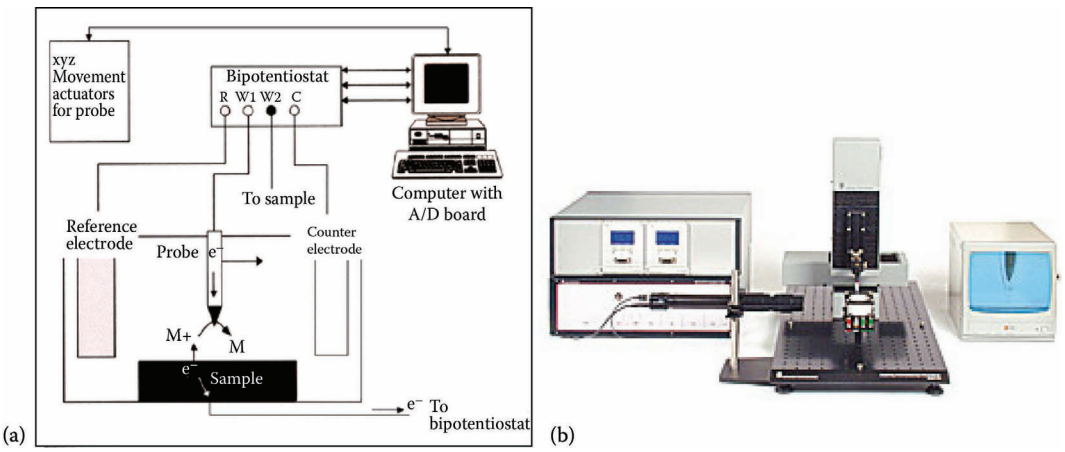

FIGURE 4.16 (a) A schematic setup for SECM (http://www.msstate.edu/Dept/Chemistry/dow1/secm/secm.html) and (b) a typical commercial product (http://www.princetonappliedresearch.com/products/SurfaceScanning.cfm).

fabrication of the example nozzles in Figure 4.17, a cleaned 25-µm-thick stainless steel foil was laminated on both sides with 25-µm-thick dry photoresist. On one side, the photoresist was then exposed and developed, and the photoresist on the back remained as a protective insulating layer. The photoresist pattern was an array of circular openings 55 µm in diameter. Direct- and pulsed-voltage experiments were then performed with a neutral salt solution of sodium chloride and glycerol mixture as the electrolyte. Pulsating-voltage EMM was found to be more effective in providing dimensional etching uniformity over the whole nozzle array. This result is based on the application of extremely high peak currents (voltages), which, in addition to giving directionality, enables breakdown and elimination of inhibiting layers, thus facilitating activation of all the openings at the same time. A desired nozzle angle of 27° was produced with an etch factor (ratio of straight-through etch to undercut) of 2 (see Figure 4.17). This way, Datta demonstrated the feasibility of fabricating arrays of hundreds to thousands of precision nozzles with microsmooth surfaces in copper and stainless steel foils. Alternate ink-jet nozzle fabrication techniques in silicon are shown in Figure 4.45.

Through-mask EMM has also been used to fabricate controlled topographies on titanium to improve its biocompatibility.[45] Arrays of very smooth, high-precision cavities 30 µm in diameter were fabricated. Such structures affect attachment and growth of both soft and hard tissues. Biocompatibility has been linked to surface structures in the micrometer and nanometer range (see also Volume III, Chapter 4).[46]

Summary The driving force for metal dissolution reactions in EMM is derived from an external current; as a consequence, the electrolyte does not have to be as aggressive as in chemical etching. In fact, even neutral salt solutions are applicable. Metal-removal rates in EMM are determined by the machining current, which can be very high if proper hydrodynamic conditions prevail within the electrochemical cell; hence EMM etch rates are generally orders of magnitude higher than those in chemical etching. More importantly, through manipulation of mass transport and current distribution, metal-removal rate in the lateral direction can be significantly influenced, thus providing better wall slope control in EMM. Other EMM benefits include minimized safety and environmental concerns. All the listed features make the EMM process a cost-effective, environmentally friendly processing technology. Newly emerging technologies such as advanced microelectronic packaging, microsensors, and MEMS/NEMS provide

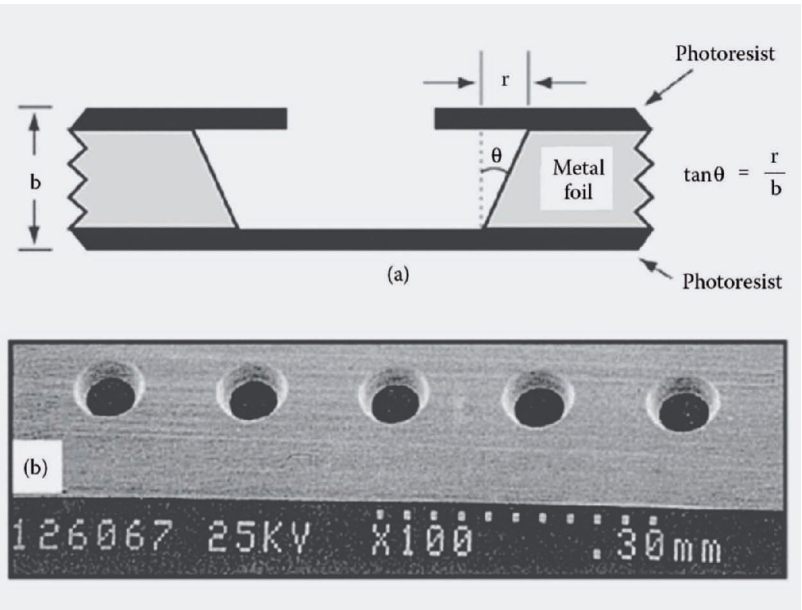

FIGURE 4.17 (a) One-side through-mask EMM with angular sidewall. (b) SEM of nozzles fabricated in 25-µm-thick stainless steel. (Courtesy of Datta, M. J., 1995. Fabrication of an array of precision nozzles by through-mask electrochemical micromachining. *Electrochem Soc* 142:3801–05.[44])

Table 4.3 Comparison of Electrochemical Machining (ECM) with Microelectrochemical Machining (μ-ECM)

Major Machining Characteristics	ECM	μ-ECM
Voltage	10–30 V	<10 V
Current	150–10,000 A	<1 A
Current density	20–200 A/cm^2	75–100 A/cm^2
Power supply, DC	Continuous/pulsed	Pulsed
Frequency	Hz–KHz range	KHz–MHz range
Electrolyte flow	10–60 m/s	<3 m/s
Electrolyte type	Salt solution	Natural salt or dilute acid/ alkaline solution
Electrolyte temperature	24–65 °C	37–50 °C
Electrolyte concentration	>20 g/L	<20 g/L
Size of the tool	Large to medium	Micro
Interelectrode gap	100–600 μm	5–50 μm
Operation	Maskless	Mask/maskless
Machining rate	0.2–10 mm/min	5 μm/min
Side gap	>20 μm	<10 μm
Accuracy	±0.1 mm	±0.02–0.1 mm
Surface finish	Good: 0.1–1.5 μm	Excellent: 0.05–0.4 μm
Problems caused by waste disposal/ toxicity	Low	Low to moderate

ample opportunities for further investigation of EMM. With a better understanding of the principles involved in manipulating high-rate anodic dissolution of metals from narrow and deep cavities, EMM will become an increasingly important processing technology for micro- and nanofabrication.[39]

In Table 4.3 we compare electrochemical machining (ECM) with microelectrochemical machining (μ-ECM).

μ-ECM has some features in common with microelectrical discharge machining (μ-EDM), a thermal technique covered in Chapter 5. In Table 5.2 μ-ECM is compared with μ-EDM.

Wet Bulk Micromachining

Introduction

As mentioned in the introduction to this chapter, wet bulk micromachining is chemical etching used to sculpt isotropic and anisotropic 3D microfeatures in single crystal semiconductor substrates. Removal of material from the surface of a crystalline material (such as Si), immersed in an alkaline or acidic solution, occurs as a result of complicated chemical reactions between the surface atoms and the etchant molecules (see Figure 4.18a). The isotropy or anisotropy of the etching refers to the orientation dependency of the etch rate: for the isotropic case, there is no orientation dependence; for the anisotropic case, there is orientation dependence (see Figure 4.18b).

Wet bulk micromachining is a technique championed in the IC industry and in micro- and nanomachining. In this section, we are mostly concerned with lithography-based chemical etching for the IC industry and micro- and nanofabrication. In this application, lithography is used to create a mask through which an etchant can etch away the underlying crystalline substrate. A major difference between the IC and MEMS fields in this regard is in the aspect ratio (height-to-width ratio) of the features crafted. In the IC industry, one deals mostly with very small, flat structures with aspect ratios of 1–2 (see Figure 4.2). In the microfabrication field, structures typically are somewhat larger, and aspect ratios (height-to-width ratio) may be as high as 400. In wet bulk micromachining, features are sculpted in the bulk of materials such as silicon, quartz, SiC, GaAs, InP, and Ge by orientation-independent (isotropic) or orientation-dependent (anisotropic) wet etchants. The technology uses pools of liquid as tools,[1] instead of the (dry) plasmas studied in

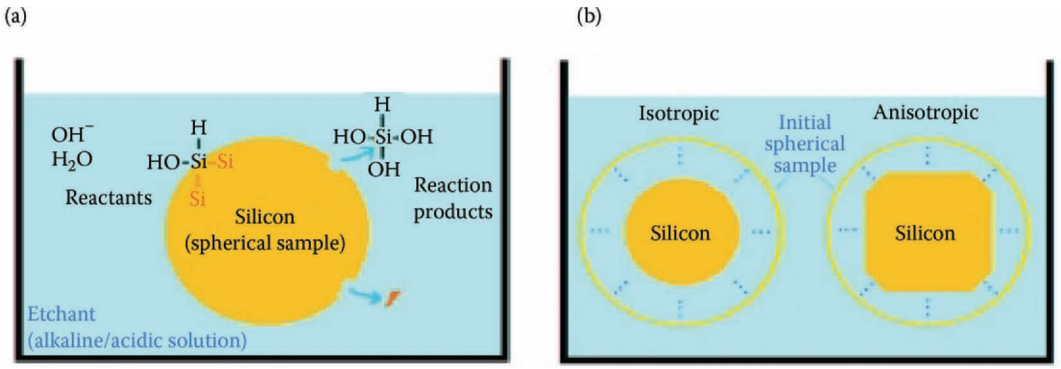

FIGURE 4.18 (a) Schematic illustration of the dissolution process during wet etching. (b) Wet etching can be isotropic or anisotropic. (Gonsalvez, M. 2003. *Atomistic modelling of anisotropic etching of crystalline silicon.* PhD diss., Helsinki University of Technology.[47])

Chapter 3. In Figure 4.19 we show some examples of high-aspect-ratio MEMS structures created using wet anisotropic etching of properly masked <100>- and <110>-oriented silicon wafers.

A vast majority of wet bulk micromachining work is based on single-crystal silicon and glass as a companion material [7740 Jena glass (Pyrex) is often used for packaging; see Volume III, Chapter 4], mostly for mechanical-type sensors such as pressure, acceleration, and gyros. There has been some work on quartz, crystalline Ge, SiC, and GaAs, and a minor amount on GaP and InP.

Wet bulk micromachining, together with surface micromachining (Chapter 7), form the two principal commercial Si micromachining tool sets used today. A third technique, micromolding—often from a lithography-defined master—also is becoming more commercially viable (Chapter 10).

The emphasis in this chapter is on the wet etching process itself. Other machining steps typically used in conjunction with wet bulk micromachining include many of the alternative subtractive techniques described elsewhere in Part II, the additive processes described in Part III, and the bonding processes that are part of the packaging processes dealt with in Volume III, Chapter 4.

A historical note on Si wet bulk micromachining, clarifying the importance of Si as a sensor material,

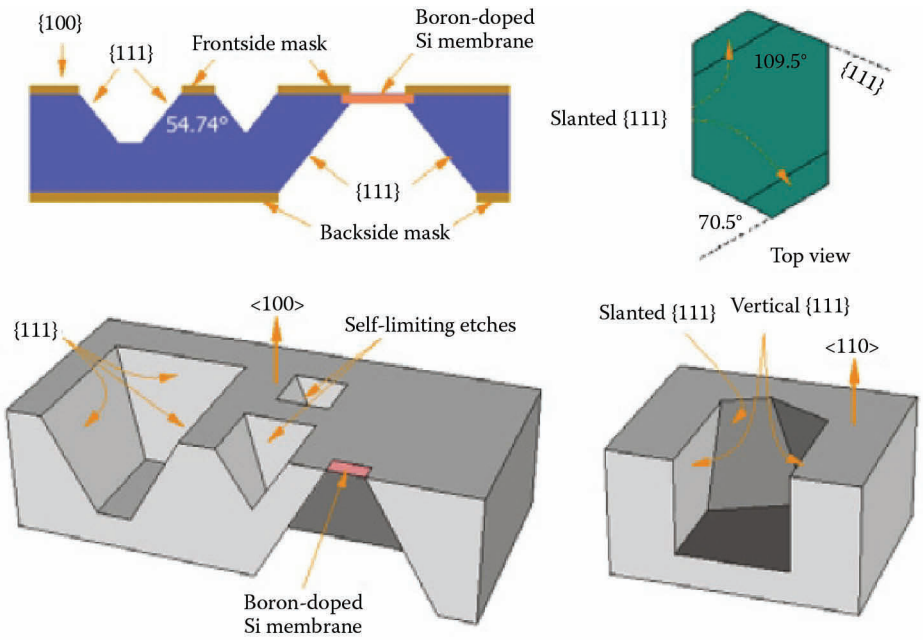

FIGURE 4.19 Examples of structures created using wet anisotropic etching in a Si <100> wafer and in a Si <110> wafer. The significance of boron doping will be clarified further below.

heads this chapter (an expanded treatise on this subject can be found in Volume I, Chapter 1). We start the current section with a review of some empirical data on wet etching of single-crystal Si, discuss mask alignment with the correct crystallographic direction, review the various etchants and masking material approaches, and then launch into describing different etch stop techniques, which catapulted micromachining into an industrially accepted manufacturing method. Subsequently, we review models explaining wet isotropic and anisotropic etching and pick up the discussion anew of anodic polishing, photoetching, and formation of porous Si in HF solutions. Next comes a discussion of the technical issues encountered in bulk micromachining, such as IC incompatibility and extensive real-estate usage. We conclude with some example applications of wet bulk micromachining.

The first MEMS modeling software was developed around wet bulk micromachining processes and mechanical MEMS structures. Such programs are reviewed in Volume III, Chapter 6.

Empirical Data on Wet Etching of Single-Crystal Si

Isotropic and Anisotropic Etched Shapes in Single-Crystal Si

In Figure 4.20, we compare a wet isotropic etch (Figure 4.20a) with examples of anisotropic etches on masked flat pieces of single-crystal Si (Figure 4.20b–e). In the anisotropic etching examples, a square (Figure 4.20b and c) and a rectangular pattern (Figure 4.20d) are defined in an oxide mask with sides aligned along the family of <110> directions on a [100]-oriented silicon surface. For a refresher on the use of < >, [], and () (the Miller indices), see Volume I, Chapter 2 (Table 2.2). The square openings are precisely aligned (within 1° or 2°) with the [110] directions on the (100) wafer surface to obtain pits that conform exactly to the oxide mask rather than undercutting it. Most [100] silicon wafers have a main flat parallel to a [110] direction in the crystal, allowing for a rough alignment of the mask (see Volume I, Figure 4.3). Etching with the square pattern results in a pit with well-defined {111} sidewalls (at angles of 54.74° to the surface) and a (100) bottom. Volume I,

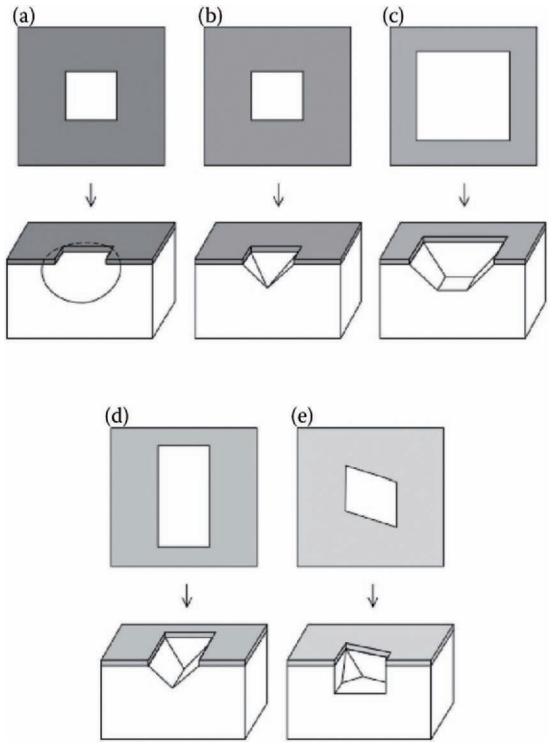

FIGURE 4.20 Isotropic and anisotropic etched features in [100] and [110] wafers. (a) Isotropic etch. (b–e) Anisotropic etch. (a–d) [100]-oriented wafers. (e) [110]-oriented wafer.

Equation 4.2, $W_0 = W_m - 2z\cot 54.74° = W_m - \sqrt{2}z$ allows one to calculate the dimensions of the hole at the bottom of the pit. For a larger square opening in the mask, the point where the {111} sidewalls of the pit intersect lays deeper inside the crystal. If the oxide opening is wide enough, that is, $W_0 > \sqrt{2}\,l$ (with l = 600 µm for a typical 6-in. wafer, this means $W_0 >$ 849 µm), the {111} planes do not intersect within the wafer. The etched pit in this particular case extends all the way through the wafer, creating a small square opening on the bottom surface (see Volume I, Figure 4.8). As shown in Figure 4.20b–d, no underetching of the etch mask is observed as a result of the perfect alignment of the concave oxide mask opening with the [110] direction. In Figure 4.20a, an undercutting isotropic etch (acidic) is shown. In the case of an anisotropic etch, misalignment results in pyramidal pits, but the mask will be severely undercut. A rectangular pattern aligned along the <110> directions on a <100> wafer leads to long V-shaped grooves (see Figures 4.20d and 4.21) or an open slit, depending on the width of the opening in the oxide mask.

Using a properly aligned mask (see Volume I, Chapter 4) on a [110] wafer, grooves with four

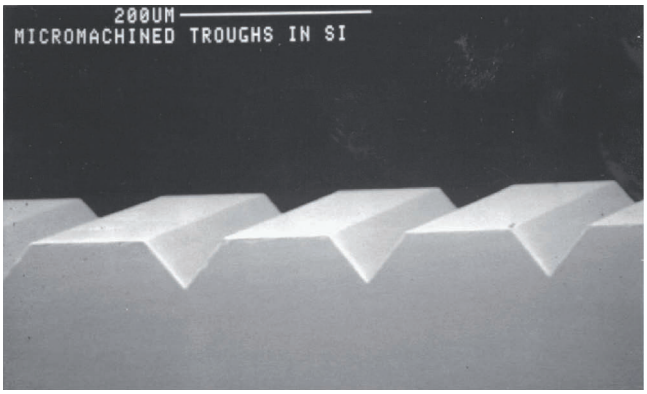

FIGURE 4.21 Long V-shaped grooves in a (100) Si wafer.

vertical and two slanted {111} planes result (see Figures 4.20e and 4.22a). Even a slight mask misorientation leads to all skewed sidewalls instead (Figure 4.22b). Before the emergence of slanted {111} bottom planes, the groove is defined by four vertical (111) planes and a horizontal (110) bottom (Figure 4.19, bottom right), and between there is a competition between {110} and {100} bottom planes. Self-stopping occurs when the tilted end {111} planes intersect at the bottom of the groove (Figure 4.22d). It is easy to etch very long, narrow grooves deeply into a [110] silicon wafer (Figure 4.23). However, it is impossible to etch a short, narrow groove deeply into it[48] because the narrow dimension of the groove

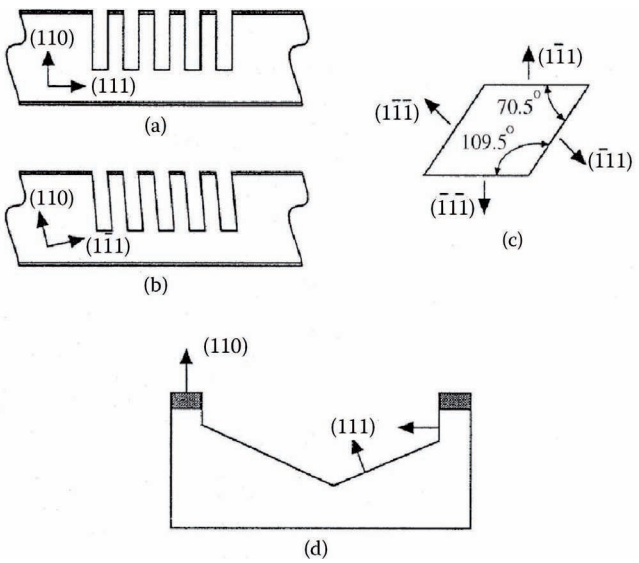

FIGURE 4.22 Anisotropic etching of [110] wafers. (a) Closely spaced grooves on correctly oriented (110) surface. (b) Closely spaced grooves on misoriented [110] wafer. (c) Orientations of the {111} planes looking down on a (110) wafer. (d) Shallow slanted (111) planes eventually form the bottom of the etched cavity.

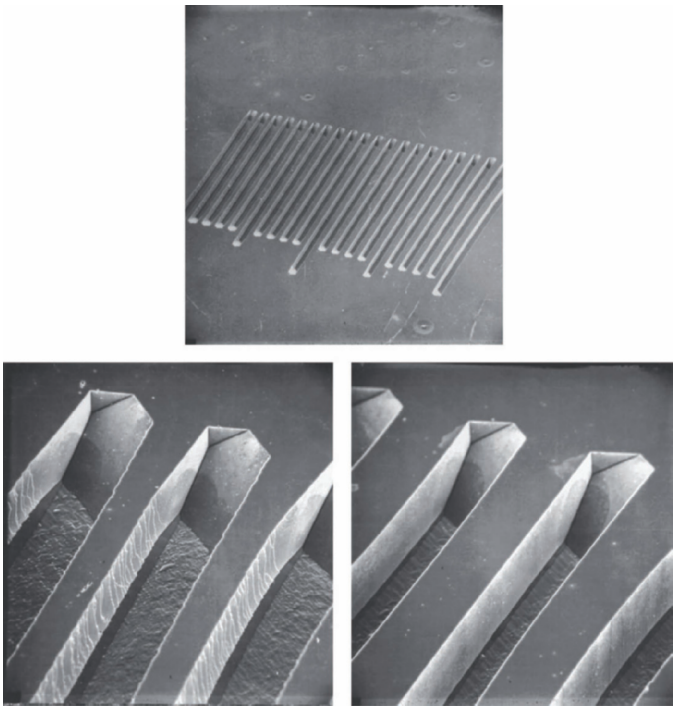

FIGURE 4.23 Test pattern of U-grooves in a <110> wafer to help in the alignment of the mask; final alignment is done with the groove that exhibits the most perfect long perpendicular walls.

is quickly limited by slow-etching {111} planes that subtend an angle of 35.26° to the surface and cause etch termination. At a groove of length L = 1 mm on the top surface, etching will stop when it reaches a depth of 0.289 mm, that is, $D_{max} = L/2\sqrt{3}$. For very long grooves, the tilted end planes are too far apart to intersect in practical cases, making the end effects negligible compared with the remaining trench-shaped part of the groove. Tuckerman and Pease[49] demonstrated the use of such trenches as liquid cooling fins for integrated circuits. The set of long, narrow grooves in a <110> wafer shown in Figure 4.23 can also be used as a test pattern to help in the alignment of the mask; final alignment is done with the groove that exhibits the most perfect long perpendicular walls (see also Figure 4.25).

The orientation of the wafer is of extreme importance, especially when machining surface structures by undercutting. Consider, for example, the formation of a bridge in Figure 4.24a.[50] When using a (100) surface, a suspension bridge cannot form across the etched V-groove; two independent truncated V-grooves flanking a mesa structure result instead.

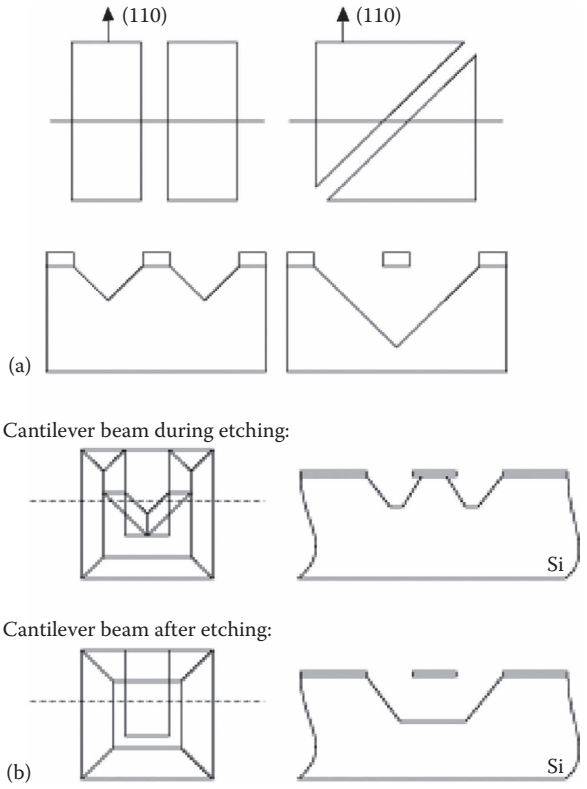

FIGURE 4.24 How to make a suspension bridge from a [100] Si wafer (a) and a diving board from a [110] Si wafer (b). (Barth, P. W., P. J. Shlichta, and J. B. Angel. 1985. *Third international conference on solid-state sensors and actuators.* Philadelphia.[50])

To form a suspended bridge, the V-groove must be oriented away from the [110] direction. Contrast this with a (110) wafer where a microbridge crossing a V-groove with a 90° angle will be undercut. Convex corners will be undercut by etchant, allowing formation of cantilevers as shown in Figure 4.24b. The diving board shown in Figure 4.20b forms by undercutting, starting at the convex corners. For more details, Table 4.4 is in the section on selection of [100]- or [110]-oriented silicon wafers, where we compare the main characteristics of etched features in [100]- and [110]-oriented wafers.

Alignment Patterns—Wagon-Wheel Masking Patterns

We just learned how a mask pattern may be aligned with the wafer flat to obtain a specific desired anisotropic etched feature. When alignment of a pattern along a certain crystallography direction is more critical, pre-etch alignment targets become useful to delineate the planes of interest because the wafer flats often are aligned to ±1° only. To find the proper alignment for the mask, a test pattern of closely spaced lines can be etched (see Figure 4.23). As discussed above, the groove with the best vertical walls determines the proper final mask orientation. Along this line, Ciarlo[51] made a set of lines 3 mm long and 8 μm wide, fanned out like spokes in a wagon wheel at angles 0.1° apart. This target was printed near the perimeter of the wafer and then etched 100 μm into the surface. Again, by evaluating the undercut in this target, the correct crystal direction could be determined. Alignment with better than 0.05° accuracy was accomplished this way.

The wagon-wheel pattern technique has also been used to obtain detailed experimental data on crystal orientation dependence of etch rates. For example, Seidel et al.[52] used a wagon-wheel or star-shaped mask (e.g., made from CVD-Si_3N_4, SiH_4, and NH_3 at 900°C), consisting of radially divergent segments with an angular separation of 1° (Figure 4.25a). By selectively masking the wafer surface material with material that is inert to the etchant (in this case, Si_3N_4) the removal of material is forced to occur vertically at the nonmasked areas and laterally under the masking spokes (Figure 4.25b). Beautiful patterns are formed as a result of the sidewalls being etched at different rates (Figure 4.25c). The etch rate for each sidewall in the wheel (distance r) is obtained from the lateral underetch rate (distance w) from $r = w\sin\theta$ (Figure 4.25b).

Seidel et al.[52] found an etch pattern emerging on a <100>-oriented wafer covered with wagon-wheel mask as shown in Figure 4.26a. The blossom-like figure is the result of the total underetching of the passivation layer in the vicinity of the center of the wagon wheel, leaving an area of bare, exposed Si. The radial extension of the bare Si area depends on the crystal orientation of the individual segments, leading to a different amount of total underetching. The observation of these blossom-like patterns is used for qualitative guidance of etching rates only. To establish quantitative numbers for the lateral etch rates, the width, w, of the overhanging passivation layer is measured with an optical line-width measurement system. Laser beam reflection is used to identify the crystal planes, and ellipsometry is used to monitor the etching rate of the mask itself.

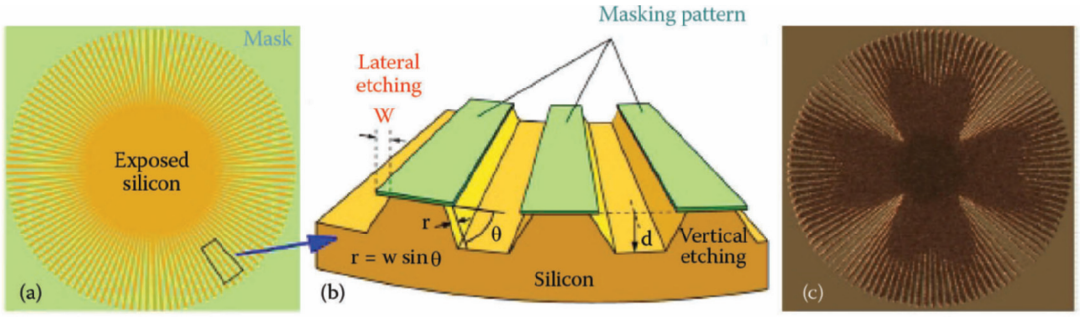

FIGURE 4.25 (a) Wagon-wheel masking pattern on silicon before etching. (b) Vertical etching (distance d) and lateral underetching (distance w). (c) Flower pattern generated during anisotropic etching. (Gonsalvez, M. 2003. *Atomistic modelling of anisotropic etching of crystalline silicon*. PhD diss., Helsinki University of Technology.[47])

Lateral etch rates determined in this way on <100>- and <110>-oriented wafers at 95°C in EDP (470 mL water, 1 L ethylene-diamine, 176 g pyrocatechol) and at 78°C in a 50% KOH solution are shown in Figure 4.27 (these two etchants are detailed further below). Etch rates shown are normal to the crystal surface and are conveniently described in a polar plot in which the distance from the origin to the polar plot surface (or curve in two dimensions) indicates the etch rate for that particular direction. Note the deep minima at the {111} planes. It can also be seen that, in KOH, the peak etch rates are more pronounced. A further difference is that with EDP the minimum at {111} planes is steeper than with KOH. For both EDP and KOH, the etch rate depends linearly on misalignment. All the above observations have important consequences for the interpretation of anisotropy of a given etch (see below). The difference between KOH and EDP etching behavior around the {111} minima has the direct practical consequence that it is more important for etching in EDP to align the crystallographic direction more precisely than in KOH.[53]

When determining etch rates without using underetching masks but using vertical etching of beveled silicon samples, results are different from working with masked silicon.[54] The etch rates on open areas of beveled structures are much larger than in underetching experiments with masked silicon, and different crystal planes develop. Herr et al.[54] conclude that crevice effects may play an important role in anisotropic etching. The model of Elwenspoek et al.,[55,56] analyzed below, is the only model that predicts such a crevice effect. The authors explain why etching rates slow down and increase anisotropy when etchants are in a small restricted crevice area and are not refreshed fast enough.

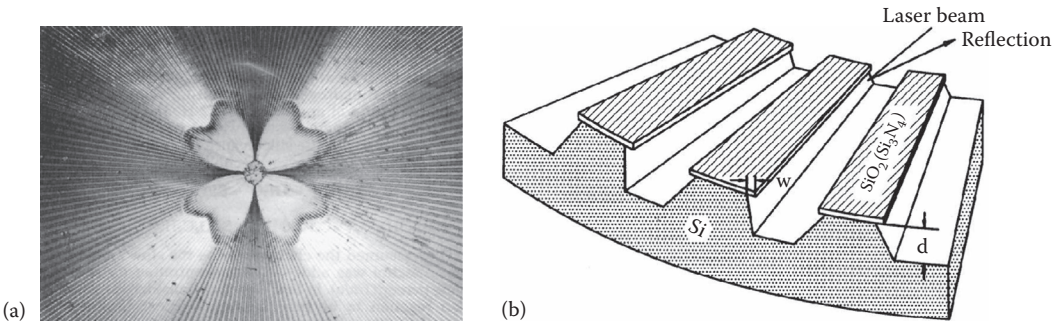

FIGURE 4.26 (a) Etch pattern emerging on a wagon wheel-masked, <100>-oriented Si wafer after etching in an EDP solution. (b) Schematic cross-section of a silicon test chip covered with a wagon wheel-shaped masking pattern after etching. The measurement of *w* is used to construct polar diagrams of lateral underetch rates as shown in Figure 4.27. (From Seidel, H., L. Csepregi, A. Heuberger, and H. Baumgartel. 1990. Anisotropic etching of crystalline silicon in alkaline solutions–part I: orientation dependence and behavior of passivation layers. *J Electrochem Soc* 137:3612–26. With permission.[52])

Selection of [100]- or [110]-Oriented Silicon Wafers

In Table 4.4, we compare the main characteristics of etched features in [100]- and [110]-oriented wafers. This table may help in the decision which orientation to use for a specific microfabrication application at hand.

From this table, it is obvious that for membrane-based sensors, [100] wafers are preferred, but an understanding of the geometric considerations with [110] wafers is important as well to fully appreciate all the possible single-crystal silicon micromachined shapes and to better understand corner compensation schemes (see below). Moreover, processes for providing dielectric isolation require that the silicon be separated into discrete regions. To achieve a high component density with anisotropic etches on [100] wafers, the silicon must be made very thin because of the aspect ratio limitations as a result of the sloping walls (see above). With vertical sidewall etching in a [100] wafer, the etch mask is undercut in all directions to a distance approximately equal to the depth of the etching. Vertical etching in [110] surfaces relaxes the etching requirement dramatically and enables more densely packed structures such as beam leads or image sensors. Kendall[48,57] describes and predicts a wide variety of applications for [110] wafers, such as fabrication of trench

Table 4.4 Matrix for Optimal Selection of Wafer Type

[100] Orientation	[110] Orientation
Inward sloping walls (54.74°)	Vertical {111} walls
The sloping walls cause a lot of real estate loss	Narrow trenches with high-aspect ratio are possible
Flat bottom parallel to surface is ideal for membrane fabrication	Multifaceted cavity bottom ({110} and {100} planes) makes for a poor diaphragm
Bridges perpendicular to a V-groove bound by (111) planes cannot be underetched	Bridges perpendicular to a V-groove bound by (111) planes can be undercut
Shape and orientation of diaphragms convenient and simple to design	Shape and orientation of diaphragms awkward and more difficult to design
Diaphragm size, bounded by nonetching {111} planes, is relatively easy to control	Diaphragm size is difficult to control (the <100> edges are not defined by nonetching planes)

capacitors, vertical multijunction solar cells, diffraction gratings, infrared interference filters, large area cathodes, and filters for bacteria.

Laser Spoiling

A laser can be used to melt or "spoil" the shallow {111} surfaces, making it possible to etch deep vertical-walled holes through a [110]-oriented wafer as shown in Figure 4.28a.[50,58,59] The absorbed energy of a neodymium-doped yttrium aluminium garnet (Nd:YAG) laser beam causes a local melting or evaporation zone, enabling etchants to etch the shallow {111} planes in the line of sight of the laser. Etching proceeds until "unspoiled" (111) planes are encountered. Some interesting resulting possibilities, including partially closed microchannels, are shown in Figure 4.28c.[58,60] Note that with this method it is possible to use [111] wafers for micromachining. The light of the Nd:YAG laser is very well suited for this micromachining technique as a result of the 1.17 eV photon energy, just exceeding the bandgap energy of Si. Details on this laser machining process can be found, for example, in Alavi et al.[60,61]

Wet Isotropic and Anisotropic Etching

Introduction

Besides for the shaping of 3D microstructures, wet etching is used for cleaning, removing surface damage, polishing, and characterizing structural and compositional features.[7] The most important parameters in wet chemical etching are bias (undercut), tolerance, etch rate, anisotropy, selectivity, overetch, feature size control, and loading effects. These controlling parameters are very similar to the parameters controlling dry chemical etching (see Chapter 3). The emphasis in this chapter is on wet etching of single-crystal Si. Wet chemical etching of Si provides a higher degree of selectivity than dry etching techniques. Wet etching is usually also faster: a few microns to tens of microns per minute for isotropic

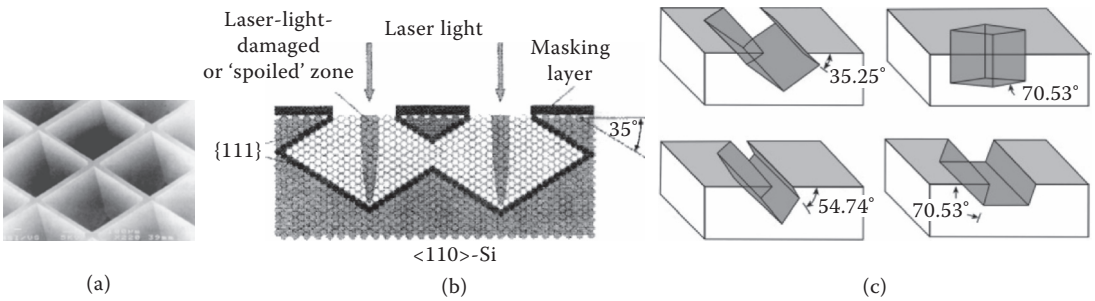

FIGURE 4.28 Laser/KOH machining. (a) Holes through a (110) Si wafer created by laser spoiling and subsequent KOH etching. The two sets of (111) planes making an angle of 70° are the vertical walls of the hole. The (111) planes making a 35.26° angle with the surface tend to limit the depth of the hole, but laser spoiling enables one to etch all the way through the wafer. (b) After laser spoiling, the line-of-sight (111) planes are spoiled, and etching proceeds until unspoiled (111) planes are reached. (c) Some of the possible features rendered by laser spoiling. 3 Transport of by-products away from surface

FIGURE 4.29 Wet etching processes.

etchants and about 1 μm/min for anisotropic wet etchants versus 0.1 μm/min in typical dry etching. More recently, however, rates of up to 6 μm/min were achieved using high-density plasmas for dry etching of Si (see Chapter 3).

Modification of the nature of the wet etchant and/or operating temperature can also alter the selectivity to the silicon dopant concentration and type and, especially when using alkaline etchants, to crystallographic orientation. Etching proceeds by reactant transport to the surface (1), surface reaction (2), and reaction product transport away from the surface (3) (see Figure 4.29). If (1) or (3) is rate determining, etching is diffusion limited, and etching is controlled by the hydrodynamics of the system; thus, the process may be enhanced by stirring. Mass transport-determined etching, being isotropic, gives rise to rounded features. This also means that the surface reactions (2) are fast and that the etch rate is not sensitive to the nature of the surface, e.g., its crystallographic orientation or morphology. Diffusion-limited processes have lower activation energies (in the order of a few kilocalories per mole) than reaction rate-controlled processes and therefore are relatively insensitive to temperature variations. If a surface reaction (2) is the slowest step and thus constitutes the rate-determining step, etching is reaction rate limited and depends strongly on the temperature, the crystallographic orientation, and/or morphology of the etching material, as well as solution composition. In other words, with surface kinetics important the etch rate is very likely to be sensitive to surface orientation. In general, reaction rate limitation is preferred because it is easier to reproduce a temperature setting than a stirring rate. The best generic etching apparatus has both a good temperature controller and a reliable stirring facility.[62,63]

Preferential or selective etching (also *structural etching*) is a type of etching that is usually isotropic but exhibits some anisotropy.[64] These etchants are used to produce a difference in etch rate between different materials or between compositional or structural variations of the same material on the same crystal plane. These types of etches are often the fastest and simplest techniques to delineate electrical junctions and to evaluate the structural perfection of a single crystal in terms of, for example, slip and stacking faults. The artifacts introduced by the defects etch into small pits of characteristic shape. Most of the etchants used for this purpose are acids with an oxidizing additive.[65–69]

Isotropic Etching

Usage of Isotropic Etchants When etching silicon with aggressive acidic etchants, rounded isotropic patterns form. The method is widely used for:

1. Removal of work-damaged surfaces
2. Rounding of sharp anisotropically etched corners (to avoid stress concentration)
3. Removing of roughness after dry or anisotropic etching
4. Creating structures or planar surfaces in single-crystal slices (thinning)
5. Patterning single-crystal, polycrystalline, or amorphous films
6. Delineation of electrical junctions and defect evaluation (with preferential isotropic etchants)

For isotropic etching of silicon, the most commonly used etchants are mixtures of nitric acid (HNO_3) and hydrofluoric acids* (HF). In the case of HNO_3, water can be used as a diluent, but acetic acid (CH_3COOH) is preferred because it prevents the dissociation of the nitric acid better and thus preserves the oxidizing power of HNO_3, which depends on the undissociated nitric acid species for a wide range of dilution.[4] The etchant is called the HNA system; we will return to this etch system below.

* Be careful when working with HF; it is deceptive because it looks like water, and even when not a strong acid, it penetrates the skin (adsorption) and slowly attacks bones.

Simplified Reaction Scheme In acidic media, the Si etching process involves hole injection into the Si valence band by an oxidant, an electrical field, or photons. Nitric acid in the HNA system acts as an oxidant; other oxidants such as H_2O_2 and Br_2 also work.[70] The holes attack the covalently bonded Si, oxidizing the material, followed by a reaction of the oxidized Si fragments with OH^- and subsequent dissolution of the silicon oxidation products in HF. It was Kooij et al.[71] who, from electrochemical measurements on the Si/HF/HNO_3 system, concluded that the holes, in the absence of photons and an applied field, are introduced by HNO_3:

$$HNO_3 + H_2O + HNO_2 \rightarrow 2HNO_2 + 2OH^- + 2h^+ \qquad \text{Reaction 4.1}$$

The holes (h^+) in Reaction 4.1 are generated in an autocatalytic process; HNO_2 generated in the above reaction re-enters into the further reaction with HNO_3 to produce more holes. With a reaction of this type, there is an induction period before the oxidation reaction takes off until a steady-state concentration of HNO_2 has been reached. This induction period has been observed at low HNO_3 concentrations.[70] After hole injection, OH^- groups attach to the oxidized Si species to form SiO_2, liberating hydrogen in the process:

$$Si^{4+} + 4OH^- \rightarrow SiO_2 + H_2 \qquad \text{Reaction 4.2}$$

HF dissolves the SiO_2 by forming the water-soluble H_2SiF_6. The overall reaction of HNA with Si is then:

$$Si + HNO_3 + 6HF \rightarrow H_2SiF_6 \text{ (water-soluble)} + HNO_2 + H_2O + H_2 \text{ (bubbles)} \qquad \text{Reaction 4.3}$$

The simplification in the above electrochemical component of the reaction scheme is that only holes are taken into account. In the actual Si acidic corrosion reaction, both holes and electrons are involved. The question of hole and/or electron participation in Si corrosion will be considered after the introduction below of the model for the Si/electrolyte interfacial energetics. We will learn from that model that the rate-determining step in acidic etching involves hole injection in the valence band, whereas in alkaline anisotropic etching, it involves electron injection in the conduction band by surface states. The reactivity of a hole injected in the valence band is significantly greater than that of an electron injected in the conduction band. The observation of isotropy in acidic etchants and anisotropy in alkaline etchants centers on this difference in reactivity.

Isotropic etching can be performed chemically, in very aggressive solutions containing HF and an oxidizing agent such as HNO_3, or electrochemically, in much less aggressive fluoride-containing solutions. Both methods offer the possibility of forming porous Si. Porous Si formation is easier to control using the electrochemical method. For electrochemical etching, an electrical contact must be made to the back side of the sample, which limits the possibilities of the process (see below).

Iso-Etch Curves By the early 1960s, the isotropic HNA silicon etch was well characterized. Schwartz and Robbins published a series of four very detailed papers on the topic between 1959 and 1976.[3–6] Most of the material presented below is based on their work.

HNA etching results, represented in the form of iso-etch curves, for various weight percentages of the constituents are shown in Figure 4.30. For this work,

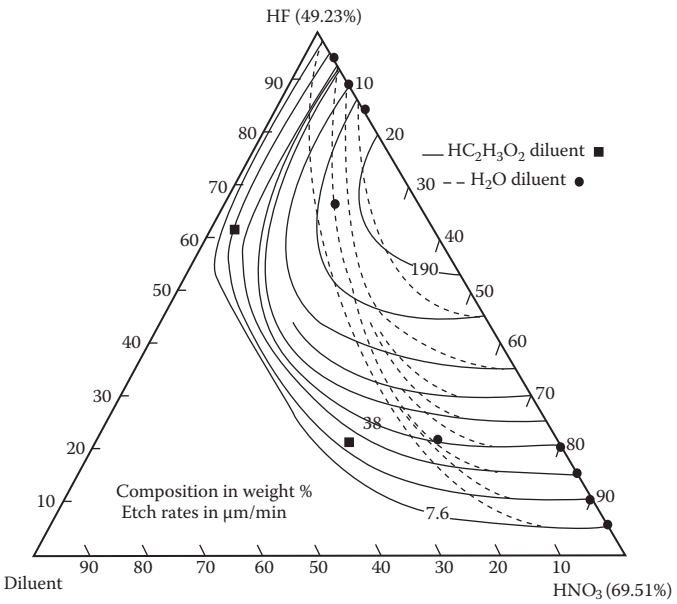

FIGURE 4.30 Iso-etch curves. (Robbins, H., and B. Schwartz. 1960. Chemical etching of silicon-II: the system HF, HNO_3, H_2O, and $HC_2C_3O_2$. *J Electrochem Soc* 107:108–11,[4] recalculated for one-sided Si etching and expressed in microns per minute.)

normally available concentrated acids of 49.2 wt% HF and 69.5 wt% HNO_3 are used. Water as diluent is indicated by dashed-line curves, whereas acetic acid is noted by solid-line curves. Acetic acid is less polar than water and helps prevent the dissociation of HNO_3, thereby allowing the formation of more of the species directly responsible for the oxidation of Si. A typical formulation for HNA is 250 mL of HF, 500 mL of HNO_3, and 800 mL of CH_3COOH. When used at room temperature, this formulation results in an etch rate of about 4–20 μm/min, increasing with agitation.[72] In Figure 4.30 we have recalculated the curves from Robbins and Schwartz[4] to express the etch rate in microns per minute and divided the authors' numbers by 2 as we are considering one-sided etching only. The highest etch rate is observed around a weight ratio HF-HNO_3 of 2:1 and is nearly 100 times faster than anisotropic etch rates. Adding a diluent slows down the etching. From these curves, the following characteristics of the HNA system can be summarized:

1. At high HF and low HNO_3 concentrations, the iso-etch curves describe lines of constant HNO_3 concentrations (parallel to the HF-diluent axis); consequently, the HNO_3 concentration controls the etch rate. Etching at those concentrations tends to be difficult to initiate and exhibits an uncertain induction period (see above). In addition, it results in relatively unstable silicon surfaces proceeding to slowly grow a layer of SiO_2 over time. The etch is limited by the rate of oxidation; therefore, it tends to be orientation-dependent and affected by dopant concentration, defects, and catalysts (sodium nitrate is often used). In this regime, the temperature influence is more pronounced, and activation energies for the etching reaction of 10–20 kcal/mol have been measured.
2. At low HF and high HNO_3 concentrations, iso-etch curves are lines parallel to the nitric-diluent axis; that is, they are at constant HF composition. In this case, the etch rate is controlled by the ability of HF to remove the SiO_2 as it is formed. Etches in this regime are isotropic and truly polishing, producing a bright surface with anisotropies of 1% or less (favoring the <110> direction) when used on <100> wafers.[73] An activation energy of 4 kcal/mol is indicative of the diffusion-limited character of the process; consequently, in this regime, temperature changes are less important.
3. In the region of maximal etch rate, both reagents play an important role. The addition of acetic acid, as opposed to the addition of water, does not reduce the oxidizing power of the nitric acid until a fairly large amount of diluent has been added. Therefore, the rate contours remain parallel with lines of constant nitric acid over a considerable range of added diluent.
4. In the region around the HF vertex, the surface reaction rate-controlled etch leads to rough, pitted Si surfaces and sharply peaked corners and edges. In moving toward the HNO_3 vertex, the diffusion-controlled reaction results in the development of rounded corners and edges, and the rate of attack on (111) planes and (110) planes becomes identical in the polishing regime (anisotropy less than 1%; see point 2).

In Figure 4.31, we summarize how the topology of the Si surfaces depends strongly on the composition of the etch solution. Around the maximum etch rates the surfaces appear flat with rounded edges, and very slow etching solutions lead to rough surfaces.[6]

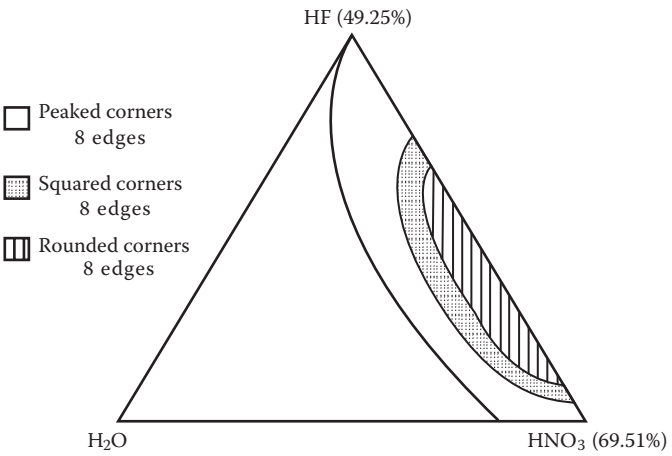

FIGURE 4.31 Topology of etched Si surfaces. (From Schwartz, B., and H. Robbins. 1976. Chemical etching of silicon-IV: etching technology. *J Electrochem Soc* 123:1903–9. With permission.[6])

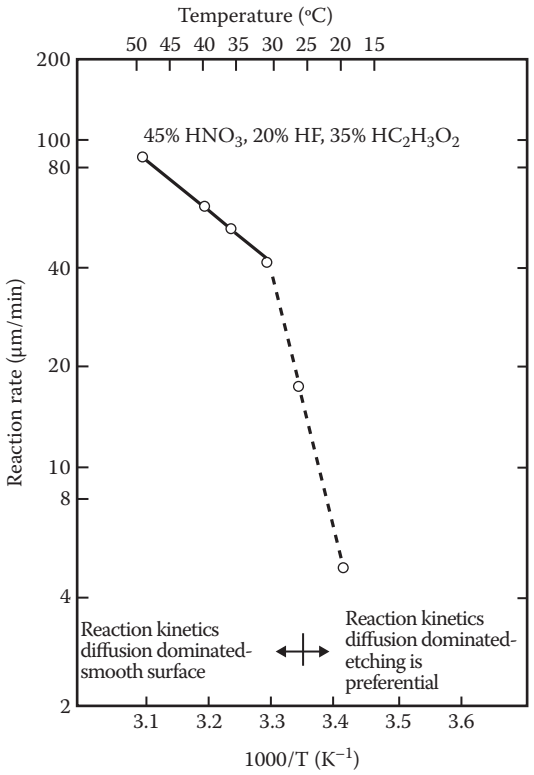

FIGURE 4.32 Etching an Arrhenius plot. Temperature dependence of the etch rate of Si in HF:HNO_3:CH_3:COOH (1:4:3). (From Schwartz, B., and H. Robbins. 1961. Chemical etching of silicon-III: a temperature study in the acid system. *J Electrochem Soc* 108:365–72. With permission.[5])

Arrhenius Plot for Isotropic Etching Schwartz and Robbins[5] studied the effect of temperature on the reaction rate in the HNA system in detail. An Arrhenius plot for etching silicon in 45% HNO_3, 20% HF, and 35% $HC_2H_3O_2$, culled from their work, is shown in Figure 4.32. Increasing the temperature increases the reaction rate. The graph shows two straight-line segments, indicating higher activation energy at less than 30°C and a lower one above this temperature. In the low temperature range, etching is preferential, and the activation energy is associated with the oxidation reaction. At higher temperatures, the etching leads to smooth surfaces, and the activation energy is lower and associated with diffusion-limited dissolution of the oxide.[5]

Loading Effects in Isotropic Etching Two HNA solutions that etch silicon isotropically at a reasonable rate (around 2 μm/min) and leave smooth walls [roughness in the order of 5 nm, as determined from scanning electron microscope (SEM) pictures] are shown in Table 4.5.[74] The etch rates given in this table are averages because the etch rate depends on the mask opening size and structure density on the wafer, resulting from the diffusion-controlled nature of the etching process.

Source: Tjerkstra, R. W. 1999. *Isotropic etching of silicon in fluoride containing solutions as a tool for micromachining.* PhD diss., University of Twente, Twente, the Netherlands.[74]

With isotropic etchants, the etchant moves downward and outward from an opening in the mask, undercuts the mask, and enlarges the etched pit while deepening it (Figure 4.33). The resulting isotropically etched features show more symmetry and rounding when agitation accompanies the etching (the process is diffusion limited). This agitation effect is illustrated in Figure 4.33. With agitation, the etched feature approaches a more ideal round cup; without agitation, the etched feature resembles a rounded box.[75] However, the flatness of the bottom of the rounded box generally is poor because the flatness is defined by agitation. Therefore, sometimes solutions are on purpose not stirred during etching because stirring enhances the etch rate in the direction of fluid flow, yielding badly shaped channels.

As we saw above, the etching of silicon in HF/HNO_3 solutions involves two processes: the oxidation of the silicon surface and the subsequent removal of the oxidized silicon by the fluoride in the solution. In the case of isotropic etching, the rate of the latter process is determined by the transport of fluoride ions to the surface (diffusion limited). This can lead to loading effects as illustrated during the isotropic etch of a spiral in Figure 4.34a.

We observe that the channels on the rim of the spiral have a larger diameter than the channels in the middle of the spiral. This is because on the rim of the spiral there is no silicon that etches and consumes fluoride ions so the ions above the mask material next to the outermost channels can diffuse to these channels. This leads to nonuniformities in

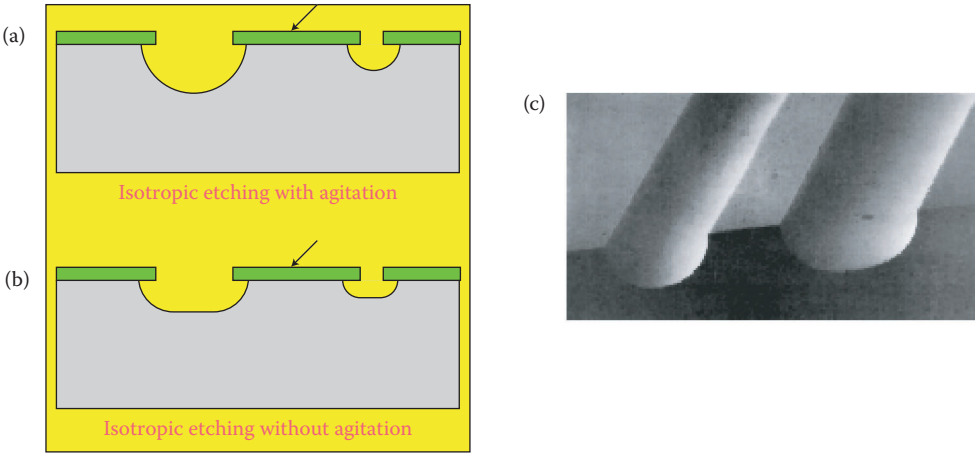

FIGURE 4.33 Isotropic etching of silicon with (a) and without (b) etchant solution agitation; (c) Examples of isotropic etching in Si. Left groove with agitation, right groove no agitation.

the widths of the channels on the rim of the spiral. Stirring the solution during etching does not necessarily help because, as we just saw, that enhances the etching in the direction of fluid flows, yielding badly shaped channels. In an attempt to solve the loading effect problem, the spiral may be surrounded with sacrificial channels with the same width and the same distance from each other as the channels in the spiral ("compensation structures") as illustrated in Figure 4.34b. The etching of these extra structures takes away the extra fluoride that would otherwise cause the broadening of the outer channels. From work by Kuiken et al.,[76] Tjerkstra[74] concluded that for short etch times (etch times in the order of seconds) the bulk concentration is reached at a distance of around $3(Dt)^{1/2}$, in which D is the diffusion coefficient and t the time.

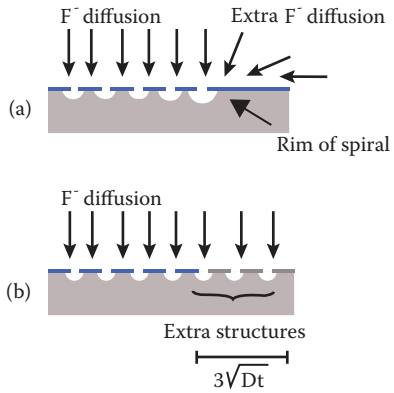

FIGURE 4.34 Side view of anisotropically etched spiral, illustrating the loading effect. (a) The fluoride ions in the area next to the etching spiral can diffuse to the outer channels. These channels etch faster than the other channels because of the extra supply of fluoride. (b) To reduce this effect, extra structures are placed around the spiral that reduce the extra supply of fluoride. This results in a uniform channel width (Tjerkstra, R. W. 1999. *Isotropic etching of silicon in fluoride containing solutions as a tool for micromachining.* PhD diss., University of Twente, Twente, the Netherlands.[74])

The enhanced etching of structures at the rim of the spiral in Figure 4.34 may also be a temperature effect. Etching is the result of an exothermic reaction; thus, the temperature of the solution increases during etching. This causes the appearance of fluid flow, as shown in Figure 4.35. The channels at the rim of the spiral may get an extra supply of fresh solution and thus etch faster.

In Chapter 3 we encountered loading effects also when we discussed dry etching, where they are more prevalent because the etchant concentration is much lower in the gas phase.

Masking for Isotropic Silicon Etchants Acidic etchants are very fast; for example, an etch rate for Si of

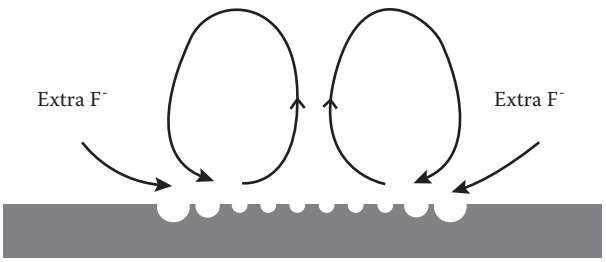

FIGURE 4.35 Enhanced etching caused by fluid flow resulting from the increased temperature of the etching solution. (Tjerkstra, R. W. 1999. *Isotropic etching of silicon in fluoride containing solutions as a tool for micromachining.* PhD diss., University of Twente, Twente, the Netherlands.[74])

Table 4.6 Masking Materials for Acidic Etchants

	Etchants		
Masking	Piranha (4:1, H_2O_2: H_2SO_4)	Buffered HF (5:1NH_4F: conc.HF)	HNA
Thermal SiO_2		0.1 μm/min	300–800 Å/min. Limited etch time, thick layers often are used because of ease of patterning
CVD (450°C) SiO_2		0.48 μm/min	0.44 μm/min
Corning 7740 glass		0.063 μ/min	1.9 μ/min
Photoresist	Attacks most organic films	OK for a short while	Resists do not stand up to strong oxidizing agents like HNO_3 and are not used
Undoped Si polysilicon	Forms 30 Å of SiO_2	0.23–0.45 Å/min	0.7–40 μm/min at RT [at a dopant concentration $<10^{17}$ cm^{-3} (*n* or *p*)]
Black wax			Usable at room temperature
Au/Cr	OK	OK	OK
LPCVD Si_3N_4		1 Å/min	Etch rate is 10–100 Å/min; preferred masking material

The many variables involved necessarily means that the given numbers are approximate only.

up to 50 μmin^{-1} can be obtained with 66% HNO_3 and 34% HF (volumes of reagents in the normal concentrated form).[64,77] Isotropic etchants are so aggressive that the activation barriers associated with etching the different Si planes are not differentiated; all planes etch equally fast, making masking a real challenge.

Although SiO_2 has an appreciable etch rate of 300–800 Å/min in the HF:HNO_3 system, thick layers of SiO_2 are often used as a mask, especially for shallow etching, as the oxide is so easy to form and pattern. A mask of nonetching Au or Si_3N_4 is needed for deeper etching. Photoresists do not stand up to strong oxidizing agents such as HNO_3, and neither does Al.

Silicon itself is soluble to a small extent in pure HF solutions; for a 48% HF, at 25°C a rate of 0.3 Å/min was observed for n-type, 2-Ω-cm (111)-Si. It was established that Si dissolution in HF is not the result of oxidation by dissolved oxygen. Diluted HF etches silicon at a higher rate because the reaction in aqueous solutions proceeds by oxidation of Si by OH^- groups.[78] A typically buffered HF (BHF) solution, also called buffered oxide etch, has been reported to etch Si at radiochemically measured rates of 0.23–0.45 Å/min, depending on doping type and dopant concentration.[79] In BHF, HF is buffered with NH_4F to control the pH value (–log[H^+]) at constant level and to replenish the depletion of fluoride ions to maintain a stable etch performance. BHF is the preferred SiO_2 etch:

$$SiO_2 + 4HF + 2NH_4F \rightarrow (NH_4)_2\,SiF_6 + 2H_2O$$

$$SiO_2 + 3HF_2^- + H^+ \rightarrow SiF_6^{2+} + 2H_2O \quad \text{Reaction 4.4}$$

By reducing the dopant concentration (*n* or *p*) to less than 10^{17} atoms/cm^3, the etch rate of Si in HNA is reduced by ≈150.[80] The doping dependence of the etch rate provides yet another means of patterning a Si surface (see next section). A summary of masks that can be used in acidic etching is presented in Table 4.6.

A simple way to detect the end-point for BHF* etching of a layer of SiO_2 on Si is to monitor the wetting properties of the surface. Whereas SiO_2 wets, Si is hydrophobic.

Dopant Dependence of Silicon Isotropic Etchants The isotropic etching process is fundamentally a charge-transfer mechanism. With isotropic etching Si at open circuit, we will learn further below, the chemical etch may have both chemical and electrochemical components. In the latter case, mobile charge carriers are injected or extracted from the solid, making the reaction sensitive to an applied potential. This also explains the etch rate dependence on dopant type and dopant concentration. Typical etch rates with an HNA system (1:3:8) for n- or p-type dopant concentrations more than 10^{18} cm^3 are 1–3 μm/min. As presented in the preceding section, a reduction of the etch rate by 150 times

* HF is inert in contact with skin but attacks bone.

is obtained in n- or p-type regions with a dopant concentration of 10^{17} cm^{-3} or smaller.[81] This presumably is because of the lower mobile carrier concentration available to contribute to the charge transfer mechanisms. In any event, heavily doped silicon substrates with high conductivity can be etched more readily than lightly doped materials. Dopant-dependent isotropic etching can also be exploited in an electrochemical setup as described in the next section. Although doping changes the chemical etch rate, attempts to exploit these differences for industrial production have failed.[81] This situation is different in the case of electrochemical isotropic etching (see next section).

Preferential Etching A variety of additives to the HNA system, mainly oxidants, can be included to modify the etch rate, surface finish, or isotropy, rendering the etching baths preferential. It is clear that the effect of these additives will only show up in the reaction-controlled regime. Only additives that change the viscosity of the solution can modify the etch rate in the diffusion-limited regime, thereby changing the diffusion coefficient of the reactants.[70,82] We will not review the effect of these additives any further; refer to Table 4.7 and the cited literature for more information.[65–69]

Problems Associated with Isotropic Etchants There are several problems associated with isotropic etching of Si. First, it is difficult to mask with high precision using a desirable and simple mask such as SiO_2 (etch rate is 2–3% of the silicon etch rate). Second, the etch rate is very agitation sensitive in addition to being temperature sensitive. This makes it difficult to control lateral and vertical geometries. Electrochemical isotropic etching (see below) and the development of anisotropic etchants in the late 1960s (see below) were able to overcome many of these problems.

A comprehensive review of isotropic etchants solutions can be found in Kern et al.,[64] including a review of different techniques practiced in chemical etching such as immersion etching, spray etching, electrolytic etching, gas-phase etching, and molten salt etching (fusion techniques). Table 4.7 lists some isotropic and preferential etchants and their specific applications.

Electrochemical Isotropic Silicon Etch—First Example of an Etch Stop For the electrochemical etching of Si, holes are needed at the substrate surface. In p-type Si, these holes are automatically present in the material. In n-type Si or with intrinsic Si, holes can be generated by, for example, illuminating the substrate with photons having energies larger than the bandgap (1.1 eV). The thus-created holes can be forced to the surface by applying a potential to an ohmic contact to the Si. In this case, a high-temperature or extremely aggressive chemical etching process is replaced by an electrochemical procedure using a much milder solution, thus allowing even a simple photoresist mask to be used.[64] In electrochemical acidic etching, with or without illumination of the corroding Si electrode, an electrical power supply is used to drive the chemical reaction by supplying holes to the silicon surface [working electrode (W-EL), see Figure 4.36a]. A voltage is applied across the silicon wafer, and a counter electrode (C-EL, usually platinum) is arranged in the same etching solution. Oxidation is promoted by a positive bias applied to the silicon, causing an accumulation of holes in the silicon at the silicon/electrolyte interface. Under this condition, oxidation at the surface proceeds rapidly while the oxide is readily dissolved by the HF solution. No oxidant such as HNO_3 is needed to supply the holes; excess electron-hole pairs are created by the electrical field at the surface and/or by optical excitation, thereby increasing the etch rate. This technique proved successful in removing heavily doped layers, leaving behind the more lightly doped membranes in all possible dopant configurations: p on p^+, p on n^+, n on p^+, and n on n^+.[87,88] This electrochemical etch-stop technique is demonstrated in Figure 4.36b.[89] A 5% HF solution is used; the electrolyte cell is kept in the dark at room temperature; and the distance between the Si anode and the Pt cathode in the electrochemical cell is 1–5 cm. Instead of using HF, one can substitute NH_4F (5 wt%) for the electrochemical etching as described by Shengliang.[90] Shengliang reports a selectivity of n-type silicon to n^+-type silicon (0.001 Ω cm) of 300 with the latter etchant. In Figure 4.36b, the current density versus applied voltage across the anode and cathode during

Table 4.7 Isotropic and Preferential Defect Etchants and Their Specific Applications

Etchant	Application/Material	Remark/Reference
HF 8 vol%, HNO_3 75 vol%, and CH_3COOH 17 vol%	n- and p-type Si, all planes, general etching	Planar etch; e.g., 5 μm/min at 25°C
1 part 49% HF, 1 part (1.5M-CrO_3) (by volume)	Delineation of defects on (111), (100), and (110) Si without agitation	Yang etch[65]
5 vol parts nitric acid (65%), 3 vol parts HF (48%), 3 vol parts acetic acid (96%), 0.06 parts bromine	Polishing etchant used to remove damage introduced during lapping	So-called CP4 etchant; Heidenreich, US Patent 2619414
HF 48%	SiO_2	Etch rate is 20–2000 nm/min; etch rate for Si is 0.3 Å/min for n-type 2 Ω cm (111); etch rate for Al is 5 nm/min
HF:NH_4F (buffered HF 28 ml HF, 170 ml H_2O, 2113 g NH_4F)	SiO_2	Etch rate is 100–500 nm/min at 25°C
1HF, 3HNO_3, 10 CH_3COOH	Delineates defects in (111) silicon; etches p^+ or n^+ and stops at p^- or n^-	Dash etch[83]; p- and n-type Si at 1300 Å/min in the [100] direction and 46 Å/min in the [111] direction at 25°C
1HF, 1(5M-CrO_3)	Delineates defects in (111); needs agitation; does not reveal etch pits on (100) well	Sirtl etch[84]
HF:H_2O_2	Titanium	880 nm/min
2HF,1(0.15M-$K_2Cr_2O_7$)	Yields circular (100) Si dislocation etch pits; agitation reduces etch time	Secco etch[69]
60 ml HF, 30 ml HNO_3, 30 ml (5M-CrO_3), 2 g $Cu(NO_3)_2$, 60 ml CH_3COOH, 60 ml H_2O	Delineates defects in (100) and (111) Si; requires agitation	Jenkins etch[85]
H_2O_2	Tungsten	20–100 nm/min
34 g KH_2PO_4, 13.4 g KOH, 33 g $K_3FE(CN)_6$ and H_2O to make up 1 L	Tungsten	160 nm/min
1 ml HCl, 9 ml saturated $CeSO_4$ solution	Chromium	80 nm/min
1 ml HCl, 1 ml glycerine	Chromium	80 nm/min
2HF, 1(1M-CrO_3)	Delineates defects in (100) Si without agitation; works well on resistivities 0.6–15.0 Ω cm n- and p-types)	Schimmel etch[86]
2HF, 1(1M-CrO_3), 1.5 H_2O	Works well on heavily doped (100) Si	Modified Schimmel
HF/$KMnO_4$/CH_3COOH	Epitaxial Si	
3 ml HCl, 1 ml HNO_3	Gold	25–50 μm/min Aqua regia
4 g KI, 1 g I_2, and 40 ml H_2O	Gold	0.5–1 μm/min
H_3PO_4 Etchants	Si_3N_4	Etch rate is 5–10 nm/min 160–180°C
KOH + alcohols	Polysilicon	85°C
H_2SO_4/H_2O_2	Organic layers	>1000 nm/min
Acetone	Organic layers	>4000 nm/min
H_3PO_3/ $HNO_3/HC_2H_3O_2$	Aluminum	Etch rate is 660 nm/min 40–50°C
HNO_3/BHF/water	Si and polysilicon	0.1 μm/min for single-crystal Si

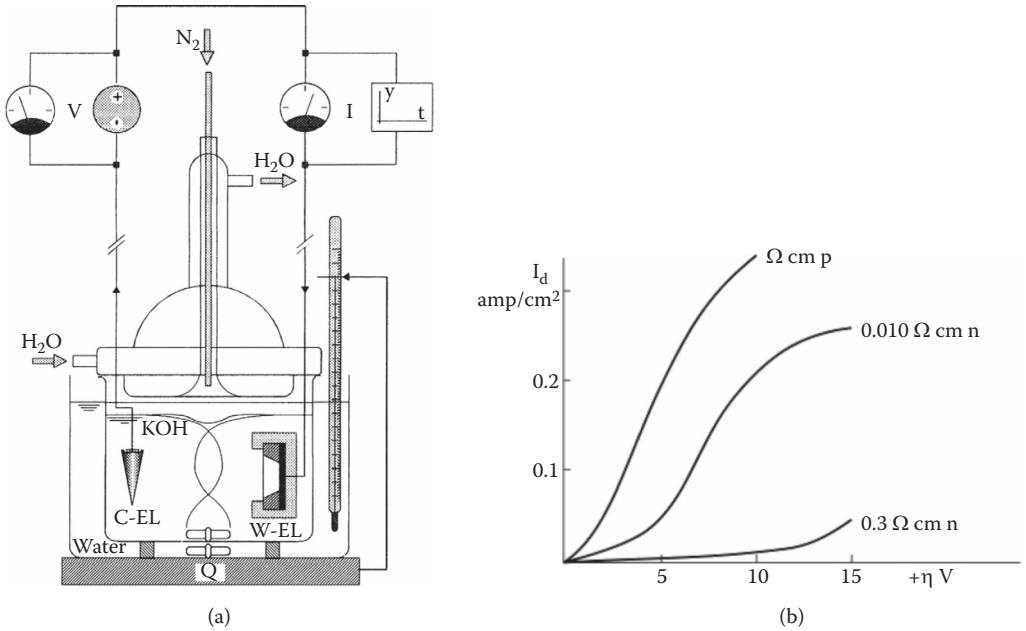

FIGURE 4.36 (a) Electrochemical etching apparatus. W-EL, working electrode (Si); C-EL, counter electrode (e.g., Pt); Q, heat supplied. (b) Current-voltage (*I-V*) curves in electrochemical etching of silicon of various doping. Etch rate dependence on dopant concentration and dopant type for HF-anodic etching of Si. (From van Dijk, H. J. A., and J. de Jonge. 1970. Preparation of thin silicon crystals by electrochemical thinning of epitaxially grown structures. *J Electrochem Soc* 117:553–54. With permission.[89])

dissolution is plotted (*I-V*). The current density is related to the dissolution rate of silicon. It can be seen that p-type and heavily doped n-type materials can be dissolved at relatively low voltages, whereas n-type silicon with a lower doping level does not dissolve at the same low voltages. Experiments in this same setup with homogeneously doped silicon wafers show that n-type silicon of about 3×10^{18} cm^{-3} (<0.01 Ω cm) completely dissolves in these etching conditions, whereas n-type silicon of donor concentrations lower than 2×10^{16} cm^{-3} (>0.3 Ω cm) barely dissolves. For p-type silicon, dissolution is initiated when the acceptor concentration is higher than 5 × 1015 cm–3 (<3 Ω cm), and the dissolution rate further increases with increasing acceptor concentration.

For more precise electrochemical isotropic etching work, the two-electrode system from Figure 4.36a is replaced with a three-electrode system and a potentiostat. The latter is an instrument used to control the potential of the semiconductor working electrode precisely with respect to a third electrode, the so-called reference electrode (REF) (for example, see Figure 4.46 for a three-electrode and potentiostat setup, and for more theoretical electrochemistry background see Volume I, Chapter 7). The current I passing between the W-EL and the C-EL is recorded as a function of the potential. No current passes through the reference electrode. The potential voltage of the W-EL can be scanned over a given potential range at a certain rate (mV/s). A typical *I-V* curve, also called a cyclic voltammogram, for a p-type silicon sample in an HF solution is shown in Figure 4.37, where the reference electrode used is an Ag/AgCl electrode.

The shape of the curve shown here is determined by the speed at which reactions occur at the silicon surface, and the rate of transport of reacting particles. In general the *I-V* curve for a Si electrode in an HF solution can be divided into three ranges: the cathodic range, the porous range, and the electropolishing range. In the cathodic range, i.e., the potential range negative to the open-circuit potential, the surface hole concentration in the Si electrode is low; therefore, no etching can take place. For p-type Si electrodes in the dark there is also no hydrogen evolution for lack of electrons. If an n-type Si electrode were used, copious hydrogen evolution would be observed in this same voltage range because n-type electrodes have plenty of electrons in the conduction band. The porous range is the potential range

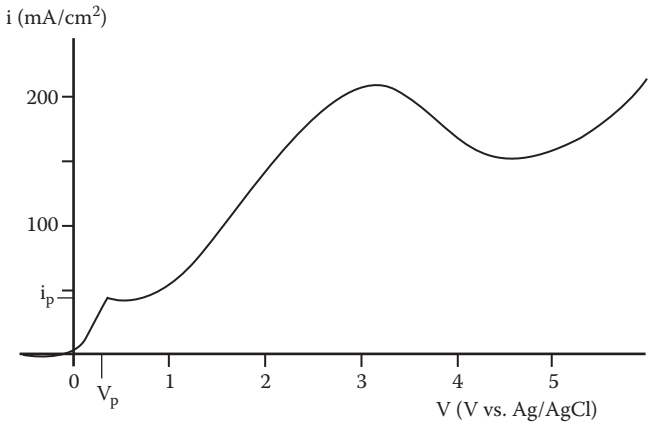

FIGURE 4.37 *I-V* curve of a p-type silicon wafer in a 5% HF solution. Resistivity of the wafer 0.01–0.018 Ωcm, scan rate 500 mV/s. (From Tjerkstra, R. W. 1999. *Isotropic etching of silicon in fluoride containing solutions as a tool for micromachining.* PhD diss., University of Twente, Twente, the Netherlands.[74])

before the potential of the first current peak (V_p in Figure 4.37) where porous Si forms. During the formation of porous Si, hydrogen gas is evolved, and the morphology of the porous Si depends, among other factors, on the doping density of the wafer, the HF concentration, and the current density. The potential range after the first current peak (V_p) is called the electropolishing range. Here, the current density exceeds the so-called critical current density, I_p, marked by the first peak in the *I-V* curve. The silicon etches, leaving behind a smooth (electropolished) surface. Porous Si does not form in this range. The critical current density depends on the fluoride concentration in the electrolyte solution, the dopant concentration in the semiconductor, the hydrodynamics of the system, and the temperature.[75] For a given Si electrode, the critical current density is given as[91]:

$$I_p = Ac^{1.5}e^{\frac{-E_a}{kT}} \qquad (4.1)$$

where the constant, A, is 3300 A cm^{-2} (wt% HF)$^{-1.5}$, c is HF concentration, the activation energy E_a is 0.345 eV, k is Boltzmann constant, and T is the temperature. When the current density is lower than I_p, a porous layer is formed on the Si substrate.

Many researchers have investigated the electrochemical etching of silicon in HF solutions, and initially the following reaction mechanisms were suggested as[9]:

$$Si + 2HF + 2h^+ \rightarrow SiF_2 + 2H^+ \qquad \text{Reaction 4.5}$$

In this scenario, in the porous Si range, two holes are necessary to dissolve each silicon atom. Thus, it was assumed that the silicon dissolves as an Si(II) species, after which it is further oxidized by water or disproportionates to an Si(IV) and Si(0) species. One ends up with the soluble SiF_6^{2-} complex [Si(IV)] and porous Si [Si(0)]. The porous Si deposited on the surface was assumed to be amorphous because it stemmed from the disproportionation reaction of SiF_2. The hydrogen evolution in the porous Si range was believed to be caused by a reaction of the silicon subfluoride:

$$SiF_2 + 2H_2O \rightarrow SiO_2 + 2HF + H_2 \qquad \text{Reaction 4.6}$$

However, porous Si was shown to be monocrystalline, and this theory had to be discarded.[92,93] It was also discovered that the freshly etched Si surface is H-terminated, making the Si surface hydrophobic.[94] Current reaction mechanisms are generally based on the assumption that the presence of a fluoride ion close to the substrate surface causes the Si-Si backbonds to be polarized, thus facilitating the breaking of these bonds.[95–97] The backbonds are broken one at a time, leaving an H-terminated surface and an SiH_xF_y compound that reacts with water and HF to form SiF_6^{2-} and H_2. The overall reaction is then:

$$Si + 2H^+ + 2h^+ \rightarrow Si(IV) + H_2 \qquad \text{Reaction 4.7}$$

At pH < 3, fluoride is mainly present in the form of HF or HF_2^-, so these components are also assumed to be involved in the reactions. It is generally assumed that the electropolishing of silicon takes place in two steps. In the first step an oxide layer is formed, and this oxide layer is subsequently dissolved by HF. Dissolution rates and thickness of the oxide layer have been studied using infrared[98] and current-time measurements.[96,99–102] The second peak in the *I-V* curve in Figure 4.37 is thought to mark a change from one type of oxide to another.[103] The overall reaction of the dissolution of Si in the polishing range is:

$$Si + 2H_2O + 4h^+ \rightarrow SiO_2 + 4H^+ \qquad \text{Reaction 4.8}$$

$$SiO_2 + 6HF \rightarrow SiF_6^{2-} + 2H_2O + 2H^+ \quad \text{Reaction 4.9}$$

For the dissolution of n-type silicon, holes have to be generated by illuminating the sample with photons having energy larger than the bandgap. If the photon flux is high enough, an *I-V* curve similar to that shown in Figure 4.37 can be obtained. If the photon flux is lower than the critical current density, porous Si forms and a potential-independent photocurrent is observed (see further below).

The acidic electrochemical technique has not been used much in micromachining and is primarily used to polish surfaces. Because the etching rate increases with current density, high spots on the surface are more rapidly etched, and very smooth surfaces result. This method of isotropic electrochemical etching has some major advantages that could make it a more important micromachining tool in the future. Such advantages include very smooth etched surfaces (e.g., with an average roughness R_a of 7 nm), room temperature and IC compatible process, usage of simpler resist schemes because the process is much milder than etching in HNA, and etching can be controlled simply by switching a voltage on or off. We will pick up the discussion of anodic polishing, photoetching, and formation of porous Si in HF solutions after gathering more insight into various etching models.

Anisotropic Etching

Introduction Anisotropic etchants shape, also "machine," desired structures in crystalline materials by etching much faster in one direction than another. When carried out properly, anisotropic etching results in geometric shapes bounded by the slowest etching and perfectly defined crystallographic planes. Anisotropic wet etching techniques, dating back to the 1960s at the Bell Laboratories, were developed mainly by trial and error. Figure 4.38 shows the cross-section of a variety of shapes formed in single-crystal Si using anisotropic etching. The thinned membrane shown in Figure 4.38a with diffused resistors may be used for a piezoresistive pressure sensor. In this application, the wafer is selectively thinned from a starting thickness of 300–500 μm to form a diaphragm having a final thickness of 10–20 μm with precisely controlled lateral dimensions and a thickness control of the order of 1 μm or better. A typical procedure involves the steps summarized in Table 4.8.[53]

The development of anisotropic etchants solved the lateral dimension control lacking in isotropic etchants. Lateral mask geometries on planar photoengraved substrates can be controlled with an accuracy and reproducibility of 0.5 μm or better, and the anisotropic nature of the etchant allows this accuracy to be translated into control of the vertical

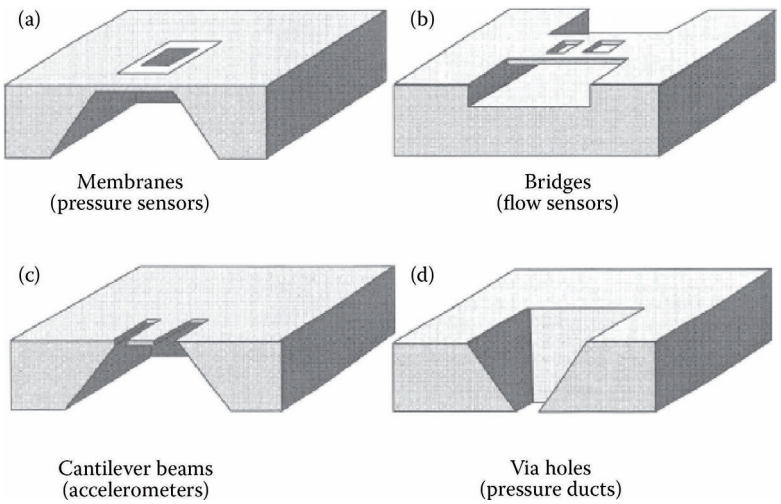

FIGURE 4.38 Anisotropic wet etching in bulk Si. Membranes for (a) pressure sensors, (b) bridges for flow sensors, (c) cantilevers for accelerometers, and (d) via holes for pressure duct are shown.

Table 4.8 Summary of the Process Steps Required for Anisotropic Etching of a Membrane in Si

Process	Duration	Process Temperature (°C)
Oxidation	Variable (h)	900–1200
Spinning resist at 5000 rpm	20–30 s	Room temperature
Prebake	10 min	90
Exposure	20 s	Room temperature
Develop	1 min	Room temperature
Postbake	20 min	120
Strippping of oxide (BHF:1:7)	±10 min	Room temperature
Stripping resist (acetone)	10–30 s	Room temperature
RCA1 (NH_3 (25%)+ H_2O+H_2O_2:1:5:1)	10 min	Boiling
RCA2 (HCl+H_2O+ H_2O_2:1:6:1)	10 min	Boiling
HF-dip (2% HF)	10 s	Room temperature
Anisotropic etch	From minutes up to 1 day	70–100

etch profile. Different etch stop techniques, needed to control the thickness of an active sensor component (such as the membrane or cantilever structures in Figure 4.38), are available. The invention of etch stop techniques truly made the application of the bulk micromachined structures shown in Figure 4.38 commercially manufacturable and viable.

Although anisotropic etchants solve problems of lateral control associated with isotropic etching, they are not problem-free. These etchants are slow—even in the fast etching <100> direction—with etch rates of about 1 µm/min or less. That means that etching through a wafer is a time-consuming process: to etch through a 300-µm-thick wafer, one needs 5 hours. They also must be run hot to achieve these etch rates (80–115°C), precluding many simple masking options. Like the isotropic etchants, their etch rates are temperature sensitive; however, they are not particularly agitation sensitive, which is considered to be a major advantage.

A wide variety of etchants have been used for anisotropic etching of silicon, including alkaline aqueous solutions of KOH, NaOH, LiOH, CsOH, RbOH, NH_4OH, and quaternary ammonium hydroxides, with the possible addition of alcohol. Alkaline organics such as ethylene-diamine, choline (trimethyl-2-hydroxyethyl ammonium hydroxide), hydrazine, and sodium silicates with additives such as pyrocatechol and pyrazine are used as well. Etching of silicon is possible without the application of an external voltage and is dopant insensitive over several orders of magnitude; however, in a curious contradiction to its suggested chemical nature, it has been shown to be bias-dependent.[104,105] This contradiction will be explained with the help of the etching models presented below.

Alcohols such as propanol and isopropanol butanol typically slow the attack on Si.[106,107] The role of pyrocatechol[108] is to speed up the etch rate through complexation or chelation of the reaction products. Additives such as pyrazine and quinone have been described as catalysts by some,[109] but this is contested by others.[110] The etch rate in anisotropic etching is reaction rate controlled and thus temperature-dependent. The etch rate for all planes increases with temperature, and the surface roughness decreases with increasing temperature; thus, etching at higher temperatures gives the best results. In practice, etch temperatures of 80–85°C are used to avoid solvent evaporation and temperature gradients in the solution.

Selected Anisotropic Etchant Systems

Overview In choosing an anisotropic wet etchant, a variety of issues must be considered:

- Ease of handling
- Toxicity
- Etch rate
- Desired topology of the etched bottom surface
- IC compatibility
- Etch stop availability
- Etch selectivity over other materials
- Mask material and thickness of the mask

The principal characteristics of four different anisotropic etchants are listed in Table 4.9. The most commonly used are KOH[10–23,52,110–118] and ethylenediamine pyrocatechol + water (EDP)[108,109,119];

Table 4.9 Principal Characteristics of Four Different Anisotropic Etchants

Etchant/ Diluent/ Additives/ Temperature	Etch Stop	Etch Rate (100) μm/min	Etch Rate Ratio	Remarks	Mask (Etch Rate)
KOH (water) 85°C 44 g/100 ml	$B > 10^{20}$ cm^{-3} reduces etch rate by 20	1.4	400 for (100)/(111) and 600 for (110)/(111)	IC incompatible, avoid in eyes, etches oxide fast, lots of H_2 bubbles	Photoresist (shallow etch at room temperature); Si_3N_4 (<1 nm/min) SiO_2 (28 Å/min)
Ethylenediamine pyrocatechol (water) 115°C 750 ml/120 g/240 ml	$\geq 7 \times 10^{19}$ cm^{-3} reduces the etch rate by 50	1.25	35 for (100)/(111)	Toxic, ages fast, O_2 must be excluded, few H_2 bubbles, silicates may precipitate	SiO_2 (2–5 Å/min), Si_3N_4 (1 Å/min), Ta, Au, Cr, Ag, Cu are not attacked, Al at a 0.33 μm/min
Tetramethyl ammonium hydroxide (TMAH) (water) 90°C	$>4 \times 10^{20}$ cm^{-3} reduces etch rate by 40	1	From 12.5–50 (100)/(111)	IC compatible, easy to handle, smooth surface finish, few studies	SiO_2 etch rate is four orders of magnitude lower than (100) LPCVD Si_3N_4
N_2H_4 (water, isopropyl alcohol) 100°C 100 ml/100 ml	$>1.5 \times 10^{20}$ cm^{-3} practically stops the etch	2.0	10 (100)/(111)	Toxic and explosive, OK at 50% water	SiO_2 (<2 Å/min) and most metallic films; does not attack aluminum

Given the many possible variables, the data in the table are only typical examples.

hydrazine-water is rarely used.[120,121] Quaternary ammonium hydroxide solutions such as tetramethyl ammonium hydroxide-water (TMAHW) and tetraethyl ammonium hydroxide-water (TEAHW) have become popular.[122,123] Each has its advantages and problems. NaOH is not used much anymore.[124]

Potassium Hydroxide The simple KOH water system is the most popular Si anisotropic etchant. A KOH etch, in near-saturated solutions (1:1 in water by weight) at 80°C, produces a uniform and bright surface. Williams and Muller[125] used 50 wt% KOH at 80°C for a reported (100) etch rate of 1.4 μm/min. Nonuniformity of etch rate gets considerably worse at more than 80°C. An abundance of bubbles are seen emerging from the Si wafer while etching in KOH. The etching selectivity between Si and SiO_2 is not very good in KOH because it etches SiO_2 too quickly. KOH is also incompatible with the IC fabrication process (e.g., aluminum bond pads are quickly attacked and damaged) and can cause blindness when it gets in contact with the eyes. The etch rate for low index planes is maximal at around 4 M (see Figure 4.39a and c from Peeters[126] and Lambrechts et al.[127])

Herr[54] found that the high-index crystal planes exhibit the highest etch rates for 6 M KOH and that for lower concentrations the etch bottoms disintegrate into microfacets. In 6 M KOH, the etch-rate order is (311) > (144) > (411) > (133) > (211) > (122). These authors could not correlate the particular etch rate sequence with the measured activation energies. This is in contrast to lower activation energies corresponding to higher etching rates for low index planes as shown further below in Figure 4.40. Their results obtained on large open-area structures differ significantly from previous ones obtained by underetching special mask patterns. The vertical etching rates obtained here are substantially higher than the underetching rates described elsewhere, and the etch rate sequence for different planes is also significantly different. These results suggest that crevice effects may play an important role in anisotropic etching.

To create vertical (100) faces, as shown in Volume I, Chapter 4 (Figure 4.10), in general only KOH works (not EDP or TMAHW), and it has to be carried out in high-selectivity conditions (low temperature, low concentration: 25 wt% KOH, 60°C). Interestingly, high-concentration KOH (45 wt%) at higher temperatures (80°C) produces a smooth sidewall, controllable and repeatable at an angle of 80°. EDP produces 45° angled planes, and TMAHW usually makes a 30° angle.[129]

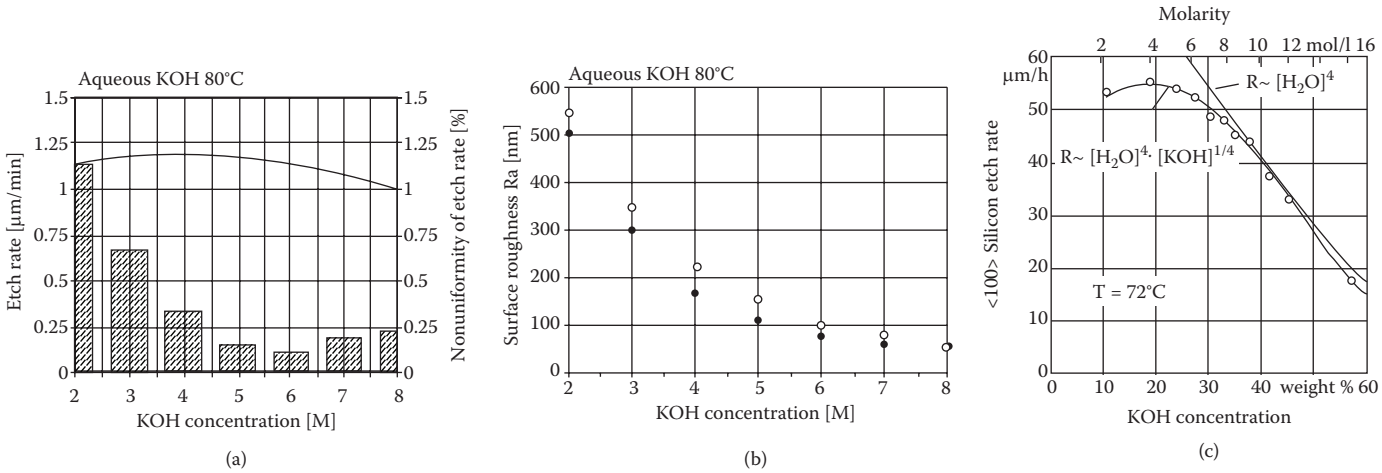

FIGURE 4.39 Anisotropic etching of silicon. (a) Silicon (100) etch rate (line) and nonuniformity of etch rate (column) in KOH at 80°C as a function of KOH concentration. The etch rate for all low index planes is maximal at around 4 M. (b) Silicon (100) surface roughness (Ra) in aqueous KOH at 80°C as a function of concentration for a 1-hour etch time (thin line) and for an etch depth of 60 μm (thick line). (c) Silicon (100) etch rate as a function of KOH concentration at a temperature of 72°C. (a and b from Peeters, E. 1994. Anisotropic etching of crystalline silicon in alkaline solutions–part I: orientation dependence and behavior of passivation layers. *J Electrochem Soc* 137:3612–26. With permission.[52])

Besides KOH,[129] other hydroxides have been used, including NaOH,[104,124] CsOH,[130] and NH_4OH.[130] A major disadvantage of KOH is the presence of alkali ions, which are detrimental to the fabrication of sensitive electronic parts.

Ethylenediamine Pyrocatechol With ethylenediamine pyrocatechol (EDP; sometimes referred to as EPW, for ethylenediamine, pyrocatechol, and water), a variety of masking materials (e.g., SiO_2, Si_3N_4, Au, Cr, Cu, Ag, and Ta) can be used. EDP is less toxic than hydrazine (see below), no sodium or potassium contamination occurs, and the etch rate of SiO_2 is much slower than with KOH. The ratio of etch rates of Si and SiO_2 using EDP can be as large as 5000:1, corresponding to about 2 Å/min of SiO_2 compared with 1 μm/min of Si, which is much larger than the ratio for Si to SiO_2 in KOH, which is at the highest 400:1.[131] Importantly, the etch rate slows down at a lower boron concentration than with KOH. A typical fastest-to-slowest hierarchy of Si etch rates with EDP at 85°C according to Barth[132] is (110) > (411) > (311) > (511) > (211) > (100) > (331) > (221) > (111). Petersen uses 750 ml of ethylenediamine, 120 g of pyrocatechol, and 100 ml of water. This cocktail, at

115°C, results in an etch rate of 0.75 μm/min, with an (100)/(111) etch-rate ratio of 35:1.[75]

Ethylenediamine in EDP reportedly causes allergic respiratory sensitization, and pyrocatechol is described as a toxic corrosive. The material is also optically dense, making end-point detection harder, and it ages quickly; if the etchant reacts with oxygen, the liquid turns a red-brown color, and it loses its useful properties. If cooled down after etching, precipitation of silicates in the solution will occur. Sometimes, precipitation during etching can happen, spoiling the results. When preparing the solution, the last ingredient added should be water because water addition causes the oxygen sensitivity. All the above make the etchant difficult to handle.

In terms of etching and masking layers, amine gallates are similar to EDP but perhaps safer.[133] Amine gallate etchants are not used much but appear promising. They are composed of a mixture of ethanolamine, gallic acid, water, pyrazine, hydrogen peroxide, and a surfactant. Etch rates as high as 2.3 μm/min have been measured on a (100) Si plane, and etch stops at lower boron concentration than it takes to stop EDP have been observed ($>3 \times 10^{19}$ cm^{-3}). Pyrazine and peroxide can be added to increase the etch rate, but they affect the surface roughness negatively.

Ammonium Hydroxide-Water and Tetramethyl Ammonium Hydroxide-Water Efforts continue to find anisotropic etchants that are more compatible with complementary metal oxide semiconductor (CMOS) processing than alkali hydroxides and that are neither toxic nor harmful. Two examples are ammonium hydroxide-water (AHW) mixtures[130] and tetramethyl ammonium hydroxide-water (TMAHW) mixtures (Tabata et al.[123] and Schnakenberg et al.[130]). Kern[77] used AHW (9.7% in water) and achieved 0.11 μm/min etch rates on (100) Si at temperatures of 85–92°C. Schnakenberg et al.[130] reported their best AHW results with a 3.7 wt% solution at 75°C for well-stirred etching baths. For the same solution, these authors demonstrated a boron-dependent etch stop at 1.3×10^{20} cm^{-3} with a selectivity of 1:8000 (see also under Etch-Stop Techniques, this chapter). Ammonia-based etchants have not become widely used for several reasons, including their slow etch rate, tendency to lead to rough surfaces (hillocks), and rapid evaporative losses.[72] A TMAHW [$(CH_3)_4NOH$] solution, on the other hand, is one of the more useful wet etchants for silicon. TMAHW does not decompose at temperatures less than 130°C, a very important feature from the viewpoint of production; it is nontoxic, not expensive, and can be handled easily. TMAHW solutions also exhibit excellent selectivity to silicon oxide and silicon nitride masks. The etchant is so selective for Si over SiO_2 that it is advisable to remove the thin native oxide of Si in HF before attempting a TMAHW etch. The solution is often already present in the clean room because it is used in many positive photoresist developers. At a solution temperature of 90°C and 22 wt% TMAH, a maximum (100) silicon etch rate of 1.0 μm/min is observed, 1.4 μm/min for (110) planes [this is higher than those observed with EDP, AHW, hydrazine water, and tetraethyl ammonium hydroxide (TEA), but slower than those observed for KOH] and an anisotropy ratio, AR(100)/(111), of between 12.5 and 50.[134] A disadvantage is that TMAHW occasionally results in the formation of pyramidical hillocks at the bottom of the etched cavity. From the viewpoint of fabricating various silicon sensors and actuators, a concentration greater than 22 wt% is preferable because lower concentrations result in more pronounced roughness on the etched surface. However, higher concentrations give a lower etch rate and lower etch ratio (100)/(111). Tabata[135] also studied the etching characteristics of pH-controlled TMAHW. To obtain a low aluminum etching rate of 0.01 μm/min, pH values less than 12 for 22 wt% TMAHW were required. At those pH values the Si (100) etching rate is 0.7 μm/min. The aluminum etch rate can also be reduced by adding silicon powder to the etchant.[136] The etch rate for TMAHW begins to slow down for boron doping levels above approximately 1×10^{19} cm^{-3} and decreases by a factor of 40 for 2×10^{20} cm^{-3}.[137]

Hydrazine (H_2N_4) Etch rates with hydrazine-water mixtures are on the order of 2 μm/min, and similar masking materials can be used as with EDP.[75] The (100)/(111) etch ratios are lower than those for KOH or EDP. Hydrazine-water is very reducing and explosive at high hydrazine concentrations (rocket

fuel), is a suspected carcinogen, and is difficult to dispose so its use should be avoided for safety reasons. However, a 50 wt% hydrazine-water solution is stable and is commonly used, and, according to Mehregany,[121] excellent surface quality and sharply defined corners are obtained in Si. Also on the positive side, the etchant has a very low SiO_2 etch rate and will not attack most metal masks except for Al, Cu, and Zn. According to Wise, on the other hand, Al does not etch in hydrazine either, but the etch produces rough Si surfaces.[138]

Arrhenius Plots for Anisotropic Etching A typical set of Arrhenius plots for <100>, <110>, and <111> silicon etching in an anisotropic etchant (e.g., EDP) is shown in Figure 4.34.[52] It is seen that the temperature dependence of the etch rate is large and that the slope differs for the different planes, that is, (111) > (100) > (110). Lower activation energies in Arrhenius plots correspond to higher etch rates. The anisotropy ratio (AR) derived from this figure is:

$$\mathrm{AR} = \frac{(\mathrm{hkl})_1 \text{ etch rate}}{(\mathrm{hkl})_2 \text{ etch rate}} \tag{4.2}$$

The AR is approximately 1 for isotropic etchants and can be as high as 400:200:1 for (110)/(100)/(111) in 50 wt% KOH/H_2O at 85°C. Generally, the activation energies of the etch rates of EDP are smaller than those of KOH. Price found that (111) planes always etch slowest, and the selectivity with respect to (100) in KOH etching can be greatly increased by adding isopropyl alcohol (IPA), a less polar diluent, used to saturate the solution.[107] The sequence for (100) and (110) etching rate can be reversed, for example, to 50:200:8 in 55 vol% ethylene/diamine/H_2O (also at 85°C). The (110) Si plane etches eight times slower and the (111) eight times faster in KOH/H_2O than in ED/H_2O, whereas the (100) etches at the same rate.[111] Working with alcohols and other organic additives often changes the relative etching rate of the different Si planes. Along this line, Seidel et al.[52,110] found that the decrease in etch rate by adding isopropylalcohol to a KOH solution was 20% for the <100> planes but almost 90% for <110> planes. As a result of the much stronger decrease of the etch rate on a (110) surface, the etch ratio of (100)/(110) is reversed.

Misalignment will change the etch rate greatly; a 1° misalignment on the [111] direction may increase the etch rate on (near) the (111) surface by 300%.[139]

Si Surface Roughness in Anisotropic Etching Aniso-tropic etchants frequently leave too rough a Si surface behind, and a slight isotropic etch is used to "touch up" the surface. The average surface roughness, R_a, of Si continuously decreases with increasing KOH concentration as can be gleaned from Figure 4.39b. The silicon etch rate, R, as a function of KOH concentration is shown in Figure 4.39a and c.[52] Because the difference in etch rates for different KOH concentrations is small, a highly concentrated KOH (e.g., 7 M) is preferred in obtaining a smooth surface on low index planes. Except at very high concentrations of KOH, the etched (100) plane becomes rougher the longer one etches. This is thought to be because of the development of hydrogen bubbles, which hinder the transport of fresh solution to the silicon surface, causing "micromasking," which results in hillock formation.[72,140] Average roughness, R_a, is influenced strongly by fluid agitation. Stirring can reduce the R_a values more than an order of magnitude, probably caused by the more efficient removal of hydrogen bubbles from the etching surface when stirring.[141] Ohwada et al.[142] noted that the use of ultrasonic agitation essentially eliminated surface roughness in KOH etching. Baum et al.[143] investigated the surface finish of (100) Si in KOH etching with an atomic force microscope and confirmed that mild ultrasonic agitation improved the surface finish considerably. Hillock formation may also be suppressed by the addition of a suitable oxidizing agent that competes with hydrogen evolution, such as by adding ferricyanide or peroxydisulfate ions. Bressers et al.[144] report a drastic reduction in hillock formation when adding 18 mM $K_3Fe(CN)_6$ to a 4 M KOH solution at 70°C, and Klaassen et al.[145] accomplish the same by adding 5 g/L ammonium peroxydisulfate to a 5-wt% TMAHW solution. Baum et al.[143] found that the inclusion in the KOH bath of oxygen and/or isopropanol results in root mean square roughness values smaller than 20 nm. The effectiveness of these additives has been related to

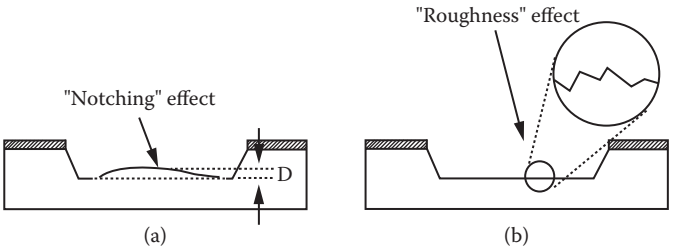

FIGURE 4.41 (a) Macroscopic roughness (notching effect) and (b) microscopic roughness on a Si membrane.

changes of the contact angle between the liquid/gas/etching interface.

A distinction must be made between macroscopic and microscopic roughness (Figure 4.41). Macroscopic roughness, also referred to as notching or pillowing, results when centers of exposed areas etch with a seemingly lower average speed compared with the borders of the areas; therefore, the corners between sidewalls and (100) ground planes are accentuated. Thus, membranes or double-sided clamped beams (microbridges) tend to be thinner close to the clamped edges than in the center of the structure. This difference can be as large as 1–2 µm, which is considerable if one is etching 10–20-µm-thick structures. Notching increases linearly with etch depth but decreases with higher concentrations of KOH. The microscopic smoothness of originally mirror-like polished wafers can also be degraded into microscopic roughness. It is this type of short-range roughness we referred to in discussing Figure 4.39b above. For more background on metrology techniques to measure surface roughness, see Volume III, Chapter 6.

Masking for Anisotropic Etchants Etching through a whole wafer (400–600 µm) takes several hours (a typical wet anisotropic etch rate is 1.1 µm/min), definitely not a fast process. When using KOH, SiO_2 cannot be used as a masking material for features requiring that long an exposure to the etchants. The SiO_2 etch rate as a function of KOH concentration at 60°C is shown in Figure 4.42. There is a distinct maximum at 35 wt% KOH of nearly 80 nm/h. The shape of this curve will be explained further below based on Seidel et al.'s etching model. Experiments have shown that even a 1.5-µm-thick oxide is not sufficient for the complete etching of a 380-µm-thick wafer (6 hours) because of pinholes in the oxide.[128]

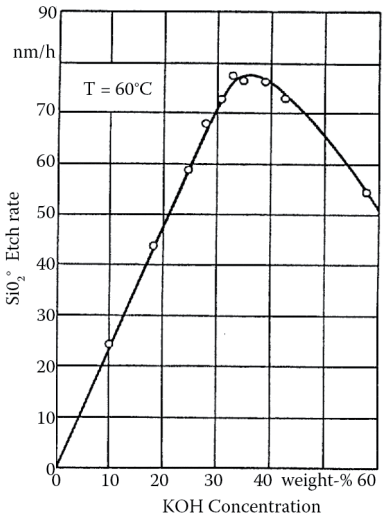

FIGURE 4.42 The SiO_2 etch rate in nanometers per hour as a function of KOH concentration at 60°C. (From Seidel, H., L. Csepregi, A. Heuberger, and H. Baumgartel. 1990. Anisotropic etching of crystalline silicon in alkaline solutions–part I: orientation dependence and behavior of passivation layers. *J Electrochem Soc* 137:3612–26. With permission.[52])

The etch rate of thermally grown SiO_2 in KOH-H_2O somewhat varies and apparently depends not only on the quality of the oxide but also on the etching container and the age of the etching solution, as well as other factors.[48] The Si/SiO_2 selectivity ratio at 80°C in 7 M KOH is 30 ± 5. This ratio increases with decreasing temperature; reducing the temperature from 80 to 60°C increases the selectivity ratio from 30 to 95 in 7 M KOH.[57] Thermal oxides are under strong compressive stress because in the oxide layer one silicon atom takes nearly twice as much space as in single-crystalline Si (see also Volume I, Chapter 4). This might have severe consequences; for example, if the oxide mask is stripped on one side of the wafer, the wafer will bend. Atmospheric pressure chemical vapor-deposited (APCVD) SiO_2 tends to exhibit pinholes and etches much faster than thermal oxide. Annealing of APCVD oxide removes the pinholes, but the etch rate in KOH remains greater by a factor of 2–3 than that of thermal oxide. Low-pressure chemical vapor-deposited (LPCVD) oxide is a mask material of comparable quality as thermal oxide. The etch rate of SiO_2 in EDP is smaller by two orders of magnitude than in KOH.

For prolonged KOH etching, a high-density silicon nitride mask has to be deposited. An LPCVD nitride generally serves better for this purpose than

less-dense plasma-deposited nitride.[146] With an etch rate of less than 0.1 nm/min, a 400-Å layer of LPCVD nitride suffices to mask against KOH etchant. The etch selectivity Si/Si_3N_4 was found to be better than 10^4 in 7 M KOH at 80°C. The nitride also acts as a good ion-diffusion barrier, protecting sensitive electronic parts. Nitride can easily be patterned with photoresist and etched in CF_4/O_2-based plasma or, in a more severe process, in H_3PO_4 at 180°C (10 nm/min).[147] Nitride films are typically under a tensile stress of about 1×10^9 Pa. If, in the overall processing of the devices, nitride deposition does not pose a problem, KOH emerges as the preferential anisotropic wet etchant. For dopant-dependent etching, EDP is the better etchant and generally better suited for deep etching because its oxide etch rate is negligible (<5 Å/min).

Summarizing, oxide and nitride films mask for anisotropic etchants to varying degrees with both mask types being used. When these layers are used to terminate a Si etch in the [100] direction, a low etch rate of the mask layer allows overetching of silicon to compensate for wafer thickness variations. A KOH solution etches SiO_2 at a relatively fast rate of 1.4–3 nm/min; therefore, Si_3N_4 or Au/Cr must be used as a mask against KOH for deep and long etching.

Back-Side Protection of Silicon Wafer during Etching In many cases it is necessary to protect the back of a wafer from an isotropic or anisotropic etchant. The back is either mechanically or chemically protected. In the mechanical method, the wafer is held in a holder, often made from Teflon®. The wafer is fixed between Teflon-coated O-rings that are carefully aligned to avoid mechanical stress in the wafer. In the chemical method, waxes or other organic coatings are spun onto the back of the wafer. Two wafers may also be glued back to back for faster processing.

Etch-Stop Techniques

Introduction

In many cases, it is desirable to stop etching in silicon when a certain cavity depth or a certain membrane thickness is reached. Nonuniformity of etched devices resulting from nonuniformity of the silicon wafer thickness can be high. Taper of double-polished wafers, for example, can be as high as 40 µm![127] Even with the best wafer quality, the wafer taper is still around 2 µm. The taper and variation in etch depth lead to intolerable thickness variations for many applications. High-resolution silicon micromachining relies on the availability of effective etch-stop layers. It is the existence of impurity-based etch stops in silicon that has allowed micromachining to become a high-yield commercial production process. Etch-rate control typically requires monitoring and stabilization of the following parameters:

- Etchant composition
- Etchant aging
- Stabilization with N_2 sparging (especially with EDP and hydrazine)
- Taking account of the total amount of material etched (loading effects)
- Etchant temperature
- Diffusion effects (constant stirring is required, especially for EDP)
- Stirring also leads to a smoother surface through bubble removal
- Trenching (also pillowing) and roughness decrease with increased stirring rate
- Light may affect the etch rate (especially with n-type Si)
- Surface preparation of the sample can have a big effect on etch rate (the native oxide retards etch start; a dip in dilute HF is recommended)

With a good temperature, etchant concentration, and stirring control, the variation in etch depth typically is 1% (see Figure 4.43).[127] A good pretreatment of the surface to be etched is a standard RCA clean (see Volume II, Chapter 1, Wafer Cleaning and Contaminants) combined with a 5% HF dip to remove the native oxide immediately before etching in KOH.

In the early days of micromachining, one of the following techniques was used to etch a Si structure anisotropically to a predetermined thickness. In the simplest mode, the etch time was monitored (in Table 4.9 we listed some etch rates for different etchants) or a bit more sophisticated; the infrared

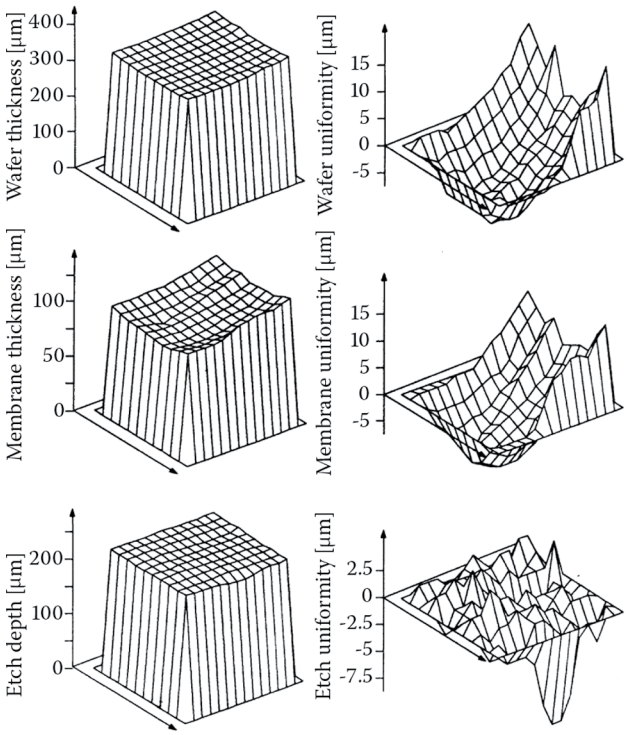

FIGURE 4.43 Map of wafer thickness, membrane thickness, and etch depth. (From Lambrechts, M., and W. Sansen. 1992. *Biosensors: microelectrochemical devices.* Philadelphia: Institute of Physics Publishing. With permission.[127])

transmittance through the etching membrane was followed. For thin membranes, the etch stop cannot be determined by a constant etch time method with sufficient precision. The spread in etch rates becomes critical if one etches membranes down to thicknesses of less than 20 µm; it is almost impossible to etch structures down to less than 10 µm with a timing technique. In the V-groove technique, V-grooves with precise openings (see Volume I, Equation 4.2, $W_0 = W_m - 2z\cot 54.74^\circ = W_m - \sqrt{2}z$) were used such that the V-groove stopped etching at the exact moment a desired membrane thickness was reached (see Figure 4.44).[148]

One can also design wider mask openings on the wafer's edge so that the wafer is etched through at those sites at the moment the membrane has reached the appropriate thickness. Although Nunn and Angell[149] claimed that an accuracy of about 1 µm could be obtained using the V-groove method, none of the mentioned techniques are found to be production worthy. Nowadays the above methods are almost completely replaced

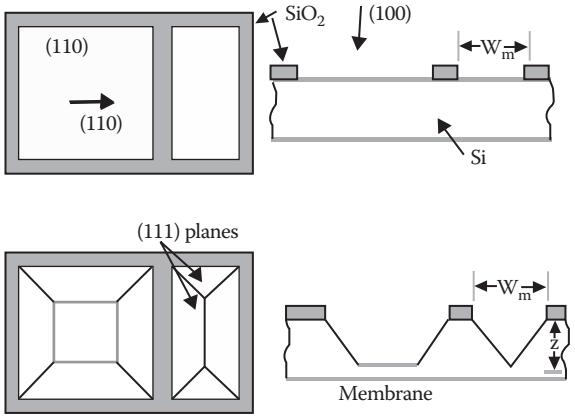

FIGURE 4.44 V-groove technique to monitor the thickness of a membrane. At the precise moment the V-groove is developed, the membrane has reached the desired thickness.

by etch-stop techniques based on a change in etch rate-dependent on doping level or the chemical nature of a stopping layer.

Boron Etch Stop

The most widely used etch-stop technique is based on the fact that anisotropic etchants, especially EDP, do not attack heavily boron-doped (p^{++}) silicon layers. Selective p^{++} doping is typically implemented using gaseous or solid boron diffusion source with a mask (such as silicon dioxide). The maximum practical depth achievable is 15 µm. The boron etch-stop effect was first noticed by Greenwood in 1969.[150] He assumed that the presence of a p-n junction was responsible. In 1971 Bogh[151] found that an impurity concentration of about $7 \times 10^{19}/cm^{-3}$ resulted in the etch rate of Si in EDP decreasing sharply (see also Table 4.9) but without any requirement for a p-n junction. For KOH-based solutions, Price[107] found a significant reduction in etch rate for boron concentrations greater than 5×10^{18} cm^{-3}. The model by Seidel et al. (see below) provides an elegant explanation for the etch stop at high boron concentrations.

From the above, it follows that a simple boron diffusion or implantation, introduced from the front of the wafer, can be used to create beams and diaphragms by etching from the back. A boron etch-stop technique is illustrated in Figure 4.45A for the fabrication of a micromembrane nozzle.[152] The SiO_2 mesa in Figure 4.45Ab leads to the desired boron p^{++} profile. The anisotropic etch from the back clears the

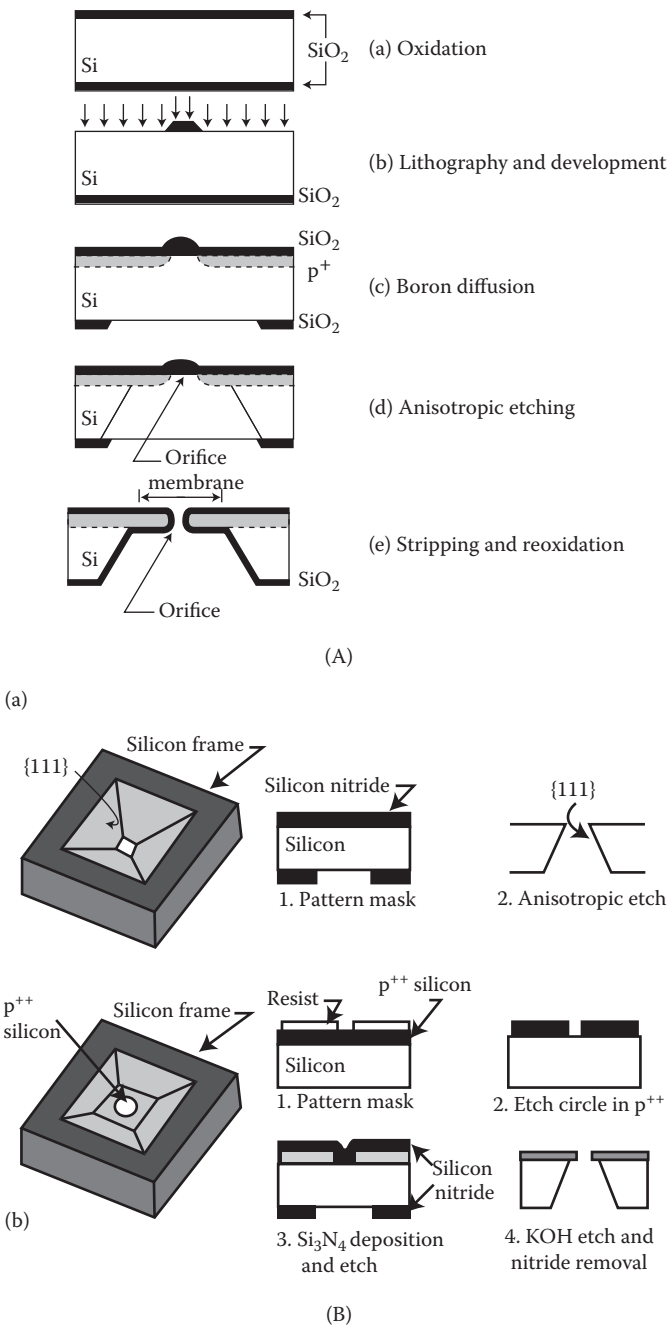

FIGURE 4.45 (A) Illustration of the boron etch stop in the fabrication of a membrane nozzle. (From Brodie, I., and J. J. Muray. 1982. *The physics of microfabrication.* New York: Plenum Press. With permission.[152]) (B) Two alternate methods to fabricate nozzles. (a) Etch stop is based on silicon nitride. (b) Etch stop is based on boron etch stop.

lightly doped p-type Si (Figure 4.45Ad). Stripping and reoxidation produce an orifice in the suspended membrane (Figure 4.45Ae). Two alternative ways of fabricating nozzles—one square and one circular—are illustrated in Figure 4.45B. The method shown in Figure 4.45Ba uses silicon nitride as an etch-stop layer to etch a square nozzle. The side of the backside opening in the silicon nitride must be larger than 71% of the wafer thickness to etch all the way through the wafer (Volume I, Equation 4.2, $W_0 = W_m - 2z\cot 54.74^\circ = W_m - \sqrt{2}z$). The approach shown in Figure 4.45Bb is again based on a p^{++} etch-stop layer. The difference with the approach in Figure 4.45A is that a uniform p^{++} doping profile is first established here, and that layer is subsequently etched into a circular pattern. Layers of p^{++} silicon with a thickness of 1–20 μm can easily be fabricated, and the boron etch stop is very effective; it is not critical when the operator takes the wafer out of the etchant. One important practical note is that the boron etch stop may become badly degraded in EDP solutions that were allowed to react with atmospheric oxygen. Because boron atoms are smaller than silicon, a highly doped, freely suspended membrane or diaphragm will be stretched; the boron-doped silicon is typically in tensile stress, and the microstructures are flat and do not buckle. Whereas doping with boron decreases the lattice constant, doping with germanium increases the lattice constant. A membrane doped with B and e still etches much more slowly than undoped silicon, and the stress in the layer is reduced. A stress-free, dislocation-free, and slow etching layer (±10 nm/min) is obtained at doping levels of 10^{20} cm^{-3} boron and 10^{21} cm^{-3} germanium.[110,153]

One major disadvantage of the boron etch-stop technique is that the extremely high boron concentrations are not compatible with standard CMOS or bipolar techniques, so they can only be used for microstructures without integrated electronics. Another limitation of this process is the fixed number and angles of (111) planes one can accommodate. The etch stop is less effective in KOH compared with EDP. Besides boron, other impurities have been tried for use in an etch stop in anisotropic etchants. Doping Si with germanium has hardly any influence on the etch rate of either the KOH or EDP solutions. At a doping level as high as 5×10^{21} cm^{-3}, the etch rate is barely reduced by a factor of two.[110]

By burying the highly doped boron layer under an epitaxial layer of lighter doped Si, the problem of incompatibility with active circuitry can be avoided; ±1% thickness uniformity is possible with modern epilayer deposition equipment. A

widely used method of automatically measuring the epi-thickness is with IR instruments, especially Fourier transform infrared (see also epitaxy in Chapter 7).[154]

Electrochemical Etch Stop

For the fabrication of piezoresistive pressure sensors, the doping concentration of the piezoresistor must be kept smaller than 1×10^{19} cm^{-3} because the piezoresistive coefficients decrease considerably above this value, and reverse breakdown becomes an issue. Moreover, high boron levels compromise the quality of the crystal by introducing slip planes and tensile stress and prevent the incorporation of integrated electronics. As a result, a boron stop often cannot be used to produce well-controlled thin membranes unless, as suggested above, the highly doped boron layer is buried underneath a lighter-doped Si epilayer. Alternatively, a second etch-stop method, an electrochemical technique, can be used. In this case, a lightly doped p-n junction is used as an etch stop by applying a bias between the wafer and a counter electrode in the etchant, a technique first proposed by Waggener in 1970.[16] Other early work on electrochemical etch stops with anisotropic etchants such as KOH and EDP was performed by Palik et al.,[155] Jackson et al.,[156] Faust and Palik,[157] and Kim and Wise.[158] In electrochemical anisotropic etching, a p-n junction is made, for example, by the epitaxial growth of an n-type layer (phosphorus-doped, 10^{15} cm^{-3}) on a p-type substrate (boron-doped, 30 Ω-cm). This p-n junction forms a large diode over the whole wafer. The wafer is usually mounted on an inert substrate, such as a sapphire plate, with an acid-resistant wax and is partly or wholly immersed in the solution. An ohmic contact to the n-type epilayer is connected to one pole of a voltage source, and the other pole of the voltage source is connected via a current meter to a counter electrode in the etching solution (see Figure 4.46a). In this arrangement, the p-type substrate can be selectively etched away, and the etching stops at the p-n junction, leaving a membrane with a thickness solely defined by the thickness of the epilayer. The incorporation of a third electrode (a reference electrode) in the three-terminal method, together with the use of a potentiostat depicted in Figure 4.46a, allows for a more precise determination of the silicon potential with respect to the solution than a two-terminal setup as we illustrated in Figure 4.36a.

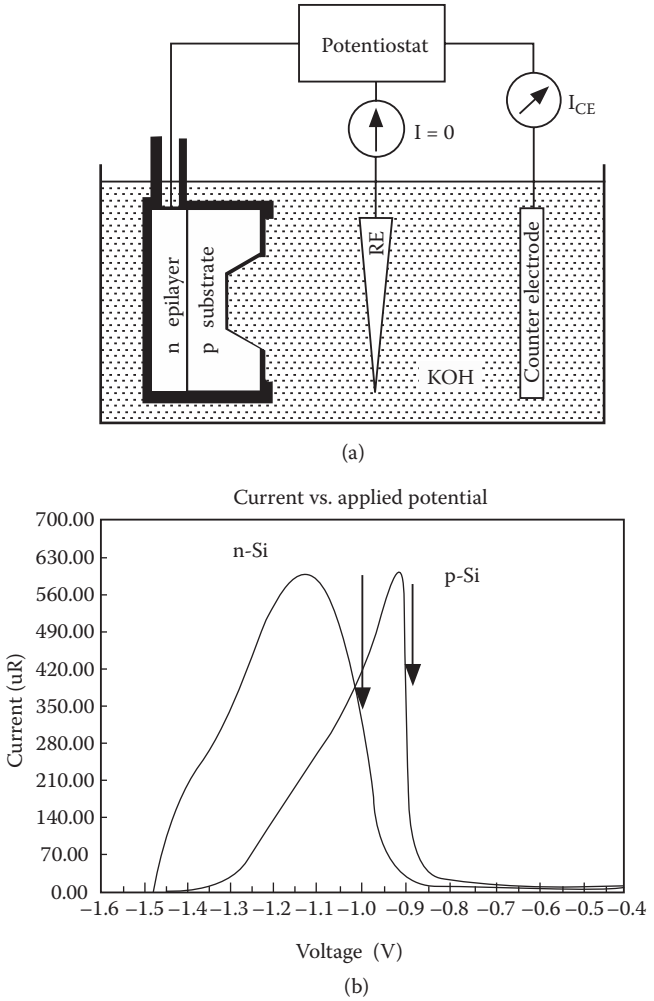

FIGURE 4.46 Electrochemical etch stop. (a) Electrochemical etching setup with potentiostatic control (three-electrode system). Potentiostatic control, mainly used in research studies, enables better control of the potential as it is referenced now to a reference electrode such as an SCE. In industrial settings, electrochemical etching is often carried out in a simpler two-electrode system, that is, a Pt counter electrode and Si working electrode. (From Kloeck, B., S. D. Collins, N. F. de Rooij, and R. L. Smith. 1989. Study of electrochemical etch-stop for high-precision thickness control of silicon membranes. *IEEE Trans Electron Devices* 36:663–69.[159]) (b) Cyclic voltammograms of n- and p-type silicon in an alkaline solution at 60°C. Flade potentials are indicated with an arrow.

At the Flade potential, marked with an arrow in Figure 4.46b, the oxide growth rate equals the oxide etch rate; a further increase of the potential results in a steep fall of the current as a result of complete passivation of the silicon surface. At potentials positive of the Flade potential, all etching stops. At potentials

negative of the Flade potential, the current increases as the potential becomes more positive. This can be explained by the formation of an oxide etching faster than it forms; that is, the silicon is etched away. Whereas electrochemists like to talk about the Flade potential, physicists like to discuss matters in terms of the flat-band potential. The flat-band potential is the applied potential at which there are no more fields within the semiconductor; that is, the energy band diagram is flat throughout the semiconductor (see Volume I, Chapter 4). The passivating SiO_2 layer is assumed to start growing as soon as the negative surface charge on the silicon electrode is cancelled by the externally applied positive bias, a bias corresponding to the flat-band potential. At these potentials, the formation of $Si(OH)_x$ complexes does not lead to further dissolution of silicon because two neighboring Si-OH HO-Si groups will react by splitting off water, leading to the formation of Si-O-Si bonds. As can be learned from Figure 4.46b, the value of the Flade potential depends on the dopant type. Consequently, if a wafer with both n- and p-type regions exposed to the electrolyte is held at a certain potential in the passive range for n-type and the active range for p-type Si, the p-type regions are etched away, whereas the n-type regions are retained. In the case of the diode shown in Figure 4.46a, where, at the start of the experiment, only p-type Si is exposed to the electrolyte, a positive bias is applied to the n-type epilayer (V_n). This reverse biases the diode, and only a reverse bias current can flow. The potential of the p-type layer in this regime is negative to the flat-band potential, and active dissolution takes place. At the moment that the p-n junction is reached, a large anodic current can flow, and the applied positive potential passivates the n-type epilayer. Etching continues on the areas where the wafer is thicker until the membrane is reached there, too. The thickness of the Si membrane is thereby solely defined by the thickness of the epilayer; neither the etch uniformity nor the wafer taper will influence the result. A uniformity of better than 1% can be obtained on a 10-µm-thick membrane. The current versus time curve can be used to monitor the etching process; at first, the current is relatively low, limited by the reverse bias current of the diode. Then, as the p-n junction is reached, a larger anodic current can flow until all the p-type material is consumed and the current decreases again to a low plateau value. The plateau indicates that a current associated with a passivated n-type Si electrode has been reached. The etch procedure can be stopped at the moment that the current plateau has been reached, and because the etch stop is basically one of anodic passivation, it is sometimes called an *anodic oxidation* etch stop. Registering an *I* versus *V* curve as in Figure 4.46b will establish an upper limit on the applied voltage, *V*,[160] and such curves are used for in situ monitoring and controlling of the etch stop. A crude endpoint monitoring can be accomplished by the visual observation of cessation of hydrogen bubble formation accompanying silicon etching. Palik et al.[161] presented a detailed characterization of Si membranes made by electrochemical etch stop.

Using the same anodic oxidation etch stop in a hydrazine-water solution at 90 ± 5°C and a simple two-terminal electrochemical cell, Hirata et al.[162] obtained a pressure sensitivity variation of less than 20% from wafer to wafer (pressure sensitivity is inversely proportional to the square of membrane thickness; see Volume III, Chapter 8). A great advantage of this etch-stop technique is that it works with Si at low doping levels of the order of 10^{16} cm^{-3}. Because of the low doping levels, it is possible to fabricate structures with a very low, or controllable, intrinsic stress. Moreover, active electronics and piezomembranes can be built into the Si without problems. A disadvantage is that the back of the wafer with the aluminum ohmic contact has to be sealed hermetically from the etchant solution, which requires complex fixturing and manual wafer handling. The fabrication of a suitable etch holder is no trivial matter. The holder 1) must protect the epicontact from the etchant, 2) must provide a low-resistance ohmic contact to the epilayer, and 3) must not introduce stress into wafers during etching.[53,126] Stress introduced by etch holders easily leads to diaphragm or wafer fracture and etchant seepage through to the episide.

Using a four-electrode electrochemical cell, controlling the potentials of the epitaxial layer and the silicon wafer separately, as shown in Figure 4.47, can further improve the thickness control of the resulting membrane by directly controlling the p/n bias

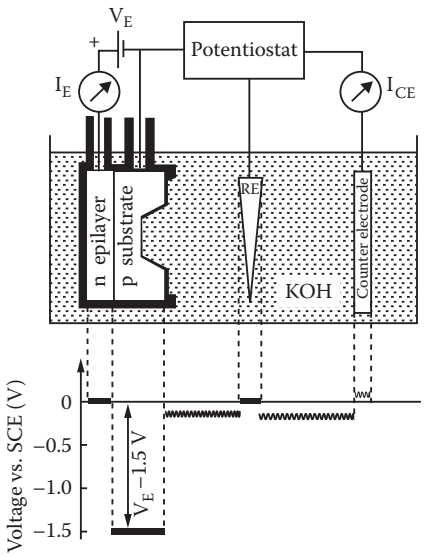

FIGURE 4.47 Four-electrode electrochemical etch-stop configuration. Voltage distribution with respect to the SCE reference electrode (RE) for the four-electrode case. The fourth electrode enables an external potential to be applied between the epitaxial layer and the substrate, thus maintaining the substrate at etching potentials. (From Kloeck, B., S. D. Collins, N. F. de Rooij, and R. L. Smith. 1989. Study of electrochemical etch-stop for high-precision thickness control of silicon membranes. *IEEE Trans Electron Devices* 36:663–69. With permission.[159])

voltage. The potential required to passivate n-type Si can be measured using the three-electrode system in Figure 4.46a, but this system does not take into account the diode leakage. If the reverse leakage is too large, the potential of the n-type Si, V_n, will approach the potential of the p-type Si, V_p. If there is a large amount of reverse diode leakage, the p-type region may passivate before reaching the n-type region, and etching will cease. In the four-electrode configuration, the reverse leakage current is measured separately via a p-type region contact, and the counter electrode current (I_{CE}) may be monitored for endpoint detection. The four-electrode approach allows etch stopping on lower quality epilayers (larger leakage current) and should also enable etch stopping of p-type epi on n-type substrates. Kloeck et al.[159] demonstrated that, using such an electrochemical etch-stop technique and with current monitoring, the sensitivity of pressure sensors fabricated on the same wafer could be controlled to within 4% standard deviation. These authors used a 40% KOH solution at 60 ± 0.5°C. Without the etch stop, the sensitivity from sensor to sensor on one wafer varied by a factor of two.

The etching solution used in electrochemical etching can be either isotropic or anisotropic. An electrochemical etch stop used in isotropic media was discussed above. In this case, HF/H_2O mixtures are used to etch the highly doped regions of p^+p, n^+n, n^+p, and p^+n systems.[87,88,163–165] The rate-determining step in etching with isotropic etchants does not involve reducing water with electrons from the conduction band, as it does in anisotropic etchants, and the etch-stop mechanism, as we will learn below, is very different. In isotropic media, the etch stop is simply a consequence of the fact that higher conductivity leads to higher corrosion currents, and the etching slows down on lower conductivity layers. A major advantage of the KOH electrochemical etch is that it retains the anisotropic characteristics of KOH without needing a heavily doped p^+ layer to stop the etching.[166]

In Figure 4.48 we illustrate the etch-stop techniques discussed so far. Figure 4.48a and b, represents two types of boron-dependent etch stops: diffused boron etch stop and buried layer boron

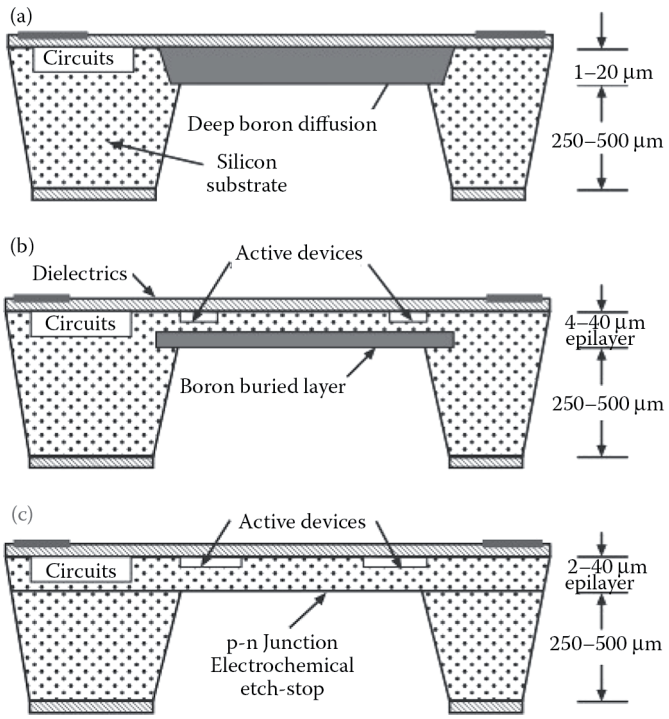

FIGURE 4.48 Typical cross-sections of bulk micromachined wafers with various methods for etch-stop formation shown. (a) Diffused boron etch stop. (b) Boron etch stop as a buried layer. (c) Electrochemical etch stop. (From Wise, K. D. 1985. *Micromachining and micropackaging of transducers.* Eds. C. D. Fung, P. W. Cheung, W. H. Ko, and D. G. Fleming. New York: Elsevier. With permission.[138])

etch stop. In Figure 4.48c we illustrate the electrochemical etch stop.[138] A comparison of the boron etch stop and the electrochemical etch stop reveals that the IC compatibility and the absence of built-in stresses, both results of the low dopant concentration, are the main assets of the electrochemical etch stop.

Photoassisted Electrochemical Etch Stop (for n-Type Silicon)

A variation on the electrochemical diode etch-stop technique is the photoassisted electrochemical etch-stop method illustrated in Figure 4.49.[168] An n-type silicon region on a wafer may be selectively etched in an HF solution by illuminating and applying a reverse bias across a p-n junction, driving the p-type layer cathodic and the n-type layer anodic. Etch rates up to 10 μm/min for the n-type material and a high-resolution etch stop render this an attractive potential micromachining process. Advantages also include the use of lightly doped n-type Si, bias- and illumination intensity-controlled etch rates, in situ process monitoring using the cell current, and the ability to spatially control etching with optical masking or laser writing. Using this method, Mlcak et al.[167] prepared stress-free cantilever beam test samples. They diffused boron into a 10^{15} cm^{-3} (100) n-type Si substrate through a patterned oxide mask, leaving exposed a small n-type region that defines two p-type cantilever beams (see Figure 4.49).

The boron diffusion resulted in a junction 3.3 μm underneath the surface. An ohmic contact on the back of the wafer was used to apply a variable voltage across the p-n junction, and both p and n areas were exposed to the HF electrolyte. The exposed n-type region was etched to a depth of 150 μm by shining light on the whole sample. The resulting n-type Si surface was at first found to be rough because porous Si up to 5 μm in height forms readily in HF solutions. The Si surface could be made smoother by etching at higher bias [4.3 V vs. saturated calomel electrode (SCE)] and higher light intensity (2 W/cm^2) to a finish with features of the order of 0.4 μm in height. Smoothing could also be accomplished by a 5-second dip in HNO_3:HF:H_3COOH or a 30-second dip in 25 wt%, 25°C, KOH. Yet another way of removing unwanted porous Si is a 1000°C wet oxidation to make oxidized porous Si (OPS) followed by an HF etch.[168] The formation of porous Si and OPS is detailed further below.

The photoassisted electrochemical etching of n-type Si is commercially exploited at Boston Microsystems Inc. (http://www.bostonmicrosystems.com).

Photoinduced Preferential Anodization (for p-Type Si)

Electrochemical etching requires the application of a metal electrode to apply the bias. The application of such a metal electrode often induces contamination

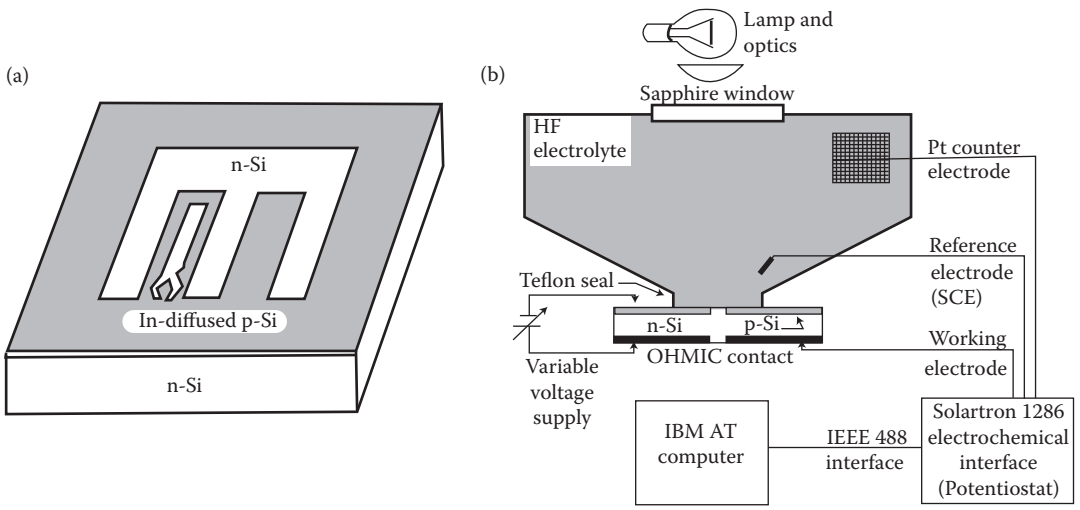

FIGURE 4.49 Photoelectrochemical etching. (a) Schematic of the photoelectrochemical etching experiment apparatus. (b) Schematic of the spatial geometry of the diffused p-type silicon layer into n-type Si used to form cantilever beam structures. (From Mlcak, R., H. L. Tuller, P. Greiff, and J. Sohn. *Proceedings: IEEE micro electro mechanical systems (MEMS '93).* Fort Lauderdale, FL: IEEE. With permission.[167])

and constitutes at least one extra process step, and extra fixturing is needed. With photoinduced preferential anodization (PIPA), it is not necessary to deposit metal electrodes. Here, one relies on the illumination of a p-n junction to bias the p-type Si anodically, and the p-type Si converts automatically into porous Si, whereas the n-type Si acts as a cathode for the reaction. The principle of photobiasing for etching purposes was known and patented by Shockley as far back as 1963.[169] In US patent 3,096,262, he writes that "light can be used in place of electrical connections … for biasing of the sample … This means a small isolated area of p-type material on an n-type body may be preferentially biased for removal of material beyond the junction by etching." The method was "reinvented" by Yoshida et al.[168] in 1992 and in 1993 by Peeters et al.[170,171] The latter group called the method PHET, for photovoltaic electrochemical etch-stop technique, and the former group coined the PIPA acronym.

In PIPA, etch rates of up to 5 µm/min result in the formation of porous layers that are readily removed with Si etching solutions. An important advantage of the technique is that very small and isolated p-type islands can be anodized at the same time. The method also lends itself to fabrication of 3D structures using p-type Si as sacrificial layers.[168] A disadvantage of the technology is that one cannot control the process very well because the current cannot be measured for endpoint detection. Application of PIPA to form a microbridge is shown in Figure 4.50. First, a buried p-type layer doped to 10^{18} cm^{-3} and an n-type layer doped to 10^{15} cm^{-3} are formed on an n-type substrate using epitaxy (Figure 4.50a). Then, the p-type layer is preferentially anodized in 10% HF solution under 30 mW/cm^2 light intensity for 180 minutes (Figure 4.50b), forming porous Si. The porous Si is then oxidized in wet oxygen at 1000°C (Figure 4.50c). Finally, the sacrificial layer of oxidized porous Si (OPS) is etched and removed with an HF solution (Figure 4.50d). The resulting surfaces of the n-type silicon are very smooth. It is interesting to consider making complicated 3D structures by going immediately to the electropolishing regime instead. Yoshida et al.[168] believe that porous Si as a sacrificial intermediate is more suitable for fabricating complicated structures.

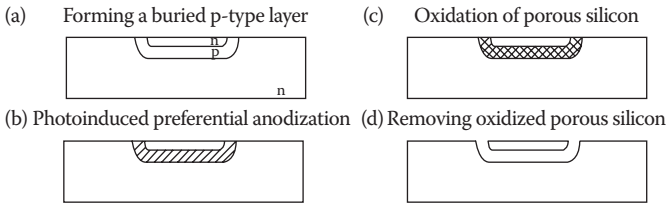

FIGURE 4.50 Photoassisted electrochemical etch stop (for n-type Si). Fabrication process for a microbridge and SEM picture of Si structure before and after PIPA. (From Yoshida, T., T. Kudo, and K. Ikeda. 1992. *Proceedings: IEEE micro electro mechanical systems (MEMS '92).* Travemunde, Germany: IEEE. With permission.[168])

The authors are probably referring to the fact that electropolishing is much more aggressive and could not be expected to lead to the same retention of the shape of the buried, sacrificial p-type layers. Peeters et al.[160] carry out their photovoltaic etching in KOH, thus skipping the porous Si stage of Yoshida et al. They, like Yosida et al., stress the fact that, in one single etch step, this technique can make a variety of complex shapes that would be impossible with electrochemical etching techniques. These authors found it necessary to coat the n-type Si part of the wafer with Pt to get enough photovoltaic drive for the anodic dissolution; this metallization step makes the process more akin to photoelectrochemical etching (PEC), and some advantages of the photobiasing process are lost.

Etch Stop at Thin Insoluble Films

Yet another distinct way (the fourth) to stop etching is by using a change in composition of material. An example is an etch stopped at a Si_3N_4 diaphragm (see Figure 4.45Ba for an example). Silicon nitride is very strong, hard, and chemically inert, and the stress in the film can be controlled by changing the Si/N ratio in the LPCVD deposition process. The stress turns from tensile in stoichiometric films to compressive in silicon-rich films (for details, see Volume III, Chapter 5). A great number of materials are not attacked by anisotropic etchants. Hence a thin film of such a material can be used as an etch stop.

Another example is the SiO_2 layer in a silicon-on-insulator (SOI) structure. A buried layer of SiO_2, sandwiched between two layers of crystalline silicon, forms an excellent etch stop because of the

good selectivity of many etchants of Si over SiO_2. The oxide does not exhibit the good mechanical properties of silicon nitride and consequently is rarely used as a mechanical member in a microdevice. As with PIPA, no metal contacts are needed with an SOI etch stop, greatly simplifying the process over an electrochemical etch-stop technique.

We classified SOI micromachining under surface micromachining in Chapter 7, where more details about this promising micromachining alternative are presented.

Chemical Etching Models for Single-Crystal Si

Introduction

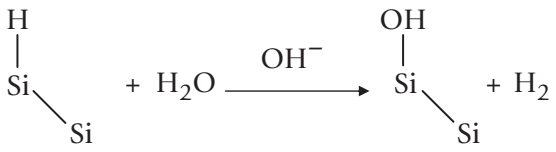
Conflicting data abound in the literature for the anisotropic etch rates of the different Si planes, especially for the higher index planes. This is not too surprising, given the multiple parameters influencing individual results: temperature, stirring, size of etching feature (i.e., crevice effects and loading effects), etchant concentration, addition of alcohols and other organics, surface defects, complexing agents, surfactants, pH, cation influence, and so on. Even the reason(s) why acidic media lead to isotropic etching whereas alkaline media lead to anisotropic etching was, until recently, not explicitly addressed in any of the models surveyed. More rigorous experimentation and standardization will be needed, as well as improved etching models, to better understand the influence of all these parameters on etch rates. In the following section we will present recent atomistic and fluctuating energy level models (see Volume I, Chapter 4) to explain anisotropic and isotropic etching of silicon. It is our hope that the reading of this section will inspire more detailed semiconductor electrochemistry work on Si electrodes. The refining of an etching model will be of invaluable help in writing more predictive Si etching software code.

Atomistic Model—Gosalvez-Kelly

The origin of the macroscopic anisotropy in the etching of Si lies in the site-specificity of the etch rates at the atomistic scale. Surface sites on different crystallographic planes react with an etchant in a different manner because their surface orientations are different. As a consequence, as pointed out by Gosalvez, the macroscopic etch rate is different for different crystal orientations.[47] The removal of Si surface atoms is a complex process that involves chemical and electrochemical reactions. As shown in Figure 4.51, the etching process takes place through sequential oxidation and etching reactions. During etching of Si, the surface, as we show here, is predominantly H-terminated, and this is true for both isotropic[94] and anisotropic etching.[172] The H-termination of the surface was established from both ex situ (after etching the surface) and in situ (during etching) infrared spectroscopy by Kelly et al.[172] In other words, removal of the native oxide from Si leaves the surface hydrogen-terminated.

Once the substitution of H (hydrophobic) by OH (hydrophilic) has taken place, a fast sequence of chemical steps (represented as "etching" in Figure 4.51) leads to the removal of the silicon atom as a $Si(OH)_4$ product. The triggering effect of the reaction by the OH ligand is attributed to the difference in electronegativities between the Si and O atoms, resulting in the polarization and weakening of the backbonds of the Si atom, which as a result, becomes more vulnerable to further attack. Although the hydroxyl group plays an important role in catalyzing the removal of the surface atom by favoring backbond attack, the real active species attacking the backbonds are polar molecules: water in alkaline etchants and HF in acidic etchants.[172]

In an alkaline medium, the first step involving the nucleophilic attack by an OH^- ion on the Si-H bond may be represented as[172]:



Reaction 4.10

The departing hydride reacts with water to give hydrogen gas, and the Si surface atom is hydroxylated. It is the presence of the OH group that polarizes the Si-Si backbond. With the OH adding to the positively polarized surface atom, the backbond is

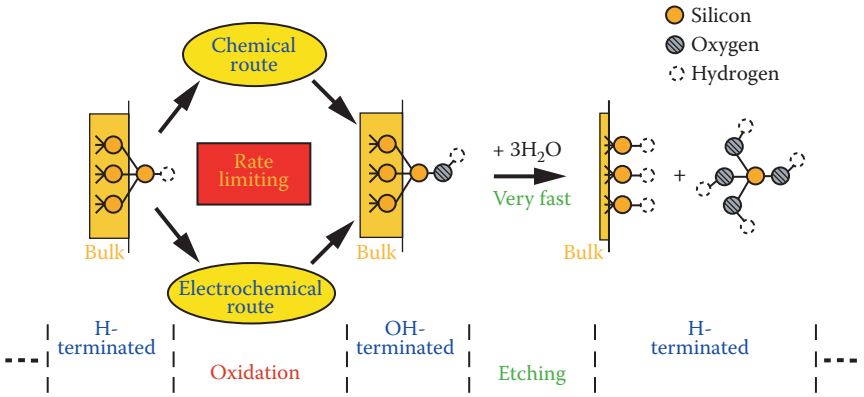


FIGURE 4.51 Schematic representation of the oxidation and etching reactions that sequentially occur for the removal of Si surface atoms. The rate limiting process (oxidation) can take place through chemical and electrochemical routes. Only the nearest underlying bulk atoms in the neighborhood of the surface site are depicted. (Gonsalvez, M. 2003. *Atomistic modelling of anisotropic etching of crystalline silicon.* PhD diss., Helsinki University of Technology.[47])

attacked by water, and an H atom attaches itself to the subsurface atom, restoring the hydrogen termination of the Si surface as shown in Reaction 4.11[172]:

Reaction 4.11

Whether the surface is hydrogenated (hydrophobic) or hydroxylated (hydrophilic) during etching depends on the relative rates of Reactions 4.10 and 4.11. The fact that in practice a predominantly H-termination is found is determined by kinetics rather than thermodynamics, and this implies that the site specificity of the whole process is a result of the rate-limiting oxidation reaction alone.[47]

The number of backbonds associated with the attacked Si atom is universally accepted as a major source for surface specificity. In the case of a (100) surface, each atom has a dihydride termination and is bonded to two subsurface Si atoms. In the (111) case, the surface is monohydride terminated with three backbonds. A dihydride is chemically less stable than a monohydride, so one expects Reaction 4.10 to be faster for a (100) surface.[173] Because it should be easier to dislodge a (100) Si atom with only two backbonds, the rate of Reaction 4.11 also should be faster than for a (111) surface. This qualitatively explains already why one expects a (111) plane to etch much more slowly than a (100) plane in alkaline media.[172] In the model of Seidel et al.[52] (see below) the energy levels of the electrons in the backbonds are associated with surface states within the bandgap of Si. The energy level of these surface states is assumed to vary for different surface orientations, being lowest for {111} planes.

We return now for a moment to Figure 4.51 and draw the readers' attention to the fact that chemical and electrochemical reaction routes provide two alternative mechanisms for the oxidation of the hydrogen-terminated sites before the removal of the resulting hydroxyl-terminated silicon. For open-circuit etching of Si, i.e., with no external circuit connecting the Si to a counter electrode, there are two possible mechanisms: chemical and electroless. The two are distinguished by the fact that the latter involves the participation of free charge carriers, giving rise to measurable currents and allowing for the possibility of controlling the etching process with a biasing potential.[172] In the electrochemical route of Si oxidation, an oxidizing agent in solution extracts/injects mobile charge carriers from/into the solid. When, for example, an oxidizing agent extracts bonding electrons from the valence band, i.e., injects holes, and the holes stay localized at the surface, they will cause bond rupture. It is important to realize that these holes are mobile so that the two reactions, the reduction of the oxidant and the oxidation of the solid, can be considered as two spatially and temporally independent electrochemical reactions. This form of etching is generally referred to as electroless because it does not involve two separate electrodes

(the same process is involved in metal corrosion). A reaction like this, involving the exchange of charge carriers, can lead to external currents when an external circuit is fashioned and can be influenced by a bias applied between the etching electrode (Si) and a counter electrode (e.g., Pt). In chemical etching, bonds in the etching agent and the solid are broken, and new bonds are formed in a localized and synchronous reaction, not involving free carriers. In this case, the reaction rate cannot be influenced by an applied bias. In the oxidation subprocess of Figure 4.51, the main difference between the chemical and the electrochemical routes lies in the size of the activated complex. In chemical oxidation, we saw (Reaction 4.10) that the hydroxyl ion acts as a catalyst. It is postulated that the hydroxyl ion reduces the energy barrier of a sizable pentavalent transition state as shown schematically in Figure 4.52.[174]

The fact that both water (reactant) and OH^- (catalyst) are involved in the reaction depicted in Figure 4.52 is made clear from the fact that etching of single-crystal silicon is possible in pure boiling water, where there is a small concentration of OH^- present, but not in concentrated HF, where the concentration of OH^- is too low to enable the oxidation subprocess in Figure 4.52. In this case, the reaction stops after the H-termination.[47] Besides the number of backbonds of the site under attack, Gosalvez concludes that the site specificity of anisotropic etching is also determined by the geometry of the transition complex; in other words, the steric hindrance of the OH-termination controls the reaction rate as well.[47] The larger the size and the more rigid the transition complex, the larger one expects the anisotropy to be. As a result of these constraints, the chemical oxidation route is very anisotropic.

The Si etching process has been found to depend on the applied potential; thus, the chemical reaction in Figure 4.52 cannot be the only oxidation subprocess. Under anodic potential, the dissolution rate becomes enhanced, and the ratio of H_2/Si is reduced because of the contribution of the electrochemical reaction path.[105] Therefore, there also must be an electrochemical route involving free charge carriers. We will detail our understanding of the electrochemical route when analyzing the Seidel et al. model (see below); here we just take advantage of the experimental evidence that the anodic current is found to be only weakly dependent on the OH^- concentration but strongly so on the water concentration (see Equation 4.3, page 275),[52,110] suggesting that water is the only active species. This is illustrated in Figure 4.53, where the process is depicted as occuring through the dissociation of the surface hydride group and subsequent reaction with a water molecule.

In contrast with the sizable pentavalent transition state involved in the chemical oxidation route (see Figure 4.52), in the electrochemical oxidation route the small surface hydride leaves plenty of space for the reaction with water molecules, and the dissociation might occur at any surface site, making the electrochemical route rather isotropic compared with the chemical route.[47]

The surface morphology of the etched surfaces also turns out to be orientation-dependent when examined at the micrometer and smaller length scales. Pyramidal hillocks and round shallow pits,

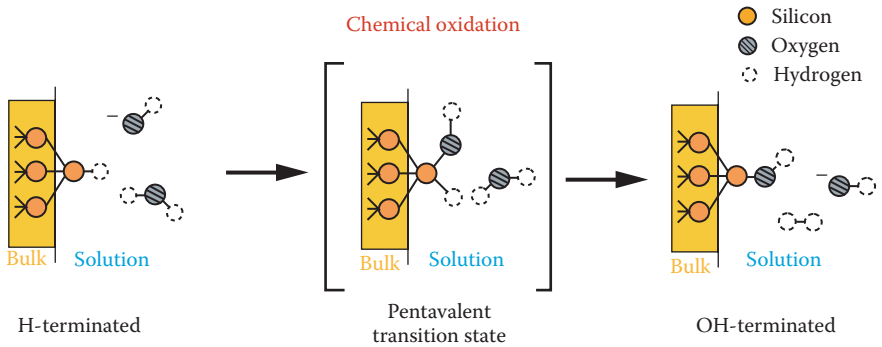

FIGURE 4.52 Schematic representation of the chemical oxidation reaction. Only the nearest underlying bulk atoms in the neighborhood of the surface site are shown. (Gonsalvez, M. 2003. *Atomistic modelling of anisotropic etching of crystalline silicon.* PhD diss., Helsinki University of Technology.[47])

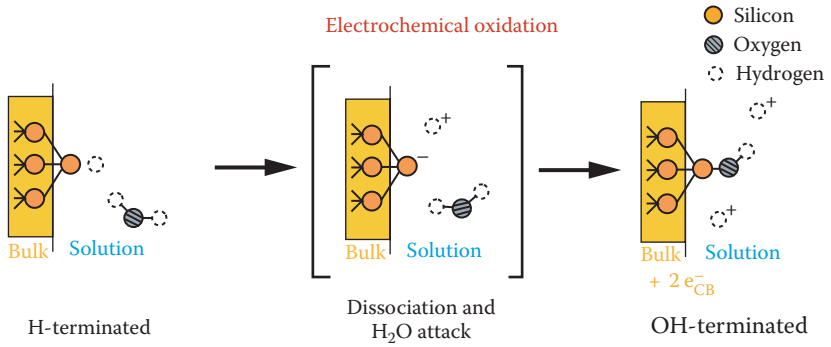

FIGURE 4.53 Schematic representation of the electrochemical oxidation reaction. Only the nearest underlying bulk atoms in the neighborhood of the surface site are shown. (Gonsalvez, M. 2003. *Atomistic modelling of anisotropic etching of crystalline silicon.* PhD diss., Helsinki University of Technology.[47])

for example, are typical for {100} planes, whereas triangular pits are found on {111} surfaces. Gosalvez writes that the macroscopic anisotropy and the surface morphology are two manifestations of the same microscopic site specificity observed at different length scales.[47] The surface microstructure during wet etching of Si then depends on the relative importance of the chemical and electrochemical oxidation routes. The etching process is most anisotropic under cathodic bias, where the etching process is completely chemical, and it becomes increasingly more isotropic as the anodic bias is increased. At sufficiently negative bias one can even eliminate the surface pits on {111} planes, or a totally chemical oxidation process results in perfectly flat {111} surfaces. In Gosalvez's view, under the usual alkaline etching conditions, without biasing potentials, the etching process is very anisotropic, and he claims that the electrochemical oxidation route has only minor effects (mainly the nucleation of pits on {111} planes). Within Gosalvez's elegant model, the etch stop at passivating anodic potentials is a result of an increased OH-termination. The high number of hydroxyl ligands on the Si surface produces the formation of silicon oxide through oxygen insertion into the Si-Si backbonds. The etching mechanism of SiO_2 in alkaline media is slow compared with that of silicon, so the etching process is stopped. This is the same effect observed when increasing the amount of dissolved oxygen in the solution. Very revealing, the effect of oxygen and other oxidizing agents, added to the etching solution, is to make the etching process more isotropic, improving the surface finish of {100} surfaces but negatively affecting that of (111), just in the same manner as the biasing potentials. In both cases, mobile charge carriers make the process more dependent on water molecules only rather than requiring the water/OH^- complex that makes a chemical process more anisotropic.

Seidel et al.'s Model

Anisotropy of Etch Rates Seidel et al.'s model is based on the fluctuating energy level model of the silicon/electrolyte interface and assumes the injection of electrons in the conduction band during the etching process. The construction of energy diagrams of the type discussed here was introduced in Volume I, Chapter 7. Consider the situation of a piece of Si immersed in an alkaline solution without applied bias (open circuit conditions). After immersion of the silicon crystal into the alkaline electrolyte, a negative excess charge builds up on the surface as a result of the higher original Fermi level of the H_2O/OH^- redox couple in the etchant as compared with the Fermi level of the solid. In other words, as explained in Volume I, Chapter 7, the electrochemical potential difference is equalized across the interface; the Fermi levels line up; or also, the work function difference is equalized. The Fermi level in a given material is equivalent to the electrochemical potential of the electrons in that material expressed per particle, or:

$$E_F = \frac{\bar{\mu}_e}{N_A} \tag{7.79}$$

(see Volume I, Chapter 7). This leads to a downward bending of the energy bands on the solid surface for

both p- and n-type silicon (Figure 4.54a and b). The downward bending is more pronounced for p-type than for n-type because of the initially larger difference of the Fermi levels between the solid and the electrolyte.

Next, hydroxyl ions cause the Si surface to oxidize, consuming water and liberating hydrogen in the process. From the measurement of the amount of Si dissolution and H_2 generation, a stoichiometric ratio of $2H_2/1Si$ was found,[108] and thus the following detailed steps, based on Palik,[128] were suggested:

$$Si + 2OH^- \rightarrow Si(OH)_2^{2+} + 2e^-$$

$$Si(OH)_2^{2+} + 2OH^- \rightarrow Si(OH)_4 + 2e^-$$

$$Si(OH)_4 + 4e^- + 4H_2O \rightarrow Si(OH)_6^{2-} + 2H_2$$

Reaction 4.12

Silicate species were observed by Raman spectroscopy.[175] Thus, the overall silicon oxidation reaction consumes four electrons first injected into the conduction band, where they stay near the surface as a result of the downward bending of the energy bands (see Figure 4.54). Raley et al.[176] first presented evidence for injection of four electrons rather than a mixed hole and electron mechanism. These authors could explain the measured etch-rate dependence on hole concentration only by assuming that the proton or water reduction reaction is rate determining and that a four-electron injection mechanism with the conduction band was involved. The injected electrons are highly "reducing" and react with water to form hydroxide ions and hydrogen:

$$4H_2O + 4e^- \rightarrow 4H_2O^- \qquad \text{Reaction 4.13}$$

$$4H_2O^- \rightarrow 4OH^- + 4H^+ + 4e^- + 2H_2 \qquad \text{Reaction 4.14}$$

It is thought that the hydroxide ions in Reaction 4.14, generated directly at the silicon surface, react in the oxidation step. The hydroxide ions from the bulk of the solution may not play a major role because they will be repelled by the negatively charged Si surface, whereas the hydroxide ions formed in situ do not need to overcome this repelling force. This would explain why the etch rates for an EDP solution with an OH^- concentration of 0.034 M are nearly as large as those for KOH solutions with a hundred-fold higher OH^- concentration of 5–10 M.[52] The hydrogen formed in Reaction 4.14 can inhibit the reaction, and surfactants may be added to displace the hydrogen (IBM, US Patent 4,113,551, 1978). Additional support for the involvement of four water molecules (Reaction 4.13) comes from the experimentally observed correlation between the fourth power of the water concentration and the silicon etch rate for concentrated KOH solutions. The Si etch rate, *R*, as a function of KOH concentration at 72°C, was shown in Figure 4.39a and c.[52] The etch rate has a maximum at about 20 wt% KOH of about 55 µm/h. The best fit for this experimentally determined etch rate, for most KOH concentrations, is[52,110]:

$$R = k[H_2O]^4\,[KOH]^{\frac{1}{4}} \qquad (4.2)$$

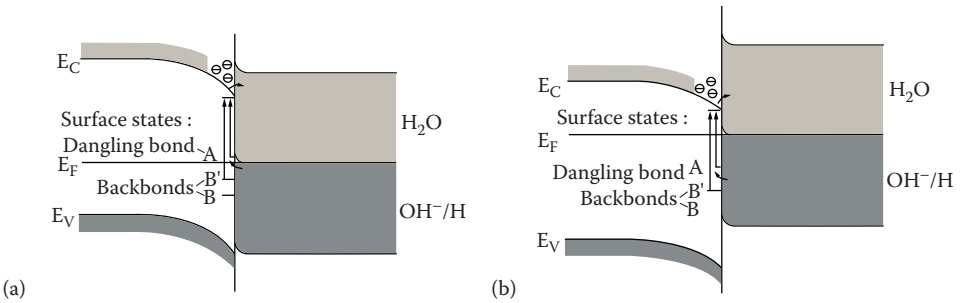

FIGURE 4.54 Band model of the silicon/electrolyte interface for moderately doped silicon (electrolyte at pH > 12): p-type silicon (a) and n-type silicon (b). We assume no applied bias and no illumination. The energy scale functions in respect to the saturated calomel electrode (SCE), an often-used reference in electrochemistry. Notice that p-type Si exhibits more band bending because its Fermi level is lower in the bandgap. For simplicity, we show only one energetic position for surface states associated with dangling bonds and backbonds; in reality, there will be new surface states arising during reactions as the individual dangling bonds and backbonds are taking on different energies as new Si-OH bonds are introduced.

The weak dependence of the etching curve on the KOH concentration (~1/4 power) supports the assumption that the hydroxide ions involved in the oxidation reactions are mostly generated from water. A strong influence of water on the silicon etch rate was also observed for EDP solutions. In molar water concentrations of up to 60%, a large increase of the etch rate occurs.[108] The driving force for the overall Reaction 4.12 is given by the larger Si-O binding energy of 193 kcal/mol as compared with a Si-Si binding energy of only 78 kcal/mol. The role of cations, K^+, Na^+, and Li^+, and even complicated cations such as $NH_2(CH_2)_2NH_3^+$ can probably be neglected.[52]

The four electrons in Reaction 4.13 are injected into the conduction band in two steps. In the case of {100} planes, there are two dangling bonds per surface atom for the first two of the four hydroxide ions to react with, injecting two electrons into the conduction band in the process. As a consequence of the strong electronegativity of the oxygen atoms, the two bonded hydroxide groups on the silicon atom reduce the strength of the two silicon backbonds (Figure 4.55). With two new hydroxide ions approaching, two more electrons (now stemming from the Si-Si backbonds) are injected into the conduction band, and the silicon-hydroxide complex reacts with the two additional hydroxide ions. Seidel et al.[52] claim that the step of activating the second two electrons from the backbonds into the conduction band is the rate-limiting step, with an associated thermal activation energy of about 0.6 eV for {100} planes.

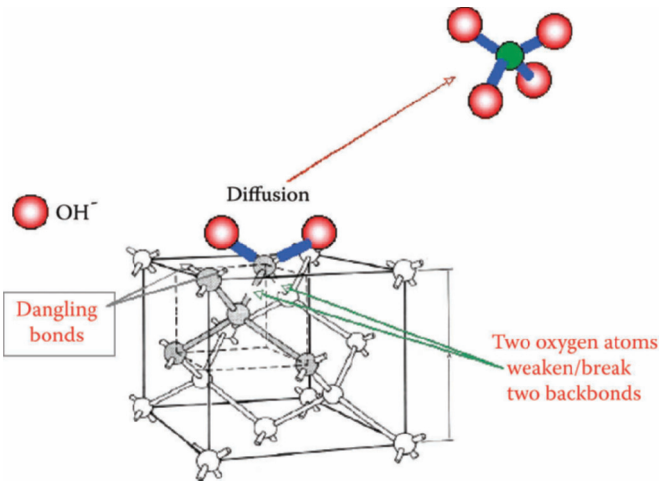

FIGURE 4.55 Two backbonds on Si {100} surfaces.

The electrons in the backbonds are associated with surface states within the bandgap (see Figure 4.54). The energy level of these surface states is assumed to vary for different surface orientations, the lowest being for {111} planes. The thermal activation of the backbonds corresponds to an excitation of the electrons out of these surface states into the conduction band. Because the energy for the backbond surface state level is the lowest within the bandgap for {111} planes, these planes will be hardest to etch. The {111} planes have only one dangling bond for a first hydroxide ion to react with. The second step, which is the rate-limiting step, involves breaking three lower energy backbonds (Figure 4.56).

The lower energy of the backbond surface states within the Si bandgap for {111} Si atoms can be understood from the simple argument that their energy level is raised less by the electronegativity of a single binding hydroxide ion compared with two in the case of the silicon atoms in {100} planes. The high etch rate generally observed on {110} surfaces is similarly explained by a high energy level of the backbond-associated surface states for these planes. Elwenspoek et al.[55,56] do not accept this "two versus three backbonds" argument (see below). They point out that the silicon atoms in the {110} planes also have three backbonds, and activation energy in these crystallographic directions should be comparable with that of {111} planes in contrast to experimental evidence. Seidel et al. would probably counterargue here that the backbonds and the energy levels of the associated surface states are not necessarily the same for {111} and {110} planes because that energy will also be influenced by the effect of the orientation of these bonds. Another argument in favor of the relatively high etching rates of {110} planes is the easier

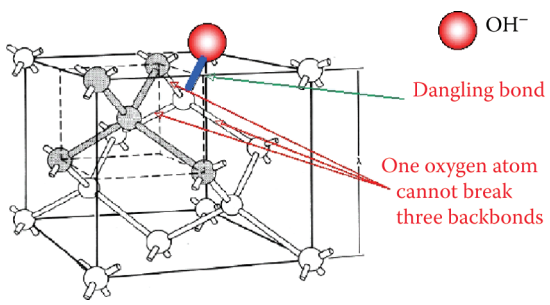

FIGURE 4.56 Three backbonds on Si {111} surfaces.

penetrability of {110} surfaces for water molecules along channels in that plane.

The final step in the anisotropic etching is the removal of the reaction product $Si(OH)_4$ by diffusion. If the production of $Si(OH)_4$ is too fast for solutions with a high water concentration, the $Si(OH)_4$ leads to the formation of a SiO_2-like complex before $Si(OH)_4$ can diffuse away. This might be observed experimentally as a white residue on the wafer surface.[177] The high pH values in anisotropic etching are required to obtain adequate solubility of the $Si(OH)_4$ reaction product and to remove the native oxide from the silicon surface. From silicate chemistry it is known that for pH values greater than 12 the $Si(OH)_4$ complex will undergo the following reaction by the detachment of two protons:

$$Si(OH)_4 \rightarrow SiO_2\,(OH)_2^{2-} + 2H^+ \qquad \text{Reaction 4.15}$$

$$2H^+ + 2OH^- \rightarrow 2H_2O \qquad \text{Reaction 4.16}$$

Pyrocatechol in an ethylenediamine etchant acts as a complex-forming agent for reaction products such as $Si(OH)_4$, converting these products into more complex anions:

$$Si(OH)_4 + 2OH^- + 3C_6H_4(OH)_2 \rightarrow$$

$$Si(C_6H_4O_2)_3^{2-} + 6H_2O \qquad \text{Reaction 4.17}$$

There is evidence by Abu-Zeid et al.[178] of diffusion control contribution to the etch rate in EDP, probably because the hydroxide ion must diffuse through the layer of complex silicon reaction products (see Reaction 4.17). The same authors also found that the etch rate depends on the effective silicon area being exposed and on its geometry (crevice and loading effects). That is why the silicon wafer is placed in a holder, and the solution is vigorously agitated to minimize the diffusion layer thickness. For KOH solutions, no effect of stirring on etching rate was noticed. Stirring here is mainly used to decrease the surface roughness, probably through removal of hydrogen bubbles.

The influence of alcohol on the KOH etching rate in Equation 4.3 is the result of a change in the relative water concentration and its concomitant pH change; it does not participate in the reaction (this was confirmed by Raman studies by Palik et al.[175]). The reversal of etch rates for {110} and {100} planes through alcohol addition to KOH/water etchants can be understood by assuming that the alcohol covers the silicon surface,[175] thus canceling the "channeling advantage" of the {110} planes. In the case of EDP, alcohol has no effect because the water concentration can be freely adjusted without significantly influencing the pH value as a result of the incomplete dissociation of EDP.

For the etching of SiO_2 shown in Figure 4.42, Seidel et al. propose the following reaction:

$$SiO_2 + 2OH^- \rightarrow SiO_2(OH)_2^{2-} \qquad \text{Reaction 4.18}$$

At KOH concentrations up to 35%, a linear correlation occurs between SiO_2 etch rate and KOH concentration. The SiO_2 etch rate in KOH solutions exceeds those in EDP by close to three orders of magnitude. For higher concentrations, the etch rate decreases with the square of the water concentration, indicating that water plays a role in this reaction. Seidel et al. speculate that at high pH values the silicon electrode is highly negatively charged (the point of zero charge of SiO_2 is 2.8), repelling the hydroxide ions while water takes over as reaction partner. An additional reason for the decrease is that the hydroxide concentration does not continue to increase with increasing KOH concentration for very concentrated solutions. The decrease of the Si/SiO_2 etch rate ratio with increasing temperature and pH of the solution (up to 35%) follows out of the larger activation energy associated with the SiO_2 etch rate (0.85 eV) and its linear correlation with the hydroxide concentration, whereas the silicon etch rate mainly depends on the water concentration.

The effect of water concentration and pH value on the etching process in the Seidel et al. model is summarized in Table 4.10.[179]

Doping Dependence of Si Anisotropic Etching A good model for anisotropic etching of Si should also be able to explain the fact that the anisotropic etchant systems of Table 4.9 exhibit drastically reduced etch rates for high boron concentrations in silicon ($\geq 5 \times 10^{19}$ cm^{-3} solid solubility limit). Other

impurities (P, Ge) also reduce the etch rate but at much higher concentrations (see Figure 4.57[52]). Boron typically is incorporated using ion implantation (thin layers) or liquid/solid source deposition (thick layers >1 µm). These doped layers are used as very effective etch stop layers (see above). Hydrazine or EDP, which display a smaller (100) to (111) etch rate ratio (~35) than KOH, exhibits a stronger boron concentration dependency. The etch rate in KOH is reduced by a factor of 5–100 for a boron concentration larger than 10^{20} cm^{-3}. When etching in EDP, the factor climbs to 250.[151] With TMAHW solutions, the Si etch rate decreases to 0.01 µm/min for boron concentrations of about 4×10^{20} cm^{-3}.[180]

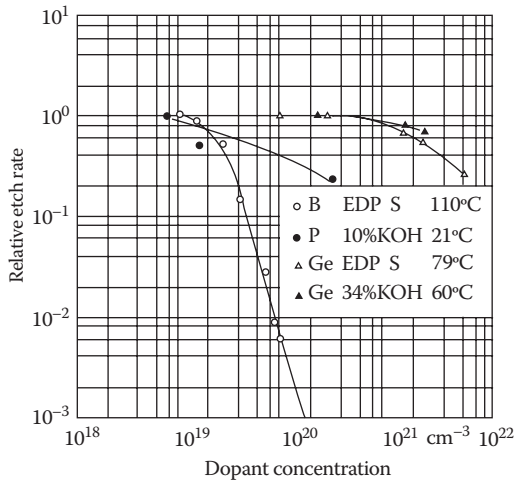

FIGURE 4.57 Relative etch rate for (100) Si in EDP and KOH solutions as a function of concentration of boron, phosphorus, and germanium. (From Seidel, H., L. Csepregi, A. Heuberger, and H. Baumgartel. 1990. Anisotropic etching of crystalline silicon in alkaline solutions–part I: orientation dependence and behavior of passivation layers. *J Electrochem Soc* 137:3612–26. With permission.)

Seidel et al.'s model, we shall see, gives the most plausible explanation for this effect.

Some of the different mechanisms that have been invoked to explain the doping dependence of Si anisotropic etching follow.

1. Several observations suggest that doping leads to a more readily oxidized Si surface. Highly boron- or phosphorus-doped silicon in aqueous KOH spontaneously can form a thin passivating oxide layer.[128,155] The boron oxides and hydroxides initially generated on the silicon surface are not soluble in KOH or EDP etchants.[75] The substitutional boron creates local tensile stress in the silicon, increasing the bond strength so that a passivating oxide might be more readily formed at higher boron concentrations. Boron-doped silicon has a high defect density (slip planes), encouraging oxide growth.
2. Electrons produced during the oxidation of silicon are needed in a subsequent reduction step (hydrogen evolution in Reaction 4.14). When the hole density passes 10^{19} cm^{-3}, these electrons combine with holes instead, thus stopping the reduction process.[155] Seidel et al.'s model follows this explanation (see below).
3. Silicon doped with boron is under tension as the smaller boron atoms enter the lattice substitutionally. The large local tensile stress at high boron concentration makes it energetically more favorable for the excess boron (>5×10^{19} cm^{-3}) to enter interstitial sites. The strong B-Si bonds bind the lattice rigidly. With high enough doping, the high binding energy can stop etching.[75] This hypothesis is similar to item 1, except that no oxide formation is invoked.

The model by Seidel et al. provides an elegant explanation for the etch stop at high boron concentrations. At moderate dopant concentration, we saw that the electrons injected into the conduction band stay localized near the semiconductor surface as a result of the downward bending of the bands (Figure 4.58). The electrons there have a small probability of recombining with holes deeper into the crystal even for p-type Si. This situation changes when the doping level in the silicon increases

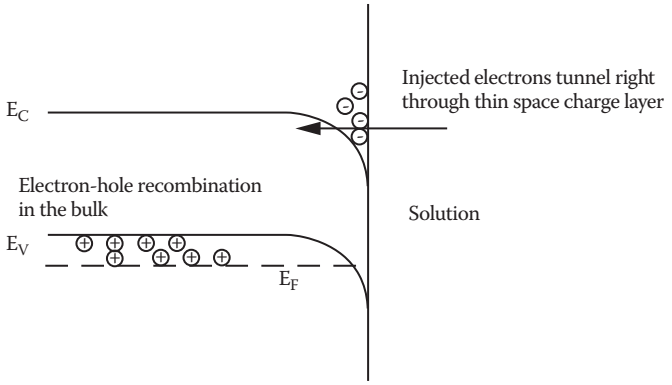

FIGURE 4.58 Si/electrolyte interface energetics at high doping level explaining etch-stop behavior.

further. At a high dopant concentration, silicon degenerates and starts to behave like a metal. For a degenerate p-type semiconductor, the space charge thickness shrinks, and the Fermi level drops into the valence band as indicated in Figure 4.58.

The injected electrons shoot (tunnel) right through the thin surface charge layer into deeper regions of the crystal, where they recombine with holes from the valence band. Consequently, these electrons are not available for the subsequent reaction with water molecules (Reaction 4.13), the reduction of which is necessary for providing new hydroxide ions in close proximity to the negatively charged silicon surface. These hydroxide ions are required for the dissolution of the silicon as $Si(OH)_4$. The remaining etch rate observed within the etch stop region is then determined by the number of electrons still available in the conduction band at the silicon surface. This number is assumed to be inversely proportional to the number of holes and thus the boron concentration. Experiments show that the decrease in etch rate is nearly independent of the crystallographic orientation, and the etch rate is proportional to the inverse fourth power of the boron concentration in all alkaline etchants.

Model of Seidel et al. Summary The key points of the Seidel et al. model can now be summarized as follows (see also Table 4.10)[179]:

1. The rate-limiting step in anisotropic etching of Si is the water reduction.
2. Hydroxide ions required for oxidation of the silicon are generated through reduction of water at the silicon surface. The hydroxide ions in the bulk do not contribute to the etching because they are repelled from the negatively charged surface. This implies that the silicon etch rate will depend on the molar concentration of water and that cations will have little effect on the silicon etch rate.
3. The dissolution of silicon dioxide is assumed to be purely chemical with hydroxide ions. The SiO_2 etch rate depends on the pH of the bulk electrolyte.
4. For boron concentrations in excess of 3×10^{19} cm^{-3}, the silicon becomes degenerate, and the electrons are no longer confined to the surface. This prevents the formation of the hydroxide ions at the surface and thus causes the etching to stop.
5. Anodic biases will prevent the confinement of electrons near the surface as well and lead to etch stop as in the case of a p^+ material.

This model applies well for lower index planes (i.e., {nnn} with $n < 2$), where high etch rates always correspond to low activation energies. However, for higher index planes (i.e., {n11} and {1nn} with n = 2, 3, 4), Herr et al.[54] found no correlation between activation energies and etch rates. For higher index planes, we must rely mainly on empirical data.

Several chemical models explaining the anisotropy in etching rates for the different Si orientations have been proposed. In the different etching models, different Si crystal properties have been correlated with the anisotropy in silicon etching:

1. According to Gandhi[181] and Kern,[77] the silicon oxidation reaction steps involve injection of holes into the Si (raising the oxidation state of Si), hydroxylation of the oxidized Si species, complexation of the silicon reaction products, and dissolution of the reaction products in the etchant solution. In this reaction scheme, etching solutions must provide a source of holes and hydroxide ions, and they must contain a complexing agent that solubilizes reacted Si species in the etchant solution, for example, pyrocatechol forming the soluble $Si(C_6H_4O_2)_3^{2-}$ species. This older model still seems to guide the thinking

of many micromachinists, although Gosalvez's atomistic model and Seidel et al.'s energy level-based model of the silicon/electrolyte interface are more powerful and predictive.

2. Because the {111} Si planes present the highest density of atoms/cm^2 to the etchant and because the atoms are oriented such that three bonds are below the plane (Figure 4.56), it is possible that these bonds become chemically shielded by surface-bonded OH or oxygen, thereby slowing the etch rate for {111} planes. In this model, it is assumed that the anisotropy is caused by differences in activation energies and backbond geometries on different Si surfaces.[182] Seidel et al.[52,110] support this explanation. They detail a process to explain anisotropy based on the difference in energy levels of backbond-associated surface states for different crystal orientations.
3. It also has been suggested that etch rate correlates with available bond density; thus, the surfaces with the highest bond density etch faster.[107] The available bond densities in Si and other diamond structures follow the sequence 1:0.71:0.58 for the {100}/{110}/{111} surfaces. However, Kendall[48] commented that bond density alone is an unlikely explanation because of the magnitude of etching anisotropy (e.g., a factor of 400) compared with the bond density variations of at most a factor of two.
4. Kendall[48] explains the slow etching of {111} planes based on their faster oxidation during etching; this does not happen on the other faces, he speculates, because of greater distance of the atoms on planes other than (111). Because the {111} planes oxidize faster, these planes may be better protected against etching. The oxidation rate in particular in oxygen follows the sequence {111} > {110} > {100}, and the etch rate often follows the reverse sequence (see also Volume I, Chapter 4 on Si oxidation in an oxygen gas stream). In the most used KOH-H_2O wet etching system, however, the sequence is {110} > {100} > {111}.
5. Besides the number of backbonds of the silicon atom under attack, Gosalvez concludes that the site specificity of anisotropic etching is also determined by the geometry of the transition complex; in other words, the steric hindrance of the OH-termination controls the reaction rate as well. The larger the size and the more rigid the transition complex, the larger one expects the anisotropy to be.
6. Madou (see below) explains why Si etches anisotropically in alkaline etchants and isotropically in acidic etchants based on the pH dependency of the energy levels at the silicon/electrolyte interface.
7. Finally, Elwenspoek et al.[55,56] (see below) propose that it is the degree of atomic smoothness of the various surfaces that is responsible for the anisotropy of the etch rates. Basically, this research group argues for the kinetics of smooth faces [the (111) plane is atomically flat] being controlled by a nucleation barrier absent on rough surfaces. The latter, therefore, would etch faster by orders of magnitude. This model also contributes to the understanding why certain etchants etch isotropically and others etch anisotropically.

Elwenspoek et al.'s Model

Elwenspoek et al.[55,56] introduced an alternative model for anisotropic etching of Si, a model built on theories derived from crystal growth. According to these authors, the Seidel et al. model does not clearly explain the fast etching of {110} planes. Those planes, having three backbonds like the {111} planes, should etch equally slowly. The activation energy of the anisotropic etch rate depends on the etching system used; for example, etching in KOH is faster than in EDP, even when the pH of the solution is the same. Seidel et al. attribute this dependence to diffusion that plays a greater role in EDP than in KOH solutions. However, Elwenspoek et al. point out that, at least for slow etching, the etch rate should not be diffusion controlled but governed by surface reactions. With surface reactions, diffusion should have a minor effect, analogous to growth at low pressure in an LPCVD reactor (see Chapter 7). Another comment focuses on the lack of understanding why certain etchants etch isotropically and others etch anisotropically.

Elwenspoek et al. note that crystal surfaces are not ideal and highlight the parallels in the process

of etching and growing of crystals; slowly growing crystal planes also etch slowly! A key to understanding both processes, growing or dissolution (etching), pertains to the concept of the energy associated with the creation of a critical nucleus on a single-crystalline smooth surface, that is, the free energy associated with the creation of an island (growth) or a cavity (etching). Etching or growing of a material starts at active kink sites on steps. Kink sites are atoms with as many bonds to the crystal as to the liquid. Kinetics depends critically on the number of such kink sites (see Figure 4.59). Remember that in Volume I, Chapter 2 we calculated that at room temperature a certain number of vacancies (n_{eq}) must be present in an ideal crystal at any temperature above 0 K (Volume I, Equation 2.59 and Figure 2.35).

A group of vacancies and adatoms can lead to a cavity (etching) or an island (growth), respectively. This aspect has remained neglected in the discussion of etch rates of single crystals until now. The free energy change, ΔG, involved in creating an island or digging a cavity (of circular shape in an isotropic material) of radius r on or in an atomically smooth surface, is given by:

$$\Delta G = -n\Delta\mu + 2\pi r\gamma \tag{4.3}$$

where n is the number of atoms forming the island or the number of atoms removed from the cavity, $\Delta\mu$ is the chemical potential difference between silicon atoms in the solid state and in the solution, and γ is the step free energy. The step free energy in Equation 4.3 will be different at different crystallographic surfaces. This can be easily understood from the following example. A perfectly flat {111} surface in the Si diamond lattice has no kink positions (three backbonds, one dangling bond per atom), whereas on the {001} face every atom has two backbonds and two dangling bonds; that is, every position is a kink position. Consequently, creating an adatom-cavity pair on {111} surfaces costs energy: three bonds must be broken and only one is reformed. In the case of {001} faces, the picture is different. Creating an adatom-cavity pair now costs no energy because two bonds must be broken to remove an atom from the {001} face, but the energy is returned by placing the atom back on the surface. In Equation 4.3 n can be further written out as:

$$n = \pi r^2 h\rho \tag{4.4}$$

where h is the height of the step (down for a cavity and up for an island), r is the diameter of the hole or island, and ρ is the density (atoms/cm^3) of the solid material. The result is:

$$\Delta G = -\pi r^2 h\rho\Delta\mu + 2\pi r\gamma \tag{4.5}$$

where $\Delta\mu$ is counted positive, and γ is positive in any case. In Figure 4.60 we show a plot of ΔG versus r. Equation 4.6 exhibits a maximum at:

$$r^* = \frac{\gamma}{h\rho\Delta\mu} \tag{4.6}$$

At r^*, the free energy is:

$$\Delta G^* = \Delta G(r^*) = \frac{\pi\gamma^2}{h\rho\Delta\mu} \tag{4.7}$$

Consequently, an island or an etched cavity of critical size exists on a smooth face. If by chance a cavity

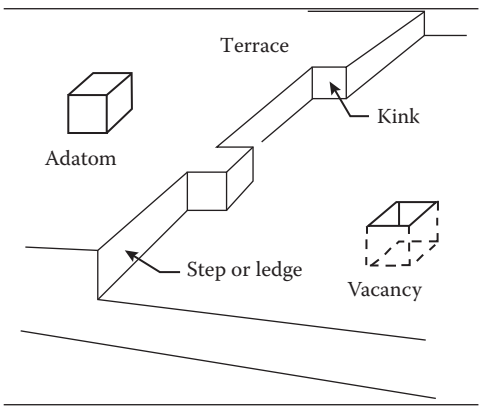

FIGURE 4.59 Perspective drawing of a crystal showing terraces, step or ledge, kinks, adatoms, and vacancies.

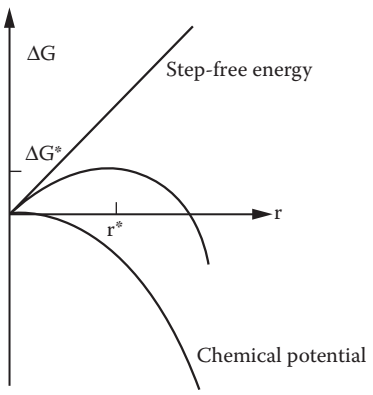

FIGURE 4.60 A plot of ΔG versus r based on Equation 4.5 exhibits a maximum.

is dug into a crystal plane smaller than r^*, it will be filled rather than allowed to grow, and an island that is too small will dissolve rather than continue to grow because that is the easy way to decrease the free energy. With $r = r^*$, islands or cavities do not have any course of action, but in case of $r > r^*$, the islands or cavities can grow until the whole layer is filled or removed. Importantly, if r^* is equal or smaller than the diameter of a single atom, every atom that leaves the surface will lead to a whole layer filled (a terrace) or removed. In the case of crystal growth, the reverse of etching, this phenomenon is called kinetic roughening. For isotropic etching $\Delta\mu$ is very large; therefore, for all crystal orientations r^* is very small. On the other hand, in light of this nucleation barrier theory, to remove atoms directly from flat crystal faces, such as the {111} Si faces, seems very difficult because the created cavities increase the free energy of the system, and filling of adjacent atoms is more probable than removal; in other words, a nucleation barrier has to be overcome. That is, in anisotropic etching, $\Delta\mu$ is small, or, based on Equation 4.7, a sizable nucleation barrier must be overcome. The growth and etch rates, R, of flat faces are proportional to:

$$R \sim e^{-\frac{\Delta G^*}{kT}} \tag{4.8}$$

Because ΔG^* is proportional to γ^2 (see Equation 4.7), the activation energy is different for different crystallographic faces, and both the etch rate and the activation energy are anisotropic. If $\Delta G^*/kT$ is large, the etch rate will be very slow, as is the case for large step free energies. Both $\Delta\mu$ and γ depend on the temperature and type of etchant, and these parameters might provide clues to understanding the variation of etch rate, degree of anisotropy, temperature dependence, and so on, giving this model perhaps more bandwidth than Seidel et al.'s model. According to Elwenspoek et al., the chemical reaction energy barrier and the transport in the liquid are isotropic, and the most prominent anisotropy effect is caused by the step free energy (absent on rough surfaces) rather than the surface free energy. However, the surface free energy and the step free energies are related: when comparing flat faces, those having a large surface free energy have a small step free energy, and vice versa. The most important difference in these two parameters is that the step free energy is zero for a rough surface, whereas the surface energy remains finite.

Flat faces grow and etch with a rate proportional to ΔG^*, which predicts that faces with a large free energy to form a step will grow and etch much slower than faces with a smaller free energy. Elementary analysis indicates that the only smooth face of the diamond lattice is the (111) plane. There may be other flat faces, but with lower activation energies, as a result of reconstruction and/or adsorption, prominent candidates in this category are {100} and {110} planes. On the other hand, a rough crystal face grows and etches with a rate directly proportional to $\Delta\mu$. The temperature at which γ vanishes and a face transitions from smooth to rough is called the *roughening transition temperature* T_R.[183,184] Above T_R, the crystal is rough on the microscopic scale. Rough crystal faces grow and dissolve with a rate proportional to $\Delta\mu$ and therefore proceed faster than flat surfaces. Imperfect crystals, for example, surfaces with screw dislocations, etch even faster with R proportional to $\Delta\mu^2$.

For the state of a surface slightly above or below the roughening temperature, T_R, thermal equilibrium conditions apply. Etching, in most practical cases, is far from equilibrium, and kinetic roughening might occur. Kinetic roughening occurs if the super- or undersaturation of the solution is so large that the thermally created islands or cavities are the size of the critical nucleus.[184] One can show that if the super- or undersaturation is larger than $\Delta\mu_c$, given by:

$$\Delta\mu_c = \frac{\pi f_0 \gamma^2}{kT} \tag{4.9}$$

(f_0 being the area one atom occupies in a given crystal plane), the growth and etch mechanism changes from a nucleation barrier-controlled mechanism to an isotropic growth/etch mechanism. The growth rate and etch rate become proportional to the chemical potential difference ($\Delta\mu$). Thus, it can be expected that if the undersaturation becomes high enough, even the {111} faces could etch isotropically, as they do in acidic etchants. If the undersaturation becomes so large that $\Delta\mu \ll kT$, the nucleation barrier breaks down. Each single-atom cavity acts as a nucleation site made in vast numbers by thermal fluctuations. The face in question

etches with a rate comparable to the etch rate of a rough surface. This situation is called *kinetic roughening*. If all faces are kinetically rough, the etch rate becomes isotropic.

The binding energy ΔE of an atom in a crystal slice with orientation (*hkl*) divided by *kT* (Boltzmann constant × absolute temperature) is known as the α factor of Jackson of that crystal face,[185] or:

$$\alpha = \frac{\Delta E}{kT} \tag{4.10}$$

At sufficiently low temperature, where entropy effects can be ignored, $kT\alpha$ is proportional to the step free energy γ, and the number of adatom-cavity pairs is then proportional to $\exp(-\alpha)$. This number is very small on the {111} silicon faces at low temperature, but 1 on the {001} silicon faces at any temperature. The consequence for {111} and {001} planes is that, at sufficiently low temperatures, the first are atomically smooth and the latter are atomically rough.

Isotropic etching requires conditions of kinetic roughening because the etch rate is no longer dominated by a nucleation barrier but by transport processes in solution and the chemical reaction. To test this aspect of the model, Elwenspoek et al. show that there is a transition from isotropic to anisotropic etching if the undersaturation becomes too small. This can occur if one etches with an acidic etchant very long or if one etches through very small holes in a mask (crevice effect). In both cases, anisotropic behavior becomes evident as aging or limited transport of the solution causes the undersaturation to become very small. No proof is available to indicate that acidic etchants are much more undersaturated than the alkaline etchants. Still, the above explains some phenomena that Seidel et al.'s model fails to address. Another nice confirmation of Elwenspoek et al.'s model is in the effect of misalignment on etch rate. A misalignment of the mask close to smooth faces implies steps; there is no need for nucleation to etch. Because the density of steps is proportional to the angle of misalignment, the etch rate should be proportional to the misalignment angle, provided the distance between steps is not too large. Nucleation of new cavities becomes very probable. This has been observed for the etch rate close to the <111> directions.[52]

Where Elwenspoek et al.'s model becomes a bit murky is in the classification of which surfaces are smooth and which ones are rough. As mentioned above for single-crystal Si, only the {111} planes are smooth at low temperatures. At this stage, the model does not explain anything more than other models; every model has an explanation for the slower {111} etch rate. However, as pointed out, these authors invoke the possibility of surface reconstruction and/or adsorption of surface species, which, by decreasing the surface free energy, could make faces such as {001} and {110} flat as well but with lower activation energies. The authors also take heart in the fact that CVD experiments often end up showing flat {110}, {100}, {331}, and, strongest of all, {111} planes. Si etching models are improving fast, but especially where the influence of the etchant is concerned, more convincing thermodynamic data are needed to estimate $\Delta\mu$ and γ.

Madou Model for Isotropic versus Anisotropic Etching of Silicon

In contrast to alkaline etching, with an acidic etchant such as HF, holes are needed for etching Si. An n-type Si electrode immersed in HF in the dark will not etch because of lack of holes. The same electrode in an alkaline medium etches readily. A p-type electrode in an HF solution, where holes are available under the proper bias, will etch even in the dark. For HF etchants, one might assume that the Ghandi and Kern model,[77,181] relying on the injection of holes, applies. In terms of the band model, this must mean that the silicon/electrolyte interface in acidic solutions exhibits different energetics from the alkaline case. It is not directly obvious why the energetics of the silicon/electrolyte interface would be pH-dependent. To the contrary, because the flat-band potential of most oxide semiconductors and most oxide-covered semiconductors (such as Si) and the Fermi level of the H_2O/OH^- redox couple in an aqueous solution are both expected to change by 59 mV for each pH unit change,[186] one would expect the energetics of the interface to be pH independent. Because the electronegativity in a Si-F bond is higher than for a Si-OH bond, one might even expect the back-bond surface states to be raised higher in an HF medium, making an electron injection mechanism

even more likely than in alkaline media. To clarify this contradiction, we analyze the band model of a Si electrode in an acidic medium in more detail. The band model shown in Figure 4.61 was constructed based on a set of impedance measurements on an n-type Si electrode in a set of aqueous solutions at different pH values. Mott-Schottky plots were constructed from the impedance measurements to determine the pH dependency of the flat-band potential. From that, the position of the conduction band E_{cs}, as well as valence band edges E_{vs}, of the Si electrode in an acidic medium at a fixed pH of 2.2 (the point of zero charge) was calculated at 0.74 eV versus SCE (an often-used reference electrode in electrochemistry) for E_{cs}, and −0.36 eV versus SCE for E_{vs}.[187,188]

We have assumed in Figure 4.61 that the bands are bent upward at open circuit (see below for justification); thus, holes in the valence band are driven to the interface where they can react with Si atoms or with competing reducing agents from the electrolyte. Because we want to etch Si, we are only interested in the reactions where Si itself is consumed. Reactions of holes with reducing agents are of great importance in photoelectrochemical solar cells.[188] For n-type Si, holes can be 1) injected by oxidants from the solution (e.g., by adding nitric acid to the HF solution); 2) supplied at the electrolyte/semiconductor interface by shining light on a properly biased n-type Si wafer; or 3) created by impact ionization, that is, Zener breakdown, of a sufficiently high reverse biased n-type Si electrode.[189] With a p-type Si wafer, a small forward bias supplies all the holes needed for the oxidation of the lattice even without light because the conduction happens via a hole mechanism. An important finding, explaining the different reaction paths in acidic and alkaline media, comes from plotting the flat-band potential as a function of pH. It was found that the band diagram of Si shifts with less than 59 mV per pH unit. Actually, the average shift is only about 30 mV per pH unit.[188] As shown in Figure 4.62, with increasing pH, the energy levels of the solution increase faster than the energy levels in the semiconductor. As a consequence, it is more likely that electron injection takes place in alkaline media as the filled levels associated with the OH^- are closer to the conduction band, whereas in acidic media the filled levels of the redox system overlap better with the valence band, favoring a hole reaction. A lower position of the redox couple with respect to the conduction band edge, E_{cs}, in acidic media explains the upward bending of the bands as drawn in Figure 4.62. With isotropic etching in acidic media, the reaction starts with a hole in the valence band, equivalent to a broken Si-Si bond. In this case, the relative position of backbond-related surface states in different crystal orientations is of no consequence, and all planes etch at the same rate. A study of the interfacial energetics helps to understand why isotropic etching occurs in acidic media and anisotropic etching in alkaline media.

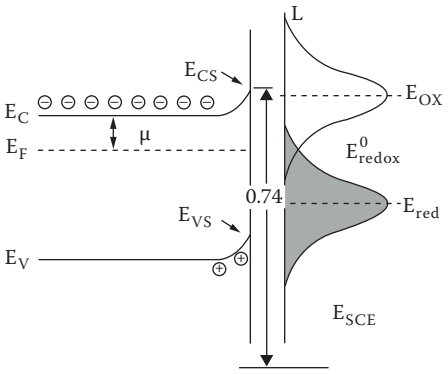

FIGURE 4.61 Band diagram for n-type Si in pH = 2.2 (no bias or illumination). Reference is the SCE. In Figure 4.40 no energy values were given; here we provide positions of the conduction band edge, E_{cs} = 0.74 eV versus SCE, and the valence band edge, E_{vs} = 0.74 eV –1.1 eV = –0.36 eV versus SCE (1.1 eV is the bandgap of Si). These values were determined by means of Mott-Schottky plots. (Madou, M. J., K. W. Frese, and S. R. Morrison. 1980. Photoelectrochemical corrosion of semiconductors for solar cells. *SPIE* 248:88–95.[187]) The separation between the Fermi energy and the bottom of the conduction band is indicated by μ.

A few words of caution regarding our explanation for the reactivity difference between acidic and alkaline media are in order. Little is known about the width of the bell-shaped curves describing the redox levels in solution.[186] Not knowing the surface concentrations of the reactive redox species involved in the etching reactions further hinders a better understanding of the surface energetics because the bell-shaped curves for oxidant and reductant will only be the same height (as drawn in Figures 4.61 and 4.62) if the concentrations of oxidant and reductant are the same. Clearly, the above picture is oversimplified;

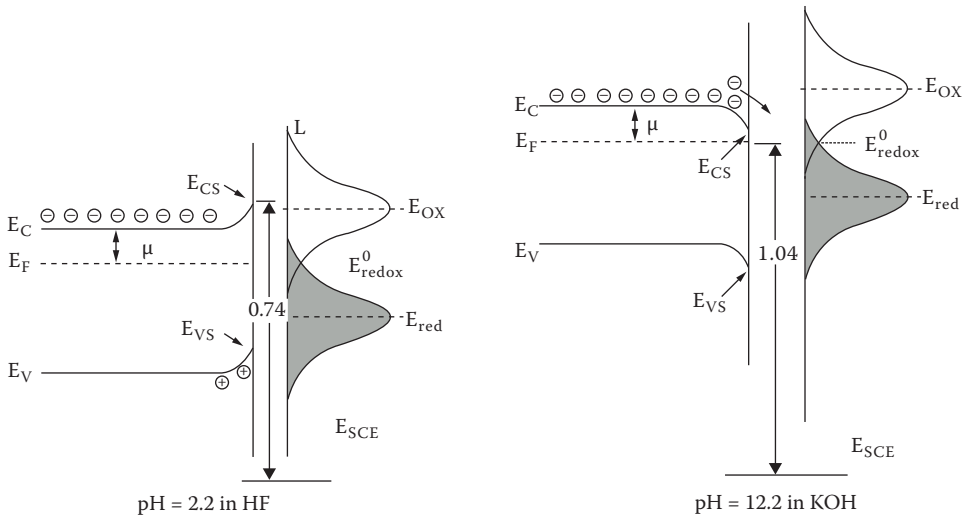

FIGURE 4.62 Band model comparison of the Si/electrolyte interface at low and high pH. Increasing the pH by 10 units shifts the redox levels up by 600 mV, whereas the Si bands only move up by 300 mV. This leads to a different band-bending and a different reaction mechanism, that is, electron injection in the alkaline media (anisotropic) and hole injection in acidic media (isotropic).

several authors have found that the dissolution of Si in HF might involve both the conduction and valence band, a claim confirmed by photocurrent multiplication experiments.[102,190] These photocurrent multiplication experiments showed that one or two holes generated by light in the Si valence band were sufficient to dislodge one Si unit, meaning that the rest of the charges were injected into the conduction band.[191] Our contention here is only that the low pH dependence of the flat-band potential of a silicon electrode makes a conduction band mechanism more favorable with alkaline-type etchants and a hole mechanism more favorable in acidic media.

Continued attempts at modeling the etch rates of all Si planes are underway. For example, Hesketh et al.[192] attempted to model the etch rates of the different planes developing on silicon spheres in etching experiments with KOH and CsOH by calculating the surface free energy. The density of surface bonds on a Si plane is indicative of the surface free energy, which can be estimated by counting the bond density and multiplying by the bond energy. Using the unit cell dimension a of Si of 5.431 Å and a silicon-to-silicon bond energy of 42.2 kcal/mol, the surface free energy, ΔG, can be related to N_B, the bond density, by the following expression:

$$\Delta G = \frac{N_B}{2} \times 2.94\ 10^{-19}\ \frac{J}{m^2} \qquad (4.11)$$

Although Hesketh et al. could not explain the etching differences observed between CsOH and KOH (these authors identified a cation effect on the etch rate!), a plot of the calculated surface free energy versus orientation yielded minima for all low index planes such as {100}, {110}, and {111}, as well as for the high index {522} planes. Fewer bonds per unit area on the low index planes produce a lower surface energy and lower etching rate. When Hesketh et al. added the in-plane bond density to the surface bond density, producing a total bond density, a correlation with the hierarchy of etch rates in CsOH and KOH was found, that is, {311}, {522} > {100} > {111}. The surfaces with the higher bond density etched faster, suggesting that the etch rate might be a function of the number of electrons available at the surface. Hesketh et al. imply that their result falls in line with the Seidel et al.'s model, although it is unclear how the total bond density relates to surface state energies of backbonds. Moreover, Hesketh's model does not take into account the angles of the bonds, and in Elwenspoek's view, the surface free energy does not determine the anisotropy.

More research should focus on the modeling of Si etch rates. The semiconductor electrochemistry of corroding Si electrodes will be a major tool in further developments. Interested readers may consult Sundaram et al.[193] on Si etching in hydrazine and Palik et al.[128] on the etch-stop mechanism in

heavily doped silicon; both explain in some detail the silicon/electrolyte energetics. A more generic treatise on semiconductor electrochemistry can be found in Morrison.[194] A free etch simulator from the University of Illinois can be found at http://mass.micro.uiuc.edu/research/completed/aces/pages/home.html. For more modeling software of Si etching, consult Volume III, Chapter 6.

Etching with Bias and/or Illumination of the Semiconductor

Introduction

The isotropic and anisotropic etching of Si we discussed thus far requires neither a bias nor illumination of the semiconductor. The etching in such cases proceeds at open circuit, and the semiconductor is shielded from light. In a cyclic voltammogram, as shown in Figure 4.63, the operational potential in this case is the rest potential, V_r, where anodic and cathodic currents are equal in magnitude and opposite in sign, resulting in the absence of flow of current in an external circuit. This does not mean that macroscopic changes do not occur at the electrode surface because the anodic and cathodic currents may be part of different chemical reactions just as in the corrosion of a metal exposed to, for example, seawater. Earlier, in the context of Si etching, we called this type of open circuit etching "electroless" etching (see page 266). As an example of "electroless" etching, consider again the isotropic etching of Si in an HF/HNO_3 etchant at open circuit where the local anodic reaction is associated with corrosion of the semiconductor:

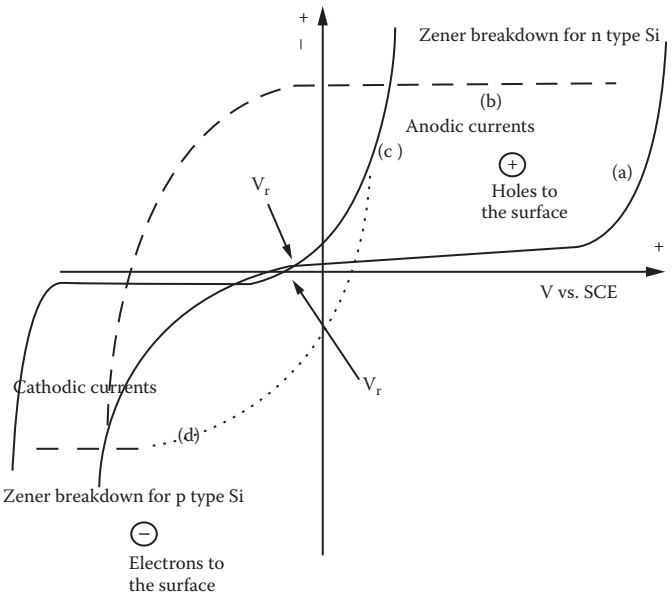

FIGURE 4.63 Basic cyclic voltammograms (*I* vs. *V*) for n- and p-type Si in an HF solution in the absence of a hole-injecting oxidant: n-type Si without illumination (a); n-type Si under illumination (b); p-type Si without illumination (c); p-type Si under illumination (d). If the reactions on the dark Si electrode determining the rest potential V_r for n- and p-type are the same, then V_r is expected to be the same as well. For clarity of the figure we have chosen V_r differently here; in practice, V_r for n- and p-type Si in HF are found to be identical.

$$\text{Local anode: } Si + 2H_2O + nh^+ \rightarrow SiO_2 + 4H^+ + (4\text{-}n)e^- \qquad \text{Reaction 4.19}$$

$$SiO_2 + 6HF \rightarrow H_2SiF_6 + 2H_2O \qquad \text{Reaction 4.20}$$

(the involvement of holes h^+ in the acidic reaction was discussed in the preceding sections), whereas the local cathodic reaction could be associated with reduction of HNO_3:

$$\text{Local cathode: } NO_3^- + 4H^+ + 3e^- \rightarrow NO + 2H_2O \qquad \text{Reaction 4.21}$$

We now explore Si etching while illuminating and/or applying a bias to the silicon sample. To simplify the situation, we first consider the case of an oxidant-free solution so that all the holes must come from within the semiconductor. Anodic dissolution of n-type Si in an HF-containing solution requires a supply of holes to the surface. For an n-type wafer under reverse bias, very few holes will show at the surface unless the high reverse (anodic) bias is sufficient to induce impact ionization or Zener breakdown (see Figure 4.63a). Alternatively, the interface can be illuminated, creating holes in the space charge region (SCR) that the field pushes toward the semiconductor/electrolyte interface (Figure 4.63b). In the forward direction, electrons from the Si conduction band (majority carriers) reduce oxidizing species in the solution (e.g., reduction of protons to hydrogen). A p-type Si sample exhibits high anodic currents even without illumination at small anodic (forward) bias (Figure 4.63c). Here, the current is carried by holes. A p-type electrode illuminated under reverse

bias gives rise to a cathodic photocurrent (Figure 4.63d). At relatively low light intensities, the photocurrent plateaus for both n- and p-types (Figure 4.63b and d respectively) depend linearly on light intensity. The photocurrent is cathodic for p-type Si (species are reduced by photoproduced electrons at the surface, e.g., hydrogen formation) and anodic for n-type Si (species are oxidized by photoproduced holes at the surface; either the lattice itself is consumed or reducing compounds in solution are). In Figure 4.64, we show the cyclic voltammograms of n-type and p-type Si in the presence of a hole-injecting oxidant. The most obvious effect is on the dark p-type silicon electrode. The injection of holes in the valence band increases the cathodic dark current dramatically. The current level measured in this manner for varying oxidant concentration or different oxidants could be used to estimate the efficiency of different isotropic Si etchants, a pointer to the fact that semiconductor electrochemistry has been underused as a tool to study Si etching. When n-type Si is consumed under illumination, we experience photocorrosion (see Figure 4.63b). This photocorrosion phenomenon has been a major barrier to the long-term viability of photoelectrochemical cells.[187]

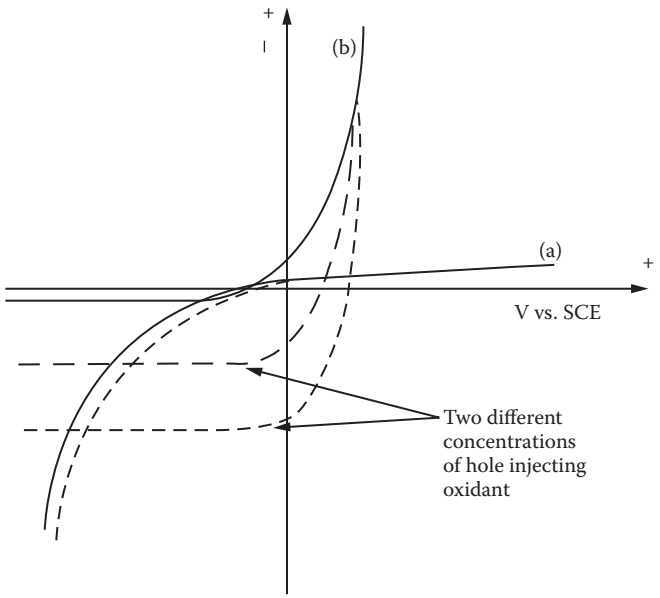

FIGURE 4.64 Basic cyclic voltammograms for n- and p-type Si in an HF solution and in the presence of a hole-injecting oxidant, for example, HNO_3: n-type Si in the dark (a); p-type Si in the dark (b). An increase of the cathodic dark current on the p-type electrodes is most obvious. The current level is proportional to the oxidant concentration.

In what follows, photocorrosion is put to good use for electropolishing and formation of microporous and macroporous layers.[189]

Electropolishing and Porous Silicon

Electropolishing In Figure 4.65 we show cyclic voltammograms for p- and n-type Si in an HF solution in the dark and under illumination. The anodic current in the dark for a p-type Si electrode presents two peaks, characterized by i_{CRIT} and v_p (first peak) and i_{MAX} and v_{MAX} (second peak). This was also illustrated, in somewhat less detail, in Figure 4.37, where we only marked the first peak with i_p and v_p (i_{CRIT} was called i_p in that graph) and did not show the oscillations at potentials positive of v_{MAX}. As can be deduced from this figure, at high light intensities, in so-called photoelectrochemical etching (PEC), the anodic curves for n-type and p-type Si are similar. The two differences are 1) a potential shift of a few hundred millivolts, and 2) the illuminated n-type Si in the anodic range only shows the first peak and then transitions into a photoplateau. At very high illuminations, a second anodic peak also appears in this case. Because of this equivalence, most of the processes described below apply for both forward-biased p-type and for n-type Si under strong illumination. PEC etching involves photocorrosion in

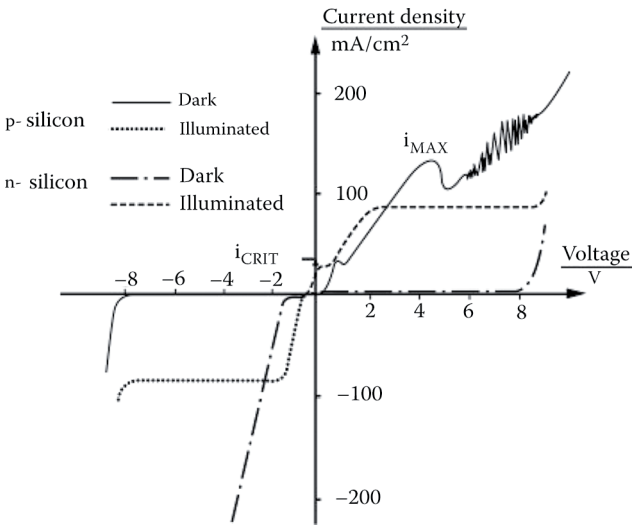

FIGURE 4.65 Cyclic voltammograms identifying porous Si formation regime and electropolishing regime. (From Levy-Clement, C., A. Lagoubi, R. Tenne, and M. Neumann-Spallart. 1992. Photoelectrochemical etching of silicon. *Electrochim Acta* 37:877–88. With permission.[189])

an electrolyte in which the semiconductor is generally chemically stable in the dark; that is, no hole-injecting oxidants are present, as in the case of an HF solution (see also experiments described in Figure 4.63). For carrying out PEC, a setup as shown in Figure 4.66a may be used with a provision to illuminate the semiconductor electrode. The Al strip shown here is used to make ohmic contact to the back side of the Si electrode. For fabricating porous Si and electropolishing, one often uses a so-called electrochemical double cell, also referred to as double tank lateral cell, as shown in Figure 4.66b. Such a cell has two platinum working electrodes, one in each part of the cell, with the Si wafer in the middle separating the two parts. When current is passed through the wafer, its anodic side will be etched. The main advantages compared with the cell in Figure 4.66a are that no back-side metallization is required and that the uniformity of the process is typically better.

The potential range to the left (more positive) of the first current peak (v_p) in Figure 4.65 was clarified earlier as the electropolishing range. Here, the current density exceeds the so-called critical current density, i_{CRIT} (see also Equation 4.1), marked by the first peak in the *I-V* curve. The silicon etches in this domain, leaving behind a smooth (electropolished) surface. It is generally assumed that the electropolishing of silicon takes place in two steps. In the first step an oxide layer forms, and this oxide layer subsequently dissolves in the HF (see Reactions 4.8 and 4.9). Hills on the surface dissolve faster than depressions because the current density is higher on high spots. As a result, the surface becomes smoother, that is, electropolishing takes place.[91] Electropolishing in this regime can be used to smooth silicon surfaces or to thin epitaxially grown silicon layers. The second peak and the oscillations in Figure 4.65 are explained as follows: at current densities exceeding i_{MAX} another type of oxide grows on top of the silicon, leading to a decrease of the anodic photocurrent (explaining the i_{MAX} peak), until a steady state is reached in which dissolution of the oxide by HF through formation of a fluoride complex in solution (SiF_6^{2-}) equals again the oxide growth rate. The oscillations sometimes observed in the anodic curve in Figure 4.65 can be explained by a nonlinear correlation between formation and dissolution of the oxide.[189]

The Al is used for ohmic contact to the Si electrode. (Picture from http://sailorgroup.ucsd.edu/research/porous_Si_intro.html.) (b) Electrochemical double cell (also referred to as double tank lateral cell). (Gaburro, Z., N. Daldosso, and L. Pavesi, eds. 2005. *Encyclopedia of condensed matter physics: porous silicon.* Amsterdam: Elsevier Ltd.[195])

Electropolishing is also possible under a layer of porous Si already formed at the porous Si/bulk silicon interface, and the porous layer may be underetched this way. The latter is the enabling technology in the Bosch advanced porous Si membrane process (APSM) (see page 293). The APSM technology makes use of porous Si to form a cavity underneath the surface of monocrystalline silicon and turns the traditional bulk micromachining process into a surface micromachining technology.

Porous Silicon

Historical Note Uhlir first discovered porous Si (PS) in 1956 at the Bell Laboratories.[7] He found that, with the appropriate current and solution composition, silicon does not dissolve uniformly, and pores are produced instead. These pores, he found, propagate primarily in the <100> direction of the Si wafer. This did not provide the smooth polish for Si that he sought, and after his curious results were reported in a Bell Labs technical note, the work was pretty much forgotten. Renewed interest in porous Si came about in the 1970s and 1980s: its high surface area was found to be useful as a model in the spectroscopic studies of chemical adsorption/

FIGURE 4.67 Bright photoluminescence of porous Si at room temperature. (Science and art from Mikael Östling, KTH.)

desorption kinetics on crystalline Si surfaces, and the material also found application as a precursor to generate thick oxide layers on Si and as a dielectric layer in capacitance-based chemical sensors (see above and further below under "Porous Si Applications").

In the late 1980s, Leigh Canham, from the Defense Research Agency in the United Kingdom, argued that the thin Si filaments generated when the pores in porous Si become large and numerous enough might display quantum confinement effects. His intuition turned out to be correct, and by 1990 Canham found that electrochemically etched PS material was fluorescent at room temperature with a bright red-orange color (see Figure 4.67).[196,197] Shortly thereafter, in 1991, Richter demonstrated electroluminescence on porous Si in the 560–480-nm range.[198]

The observation that porous Si features a large photoluminescence (PL) effect in the visible range (at room temperature!) was a very surprising result because the PL efficiency of bulk Si (Si) is very low as a result of its indirect energy bandgap (typical room temperature light emission efficiencies for silicon are much less than 0.001%; in contrast, GaAs LEDs routinely have quantum efficiencies of 1–10%, and approaching 30% for specialized LEDs). As expected from the quantum confinement-induced blue shift, the emitted color is at an energy that is significantly larger than the bandgap energy for bulk Si (which occurs in the infrared region of the spectrum $E_g = 1.1$ eV) (see Figure 4.68 and Volume I, Chapter 3). The underlying mechanism for this blue shift is the result of the quantum-confined structures formed in the porous Si pore walls. High-porosity porous Si material emits green/blue light, whereas low porosity emits red light.

The discovery of efficient visible light emission from porous Si initiated an explosion of work focused on creating Si-based optoelectronic switches, displays, lasers, and so on. However, problems with the material's chemical and mechanical stability and the aging of its optoelectronic properties (see Figure 4.73) led to a waningof the interest in porous Si as an optoelectronic material by the mid-1990s (http://chem-faculty.ucsd.edu/sailor/research/porous_Si_intro.html). By the late 1990s, optoelectronic properties research of porous Si got a new lease on life, however, because of the potential of porous Si for photonic crystals (see below and Volume I, Chapter 5).[197] Porous Si might represent a simple way of making photonic crystals as explained in the section on Macroporus Silicon. Other unique features of porous Si, such as its large surface area, its controllable pore size, its convenient surface chemistry, and its compatibility with conventional silicon microfabrication technologies, also inspired research into applications far outside the optoelectronics field. Additional applications include biocompatible interfaces, biosensing, and drug delivery. An overview of porous

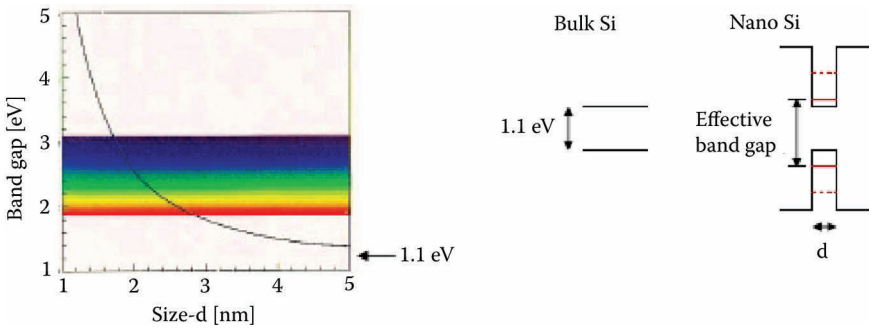

FIGURE 4.68 Bandgap widening of silicon in porous silicon.

Table 4.11 Porous Si Application Fields and Examples[195]

Application Area	Role of PS	Key Property
Optoelectronics	LED Waveguide Field emitter Optical memory	Efficient electroluminescence Tunability of refractive index Hot carrier emission Nonlinear properties
Microoptics	Fabry-Perot filters Photonic band gap structures All optical switching	Refractive index modulation Regular macropore array

Microelectronics	Microcapacitor Insulator layer Low-k material	High specific surface area High resistance Electrical properties
Wafer technology	Buffer layer in heteroepitaxy SOI wafers; see also Eltran process	Variable lattice parameter High etch selectivity
Micromachining	Thick sacrificial layer	Highly controllable etching patameters
Biotechnology	Tissue bonding Biosensors	Tunable chemical reactivity Enzyme immobilization

Si applications is listed in Table 4.11. Today, porous Si, together with carbon nanotubes, is often used to illustrate nanotechnology products/applications that are relatively easy to make/implement.

Porosity in Si Porosity P of a material is the volumetric fraction of air in the material and is defined as:

$$P = \frac{V_{voids}}{V_{material}} = \frac{m_{original} - m_{anodized}}{m_{original} - m_{dissolved}} \qquad (4.12)$$

For example, porous Si with $P = 10\%$ means that there is 10% air and 90% silicon in the material. The tunable pore size range in porous Si can be divided into (International Union of Pure and Applied Chemistry definition)[195]:

1. Microporous: $d < 2$ nm
2. Mesoporous: 2 nm $< d <$ 50 nm
3. Macroporous: $d > 50$ nm

The geometry of porous Si varies from a sponge-like layer consisting of nanoscale branch-shaped fractal-like pores to straight pore arrays. These geometries depend on various conditions, such as the doping level and doping type of the Si substrate, the current density, HF concentration, and crystal orientation. The porous Si porosity can vary between 5% and 85%, and pore size can differ by three orders of magnitude, 20 Å to 10 µm, and the exact underlying formation mechanism, we shall see, is still under debate. The word *nanoporous* is sometimes used for the smallest-pore regime.

Accurate determination of pore size distribution in porous Si is usually performed by the analysis of adsorption isotherms of gases at low temperature in the so-called Barret-Joyner-Halenda, or BJH, method.[199] The physical adsorption of gases by a porous surface is increased relative to a nonporous one because of capillary condensation in the pores. This increase in adsorption starts when the gas pressure is high enough to fill the smallest pores. The specific surface area A of porous Si, determined by Brunauer-Emmett-Teller, or BET, ranges from A_{BET} = 1–1000 m^2/cm^3.[200] The structure of the pores in nanoporous Si can best be observed by transmission electron microscopy (TEM), and its thickness can be monitored with an infrared (IR) microscope. Structural properties of porous Si have also been investigated by a wide variety of other techniques such as electron microscopy, scanning probe microscopy, x-ray scattering techniques, x-ray absorption

techniques, and Raman spectroscopy. For example, Raman measurements were used to demonstrate the crystallinity of the porous Si skeleton and infer information on the size of the Si nanocrystals.

The very reactive porous Si material etches or oxidizes very rapidly. Heat treatment in an oxidizing atmosphere leads to oxidized porous Si (OPS). The oxidation occurs throughout the whole porous volume, and SiO_2 layers several micrometers thick can be obtained in times that correspond to the growth of a few hundred nanometers on regular Si surfaces (1100°C in oxygen for 30 minutes is sufficient to make a 4-µm-thick film).[201] Porous Si is low-density and remains single-crystalline, providing a suitable substrate for epitaxial Si film growth. These properties have been used to obtain dielectric isolation (fully isolated by porous oxidized silicon, or FIPOS) and to make silicon-on-insulator (SOI) wafers (see porous Si applications in Table 4.11); in dry etching (see Chapter 3), as prepared, porous Si etches six to seven times faster compared with single-crystal Si.[202] A typical etch rate of porous Si in a reactive ion etching (RIE) station, with SF_6 as the gas, is 6.8 µm/min (whereas for nonporous Si it is 1.5 µm/min), and in a high-density plasma station the etch rate is 66 µm/min (Si, 10 µm/min). The dry etching rate of porous Si depends on the porous Si porosity, aging of the layer, and thermal treatment. The etch rate of thermally treated porous Si layers is significantly smaller than that of freshly etched layers (0.33 µm/min in a high-density plasma).[203] By treatment of the porous Si with NH_3 at high temperatures, it is possible to make thick Si_3N_4 films. Even at 13 µm, these films show little evidence of stress in contrast to stoichiometric LPCVD nitride films.[204]

Porous Silicon Fabrication

Microporous Silicon Whether one is in the regime of electropolishing or porous Si formation depends on both the anodic current density and the HF concentration. The surface morphology produced by the Si dissolution process critically depends on whether mass transport or hole supply is the rate-limiting step. Porous Si formation is favored for high HF concentrations and low currents (low anodic bias for p-type and weak light intensities for n-type Si), where the positive charge supply (holes) is limiting, whereas smooth etching is favored for low HF concentration and high currents (higher anodic bias for p-type Si and strong light intensity for n-type Si), where mass transport is limiting.

For current densities less than i_{CRIT} (Figure 4.65), holes are depleted at the surface, and HF accumulates at the electrode/electrolyte interface. As a result, a dense network of fine holes forms.[202,205] Thus, porous Si typically forms when using low current densities in a highly concentrated HF/water or an HF/ethanol solution—in other words, by limiting the oxidation of silicon resulting from hole and OH^- deficiency. In view of the Si etching models introduced earlier, one observes that aqueous HF is less suitable for the porous etching process because the silicon surface is hydrophobic in water. The porous layer can be made more structurally uniform if an ethanolic solution (e.g., 1 part of 48% HF and 1 part ethanol) is used—this increases the wettability of the silicon and allows better surface wetting by the acid. Ethanolic etch solutions also reduce the formation of hydrogen gas bubbles because ethanol acts as a surfactant and prevents bubbles sticking to the silicon surface. The potential range in Figure 4.65 where porous Si forms is at potentials below (toward negative potentials) the first current peak (v_p; see also Figure 4.37). During the formation of porous Si, hydrogen gas evolves, and the morphology of the porous Si depends, among other factors, on the doping density of the wafer, orientation, the HF concentration, and the current density (and thus the light intensity for n-type Si and the voltage for p-type Si). As pointed out earlier, porous Si was shown to be monocrystalline,[92] and the suggested reaction mechanism is based on the assumption that fluoride ions close to the surface cause the Si-Si backbonds to be polarized, thus facilitating the breaking of these bonds.[206] The Si backbonds are broken, leaving an H-terminated surface and a SiH_xF_y compound that reacts with water and HF to form SiF_6^{2-} and H_2. The overall process, as introduced earlier, is given by Reaction 4.7.

As sketched in Figure 4.69, microporous silicon is easy to obtain: a few minutes of anodization in an HF solution suffices (a typical anodization rate is 0.3 µm/min).

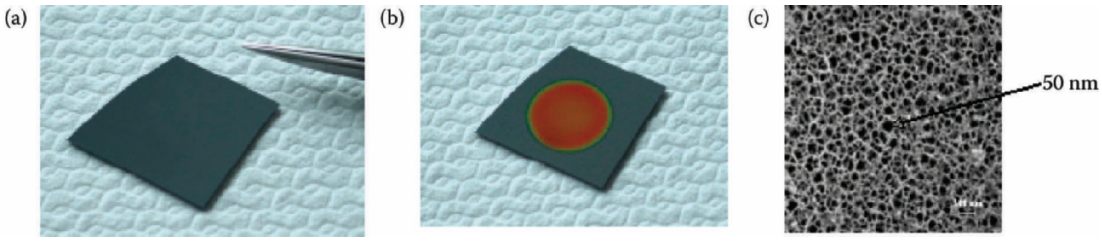

FIGURE 4.69 (a) Si piece. (b) Porous Si in circular area. (c) SEM of porous Si nanosponge.

Porous Si can also be formed chemically through Reactions 4.19 and 4.21. This is a much less common technique to form porous Si. The purely chemical process is called stain etching, or chemical etching (with no current flow), and is performed in an HF-HNO_3 solution. In this case, the difference between chemical polishing and porous Si formation conditions is more subtle. In the chemical polishing case, all reacting surface sites switch constantly from being local anode (Reaction 4.19) to being local cathode (Reaction 4.21), resulting in nonpreferential etching. If surface sites do not switch fast between being local anode and cathode, charges have time to migrate over the surface. In this case, the original local cathode site remains a cathode for a longer time, and the corresponding local anode site, somewhere else on the surface, also remains an anode to keep the overall reaction neutral. A preferential etching results at the localized anode sites, making the surface rough and causing porous Si to form.[207] Any inhomogeneity, for example, some oxide or a kink site at the surface, might increase such preferential etching.[207] Unlike porous Si fabricated by electrochemical means, chemically etched porous Si film thickness is self-limiting.

Depending on porosity and/or pore size, porous Si has the general properties summarized in Table 4.12 (single-crystal Si values are listed as reference). Remember that these properties can be tailored by the process conditions.

The electrical resistivity of porous Si is up to five orders of magnitude higher than that of intrinsic nonporous Si. The reason is that porous Si is depleted of free carriers. This depletion occurs either because 1) energy gap widening caused by quantum confinement, which reduces the thermal generation of free carriers, or 2) trapping of free carriers. Trapping of free carriers takes place during the preparation of the porous Si, and again there are two possible explanations: 1) the binding energy of the dopant impurities is increased, or 2) the formation of more surface states occurs. It has been shown that the dopants are still present in the porous Si in a concentration unchanged from the original Si, but that the dopants are in a neutral state. The electrical transport through porous Si is very much affected by the disordered structure of the porous Si skeleton that restricts the conduction paths to a highly constrained geometry, which for certain types of porosities forms a percolated or fractal geometry. As a consequence, conductivity is thermally activated, strongly frequency-dependent, and highly dispersive. Several models have been proposed to explain the electrical transport properties in porous Si. They differ on the

TABLE 4.12 General Properties of Porous Si

Property	Porous Si Value	Single-Crystal Si Value
Young's Modules E	83 GPa (P = 20%)–0.87 GPa (P = 90%)	160 GPa
Thermal conductivity	1.2 W/mK (nano)–80 W/mK (meso)	157 W/mK
Electrical resistivity	10^{10}–10^{12} Ω cm nanoporous	
Optical bandgap	1.4 eV (P = 70%)–2.0 eV (P = 90%)	1.12 eV
Refractive index	1.2–2.8	3.94
Oxidation 1100°C for 30 min in oxygen	4 μm FASTER	<0.5 μm SLOWER
Dry etching (SF_6 gas)	66 μm/min FASTER	10 μm/min SLOWER

transport paths and mechanisms assumed. The proposed transport paths range from transport in the Si nanocrystals (with diffusion or tunneling between the Si nanocrystals or at their surface) to transport in the amorphous and disordered matrix surrounding the nanocrystals, or through both.

The nanoporous Si structures may have dimensions in the low nanometer range. If the structure size reaches a value less than, e.g., 3 nm, quantum effects can occur; therefore, nanoporous samples can exhibit strong visible photoluminescence and electroluminescence. Raman spectroscopy gives indirect information about the nanostructure of porous Si and has shown that the nanocrystals alter the selection rules relating to the interaction of optical phonons with incident photons (see Volume I, Chapter 5). This results in the efficient photoluminescence and electroluminescence of porous Si compared with nonporous Si. The first and most favored explanation for the visible light emission in porous Si is the quantum confinement of excitons in nanometer-sized Si nanostructures. The nature of the energy gap is still indirect even though a quasidirect bandgap can be formed in ultrasmall Si nanocrystals. The other properties of porous Si listed in Table 4.12 will be highlighted in the text below.

Macroporous Silicon In addition to micropores, well-defined macropores ($d > 50$ nm) can also be made in Si by photo and/or bias etching in HF solutions. The macroporous material exhibits very low values of porosity ($P < 10\%$) and high levels of roughness. Macropores have sizes as large as 10 μm, visible with a scanning electron microscope (SEM) rather than the transmission electron microscope (TEM) typically used for nanoporous material. The two types of pores often coexist, with micropores covering the walls of macropores. This is not a matter of a broad fractal-type distribution of pores because the formation mechanism for the large pores is different.

Conditions of lower HF concentration and higher current density tend to offer larger diameter pores. Electrochemical etching of macropores or macroholes has been reported, for example, with n-type silicon in 2.5–5% HF under high voltage (>10 V), low current density (10 $mAcm^{-2}$), under illumination,

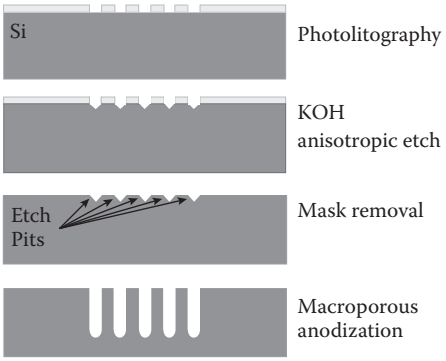

FIGURE 4.70 Schematic lithographic procedure resulting in the definition of pore-starting etch pits. (Gaburro, Z., N. Daldosso, and L. Pavesi, eds. 2005. *Encyclopedia of condensed matter physics: porous silicon.* Amsterdam: Elsevier Ltd.[195])

and in the dark.[189] In the latter case, Zener breakdown in silicon (electric field strength in excess of 3×10^5 V/cm) causes the hole formation (see also Volume I, Chapter 4 on Zener diodes and Volume I, Figure 4.43). In the case of lightly doped n-type silicon, the macropores are formed at much higher anodic potentials than those used for micropore formation.[208] More details on models explaining porous Si formation follow below. By using a pore initiation pattern, the macropores can be localized at any desired location. This option is limited to macroporous porous Si because present lithographic resolution lowest limits are typically in the range of 65 nm (Figure 4.70).

The dramatic effect of the use of a pore initiation pattern is illustrated in the comparison of Figures 4.71 and 4.72.[91,209] In Figure 4.71 we show representative porous Si layers without the use of a pore initiation pattern. Figure 4.71a illustrates nanoscale pores (mesoporous Si),[203] and Figure 4.71b shows microscale pores (macroporous Si).[91] The 45° bevel cross-section in Figure 4.71b is of an n-type sample ($10^{15}/cm^3$ phosphorus-doped) and shows a random pattern of macropores. In contrast, the macroscale pores in Figure 4.72 all start at the micropit initiation points. Pores orthogonal to the surface with depths up to a whole wafer thickness can be made, and aspect ratios as large as 250 are possible.

The periodic arrays of macropores shown in Figure 4.72 can form a 2D photonic crystal. Photonic crystals, we recall, are materials with a periodically varying index of refraction, and in porous

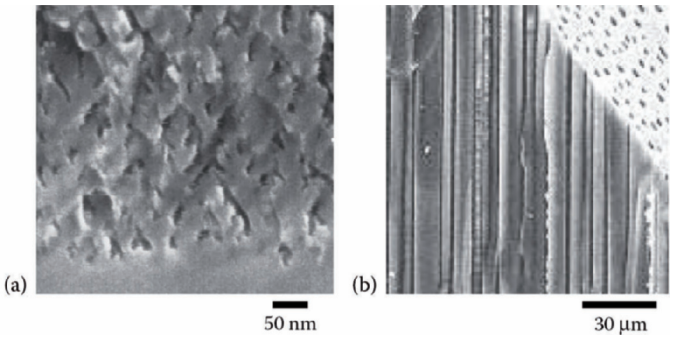

FIGURE 4.71 Representative porous Si layers. (a) Nanoscale pores (mesoporous Si). (Tserepi, A., et al., 2003. Dry etching of porous silicon in high density plasmas. *Physica Status Solidi (A)* 197:163–67.[203]) (b) Microscale pores (macroporous Si). (Lehmann, V. 1993. The physics of macropore formation in low doped n-type silicon. *J Electrochem Soc* 140:2836–43.[91]) Random: surface, cross-section, and a 45° bevel of an n-type sample (10^{15}/cm^3 phosphorus-doped) showing a random pattern of macropores. Pore initiation was enhanced by applying 10-V bias in the first minute of anodization followed by 149 minutes at 3 V. The current density was kept constant at 10 mA/cm^2 by adjusting the back-side illumination. A 6% aqueous solution of HF was used as an electrolyte.

Si, air alternates with Si (see Volume I, Chapter 5). Grüning et al.[210] realized such a photonic crystal with a photonic bandgap in the near IR using macropores in n-type silicon etched under back-side illumination.

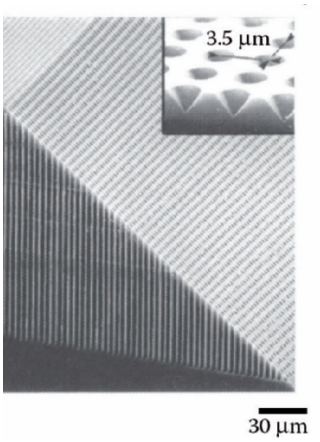

FIGURE 4.72 SEM image of well-ordered localized or arrayed straight macropores. Inset, SEM image is an artificial micropit array formed in advance of Si electrochemical etching. Localized: surface, cross-section, and a 45° bevel of an n-type sample (10^{15}/cm^3 phosphorus-doped) showing a predetermined pattern of macropores (3 V, 350 min, 2.5% HF). Pore growth was induced by a regular pattern of pits produced by standard lithography and subsequent alkaline etching (inset top right). (From Lehmann, V. 1993. The physics of macropore formation in low doped n-type silicon. *J Electrochem Soc* 140:2836–43. With permission.[91])

Summarizing, we have learned that single-crystal silicon can be turned into a porous material with porosity and pore sizes determined by the current density, type, and concentration of the dopant, as well as the hydrofluoric acid concentration. Also, a transition from pore formation to electropolishing is reached by increasing the current density and/or by decreasing the hydrofluoric acid concentration. Electropolishing is even possible under a layer of porous silicon (PS) already formed. The latter is the enabling technology in the Bosch APSM process (see page 293), which makes use of PS to form a cavity underneath the surface of monocrystalline silicon.

In Chapter 7 we learn that PS can also be formed under similar conditions from LPCVD polysilicon, with pores roughly following the grain boundaries of the polysilicon. We will see how, by changing the conditions from pore formation to electropolishing and back to PS, enclosed cavities may be formed with porous polysilicon walls (plugs) and "floor and ceiling" of silicon nitride layers.

Porous Silicon Drying and Aging When drying a porous Si film in air, a water meniscus forms in the pores, and this results in stress exerted on the pore walls. Depending on the size of the structure (porosity) and the surface tension of the liquid, cracking of the porous Si layer is always a possibility. This limits the maximum porosity obtainable and also suggests different procedures for drying, for example, by working with very low surface tension liquids in the pores when drying. This may be accomplished by rinsing the freshly made porous Si with pure ethanol that has a lower surface tension than water (22 mJ/m^2 compared with 72 mJ/m^2); an alternative is to use pentane (with a surface tension of 14 mJ/m^2). The best results, however, have been obtained by supercritical drying in CO_2 (>95% porosity), where drying is performed above the supercritical point of a liquid, usually CO_2.[211] Other methods include freeze drying and using very slow evaporation rates. Pentane drying is the easiest to implement. Pentane has a very low surface tension and shows no chemical interaction with porous Si (unlike ethanol). Using pentane as drying liquid strongly reduces the

capillary tension, but because water and pentane are nonmiscible, ethanol or methanol has to be used as intermediate rinsing liquid. Using this drying technique, PS layers with porosity values up to 90% and thickness up to 5 µm exhibit no cracking after drying. Supercritical drying requires a specific apparatus but is more effective in preventing cracking of the film; thus, porous layers of porosity values up to 95% were demonstrated.[211]

In the electrolyte and immediately after drying, the pore walls are mostly H-terminated. The hydrogen termination is replaced by oxygen to form native oxide rapidly in air.[211] This changes the properties of the porous Si over time, making it one of the major problems preventing the implementation of porous Si in practical applications. An example of the nefarious effect of porous Si aging is its effect on photo- and electroluminescence of porous Si. The so-called luminescence fatigue shown in Figure 4.73 is explained by photochemical reactions occurring on the surface of the Si nanocrystals. As the time passes, a shift to the blue region in the peak position and both decreases and increases in the PL intensity have been reported. The blue shift has been attributed to the decrease in dimension of porous Si pillars resulting from the oxidization of the surface with time, which supports the quantum confinement effect.

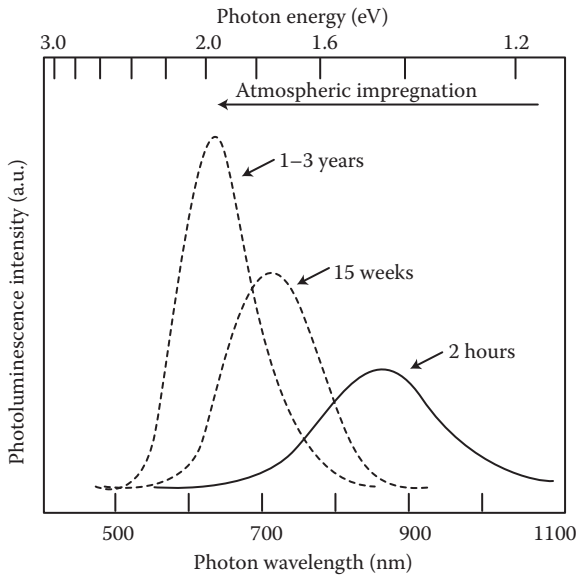

FIGURE 4.73 Aging of the luminescence of porous Si. (Thönissen, M., and M. G. Burger, eds. 1997. *Properties of porous silicon*. Washington, DC: IEEE.[211])

Because of the large surface area of the porous Si, the silicon/oxygen ratio may be large, resulting in a significant impact on the properties of porous Si. Several methods for surface passivation have been reported in the literature, and they seem to lead to more stable luminescence.[211] To name a few, controlled oxidation by anodic or chemical oxidation, rapid thermal oxidation, capping of the porous Si layer by a dielectric or metal, thermal nitridation, and thermal carbonization.[211]

Porous Si Models The critical question about any kind of porous Si formation, nano- or macroporous, is why there is a difference in dissolution rate between pore tip and pore walls? Unagami[205] proposed that insoluble silicates passivate the pore walls, resulting in the formation of a porous Si layer, but this does not explain why such selective passivation takes place in the first case. Parkhutik et al.[212] compared porous Si formation with that of porous alumina formation (see Volume III, Chapter 5). In this model a passive layer (e.g., an oxide) exists at the bottom of each pore and results in the electric field enhancement at the pore tips. Poreformation in this case is a consequence of the dissolution of the passive layer enhanced by the local electrical field, which is stronger at the sharp tips. The competition between growth and dissolution of the passive layer gives rise to a time-evolving electrolyte/passive film interface defining the surface of the pore. This model predicts the correct dependence of pore size on HF concentration. In 1970, Theunissen et al. proposed that porous Si forms in n-type Si as a result of Zener breakdown because of electric field enhancement at the pore tip.[87,163] However, Theunissen's model cannot explain other kinds of porous Si formation without this breakdown condition (e.g., what about porous p-type Si). In 1985, Beale et al.[211] expanded Theunissen's model by introducing the involvement of a space charge region (SCR), which forms at the surface region of the Si in contact with the electrolyte and acts as a Shottky barrier, as illustrated for p-type Si in Figure 4.74. The SCR is depleted of holes and prevents charge transfer at the interface between the electrolyte and the Si surface. When a pore wall becomes sufficiently thin (small d in Figure 4.74), space charge regions from opposite sides of the pore

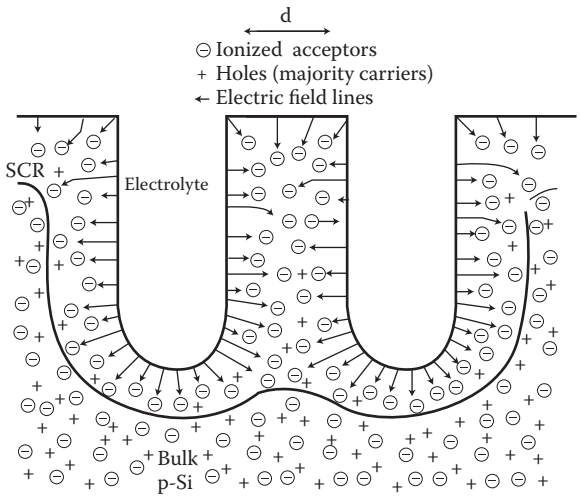

FIGURE 4.74 Space charge regions (SCRs) at the semiconductor/electrolyte interface form an insulating layer that prevents charge transfer. As two space charge regions in a wall pore wall of thickness *d* overlap that wall will passivate, and current is directed to the bottom of the pore. The example shown here involves p-type Si. (Lehmann, V., et al. 1999. *J Electrochem Soc* 146:2968–75.)

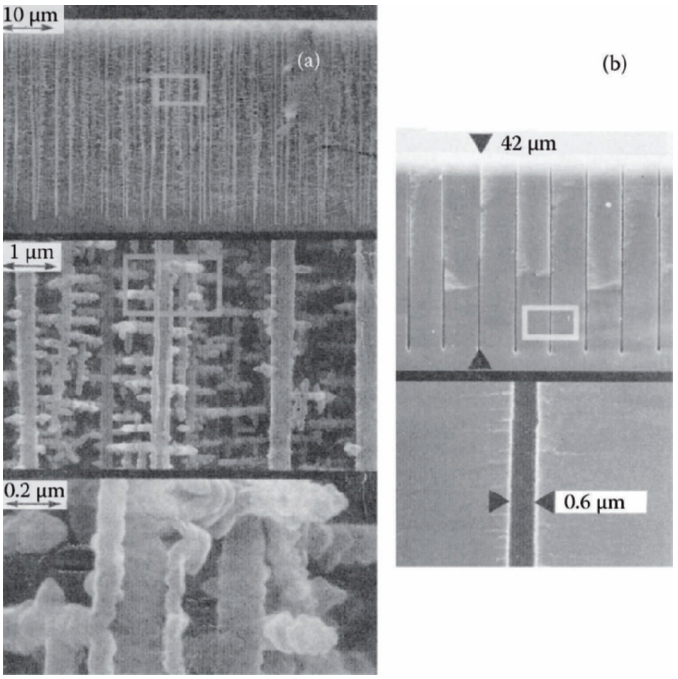

FIGURE 4.75 Comparison of macropores made with breakdown holes (a) and macropores made with light-created holes (b). (a) An oxide replica of pores etched under weak back-side illumination visualizes the branching of pores produced by generation of charge carriers resulting from electrical breakdown (5 V, 3% HF, room temperature, 10^{15}/cm^3 phosphorus-doped). (From Lehmann, V. 1993. The physics of macropore formation in low doped n-type silicon. *J Electrochem Soc* 140:2836–43. With permission.[91]) (b) Single pore associated with KOH pit. (From Lehmann, V., and H. Foll. 1990. Formation mechanism and properties of electrochemically etched trenches in n-type silicon. *J Electrochem Soc* 137:653–59. With permission.[213])

wall overlap, thus decreasing charge transfer at the interface even further. Consequently, current is selectively directed to the pore tips' region, and pore walls stop thinning when $d < 1/2$ SCR. Pore formation in this model is a self-adjusting electrochemical mechanism. The limitation is a result of the depletion of holes in the pore walls, causing them to stop etching, whereas holes continue to be collected at the pore tip, where they continue to promote Si dissolution. No passivating layer is involved to protect the pore wall in this model. The only decisive differences between pore tips and pore walls are their geometry and their location. Holes generated by light or Zener breakdown are collected at pore tips. Every depression or pit in the surface initiates pore growth because the electrical field at a curved pore bottom is much larger than that of a flat surface as a result of the effect of the radius of curvature. The latter leads to higher current and enhances local etching.[208] Zener breakdown and illumination of n-type Si lead to different types of pore geometry.[91,163,213] Branched pores with sharp tips form if holes are generated by breakdown (see Figure 4.75a).[91] Unbranched pores with larger tip radii result from holes created by illumination (see Figure 4.75b).[213] The latter difference can be understood as follows: the electric field strength is a function of bias, doping density, and geometry. High doping level density or sharp pore tips will lower the required bias for breakdown; therefore, macropores will tend to follow pores with the sharpest tips. Because every tip causes a new breakdown and hole generation, the position of the original pore tip becomes independent of the other pores, branching of the pores is possible, and fir tree-type fractal-like pores can be observed. With illumination the pore radius may be larger because the breakdown field strength is not necessary to generate charge carriers; thus, the pores remain unbranched.

To obtain the necessary depletion layers in both n- and p-type Si under anodic bias, Beale et al. had to assume Fermi level pinning at midgap (for example, see the energy diagram for n-Si in HF in Figure 4.62).

Yet another model, the diffusion-limited model developed by Smith et al.,[214] describes the formation

of porous Si in terms of a stochastic random walk. During pore formation, a hole diffuses to the silicon/electrolyte interface and reacts with a Si surface atom. The nature of the random walk presents the pore tip as the most likely contact site for a hole diffusing from the bulk Si region and provides a similar selective dissolution mechanism of surface irregularities as the Beale model. The rate of pore growth, in this model, is limited by the diffusion of holes to the growing pore tip. A characteristic diffusion length, function of dopant concentration, current density, and so on control the different pore morphologies. Unlike the Beale model, this model applies very generally to all electrochemical phenomena. Smith et al. confirmed that the porous Si geometry simulated by random walk and diffusion-limited model is similar to the geometry of formed porous Si.

In 1990, Lehmann et al.[197] proposed a model for nanoporous Si formation based on the quantum confinement effect. As described above, it is well known that porous Si is luminescent in the visible region. Lehmann et al. expanded the quantum confinement effect to explain porous Si formation. The increase in bandgap for quantum wires and quantum dots in the pore walls decreases the mobile carrier concentration, i.e., produces the barrier to charge transfer.[197] As a result, the current is again limited to the pore tips, resulting in porous layer formation. Obviously this model can only account for nanoporous Si formation.

As for the direction of the pores in porous Si, there will be a natural tendency to follow the direction of the strongest field with the highest supply of holes, i.e., in the <001> direction on a (001) substrate. The <100> and <113> directions have been found to be the preferred growth directions of the macropores in both p- and n-type silicon.[215] The growth direction depends on the surface orientation. When using a {111} surface, three equivalent <113> macropores start to grow into the substrate. The macropore walls consist of (111) facets that can be observed by TEM. These pores can intersect and form a 3D pore network in the silicon, making for a possible 3D photonic crystal. The resulting structure is slightly different from the Yablonovite photonic crystal introduced in Volume I, Chapter 5; the pores are tilted about 29° off the vertical axes, whereas in the Yablonovite they have an angle of about 35° (see Volume I, Chapter 5). Large pore formation for (100) and (111) Si is illustrated in Figure 4.76.

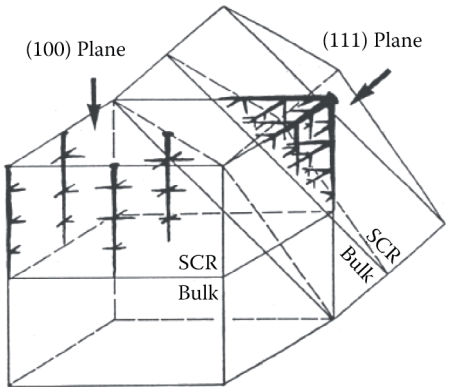

FIGURE 4.76 Large pore-formation for (100) and (111) Si; SCR, space charge region.

Lehmann has shown that square pore cross-sections and pore arrays of high porosity can be produced by subsequent alkaline etching of macroporous Si.[216] With the proper choice of etchants, the rounded pore walls can be etched to reveal (100) or (110) faces.

It was also determined that the macrohole formation in porous Si depends on the wavelength of the light used. It was found that no pore formation occurs below ~800 nm. Depending on the wavelength, the shape of the pores can be manipulated as well.[213] For wavelengths above 867 nm, the depth profile of the pores changed from conical to cylindrical. The latter was interpreted in terms of the influence of the local minority carrier generation rate. Carriers generated deep in the bulk would promote the pore growth at the tips, whereas near-surface generation would lead to lateral growth.

In 1993, Cahill et al.[217] reported the creation of 1–5-μm-diameter pores with pore spacings (center to center) from 200–1000 μm. Until this finding, the pores typically formed were spaced in the range of 4–30 μm center to center and 0.6–10 μm in diameter. Making highly isolated pores presents another challenge. In the previous work, the relatively close spacing of the pores allowed the authors to conclude that the regions between the pores were almost totally depleted and that practically all carriers were collected by the pore tips. In such a case, neither the pore sidewalls nor the wafer surface etched as all

holes was swept to the pore tips. Because the surface was not attacked by pore-forming holes, the quality of the pore initiation mask lost its relevance. In Cahill et al.'s case, on the other hand, a long-lived mask (>20 h) is needed to help prevent pore formation everywhere except at initiation pits. The mask used was a SiC layer sandwiched between two layers of Si nitride. The silicon nitride (insulator) directly atop the Si (semiconductor) serves to insulate the silicon carbide (semiconductor) from the underlying silicon substrate. Because the silicon carbide proves very resistant to HF, loss of thickness does not show during the procedure. The top nitride serves to protect the carbide during anisotropic pit formation. By lowering the bias applied to the Si substrate to less than 2 V with respect to SCE, side branching is avoided.

The Si anisotropy common with alkaline etchants surprisingly shows up here with acidic isotropic etchants. For example, with breakdown-supplied holes, <100>-directed macroholes with <110> branches form (see Figure 4.76),[91] and with <111>-directed wafers, <113> branches form (see Figure 4.76), leading to a complex network beneath the silicon surface. Pyramidal pore tips were also observed when the current density was limited by the bias ($i < i_p$).[91] Isotropic pore pits form when the current is larger than the critical current density, that is, isotropy in HF etching can be changed into anisotropy when the supply of holes is limited. We refer here to the Elwenspoek et al. model (see above), which predicts that in confined spaces etching will tend to be more anisotropic, even when using a normally isotropic etchant such as HF.

The enhanced photoluminescence efficiency of porous Si—compared with Si—has motivated active research toward other porous semiconductor materials. For example, highly porous InP, SiC, GaP, $Si_{1-x}Ge_x$, and Ge structures have all been investigated. Among the first examples of strong anisotropy in porous etching of semiconductors other than Si was that reported by Takizawa et al.,[203] who reported pores in <111> A-oriented InP in HCl with an aspect ratio larger than 100. Some other preliminary evidence was collected on GaAs[218] and GaP.[210] Pore formation in TiO_2 anodic and alumina films is described in more detail in Volume III, Chapter 5.

Porous Silicon Applications Uhlir's discovery has led to all types of interesting new devices from quantum structures, chemical sensors and biosensors, permeable membranes, and photoluminescent and electroluminescent devices to a basis for making thick SiO_2 and Si_3N_4 films.[201,204] Some of these applications are listed in Table 4.11 introduced earlier. Besides its use for dielectric isolation and the fabrication of SOI wafers, porous Si has been introduced in a wide variety of other applications: Luggin capillaries for electrochemical reference electrodes, high surface area gas sensors, humidity sensors, sacrificial layers in silicon micromachining, and so on.

We already highlighted the fact that porous Si exhibits photoluminescent and electroluminescent behavior; light-emitting porous Si (LEPOS) was demonstrated. If a LEPOS device could be integrated monolithically with other structures on silicon, a big step in micro-optics, photon data transmission, and processing would be achieved. To explain the blue shift of the absorption edge of LEPOS of about 0.5 eV compared with bulk silicon[197] and room temperature photoluminescence,[196] Searson et al.[219] proposed an energy-level diagram for porous Si where the valence band is lowered with respect to bulk silicon to give a bandgap of about 1.8 eV (see Figure 4.68).

Porous Si can easily be etched in relatively harmless solutions like diluted aqueous KOH solutions, making it an attractive sacrificial material. The surface and bulk properties of porous Si are easily modified; for example, oxidization of the material makes it useful as an insulating material in gas sensors; metallization enables its use in microelectronics; and nitridation of the material is possible as well.

The large specific surface area (e.g., 200 m^2/cm^3) and the very small diameters of the pores make porous Si an interesting material for several analytical MEMS and NEMS devices. Given the large specific area per unit volume, the electrical transport is strongly influenced by external factors such as residual electrolyte and ambient atmosphere. The latter property is very interesting for sensor applications. Certain gases—for example, NO—have the capability of modifying the free carrier population. Changes in the electrical conductivity in the presence of subparts per million concentrations of such gases can be detected at room temperature operation. Other

gaseous species (for example, polar liquid vapors) also affect electrical transport via electric field interactions with charge carriers.

An optical biosensor based on porous Si also has been demonstrated. PS samples were prepared in such a way that the porous Si films displayed Fabry-Perot fringes in their white-light reflection spectrum. When biological molecules are then chemically attached as recognition elements to the porous Si surface and exposed to the appropriate complementary binding pair, binding occurs and is observed as a shift in the Fabry-Perot fringes.[220,221]

Lammel et al.[222] fabricated tunable optical filters based on porous Si—filters that can be used in reflective or transmission mode. The ratio of voids to total volume of porous Si determines its refractive index, and because porosity can be adjusted by varying the current density, these authors were able to micromachine a multilayer stack of porous Si of different indices by modulating the current density during porosification (in principle, indices between 1.6 and 2.1 can be obtained this way). The process was applied to an area of single-crystal Si delineated by a Si nitride window. The porosified Si plate was released from the substrate by subsurface electropolishing. During chemical release, two suspension arms lift the plate out of the plane automatically by internal stress release. The suspension arms are also provided with Cr/Ni heater wires to actuate the filters. By tilting the freestanding plate of porous Si with the thermal bimorph suspension arms, a wavelength scan is possible. Using this process, Lammel et al. achieved a 20-nm wavelength resolution in the visible part of the spectrum. Figure 4.77 is an SEM of the described porous Si plate optical filter.

Another more recent interest in porous Si stems from the ability to culture mammalian cells directly onto porous Si. Initial research findings from DeMonfort University suggest that the material may be biocompatible (http://www.findarticles.com/m0WVI/ 1999_April_6/54338205/p1/article.jhtml and L.T. Canham[223]). In this vein porous Si can also be used for sieving to filter very small particles. For more on biocompatibility of single-crystal Si, polycrystalline Si, and porous Si, see also Volume III, Chapter 5.

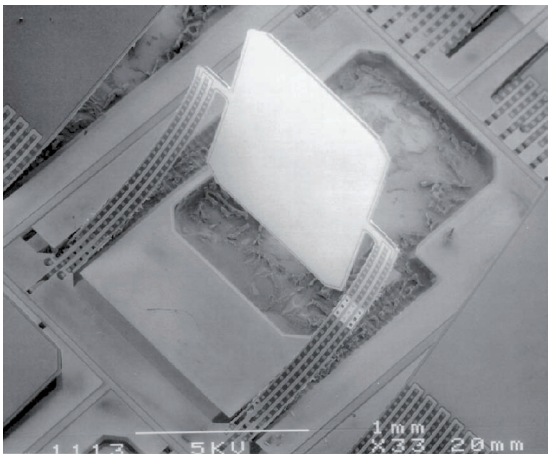

FIGURE 4.77 Optical filter of porous Si. SEM of a freestanding porous Si microplate containing a multilayered optical interference filter. The wavelength can be tuned by tilting the microplate using the integrated thermal bimorph microactuator. The tilt angle is a function of the actuator DC voltage. This filter element can be used to build a microspectrometer. (Courtesy of Dr. Gerhard Lammel, EPFL, Lausanne, Switzerland.[222])

Porous Si also enabled an elegant new micromachining technology at Bosch with their advanced porous silicon membrane (APSM) process. This technology makes use of porous Si to form a cavity underneath the surface of a single-crystalline silicon membrane, which helps to make the wafer manufacturing process fully CMOS-compatible and turns the traditional bulk micromachining process into a surface micromachining technology. Armbruster et al.[224] reported this new micromachining technology for the fabrication of monocrystalline silicon membranes covering a vacuum cavity for applications such as piezoresistive pressure sensors. In Figure 4.78 we compare a silicon-based absolute pressure sensor made with traditional bulk micromachining with the same device made with the new porous Si-based APSM process. The new process evidently produces not only cavities inside a device in a shorter amount of time, uses no wafer-bonding steps, and constitutes an all-silicon process, but it is also is CMOS-compatible. The main process steps, illustrated in Figure 4.79, are (a) local anodic etching of a layered porous Si (LPCVD Si_3N_4 is used as a mask). (b) One of the following processes is used: 1) conversion of part of the porous material to oxidized porous Si and etching it away, 2) direct electropolishing of part of the porous Si, or 3) thermal rearrangement of

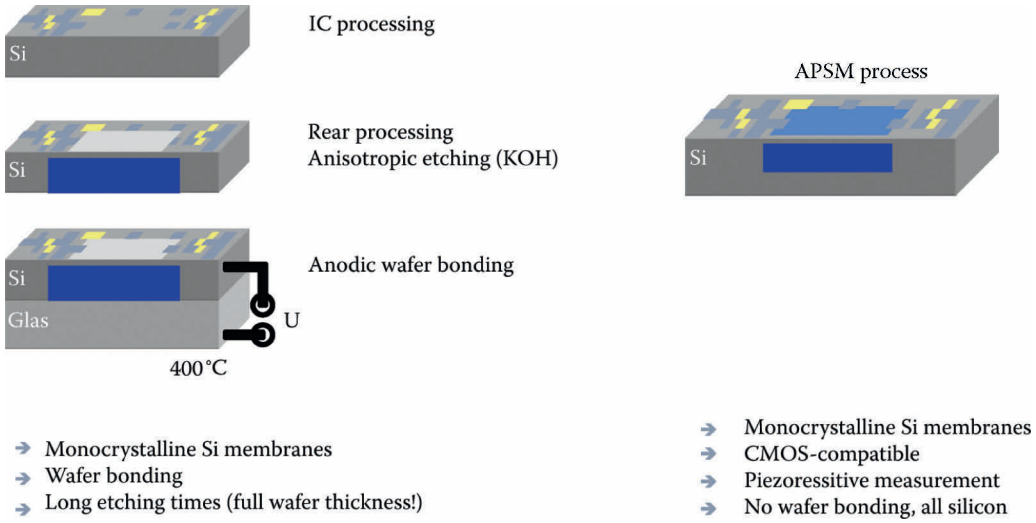

FIGURE 4.78 Comparison of a bulk Si micromachined absolute pressure sensor (left) with such a sensor made with the new Bosch porous Si-based APSM process (right). (From a Bosch presentation.)

part of the porous layer. These three different techniques all lead to a cavity underneath a suspended porous membrane, and (c) epitaxial growth of a silicon membrane layer over the remaining porous Si membrane. As we saw earlier, porous Si remains single-crystalline, providing a suitable substrate for epitaxial Si growth. The layer thicknesses of the porous layer over the cavity and the cavity layer may be 1–10 µm or more, depending on the application.

The degree of porosity of the porous Si layer in the APSM process deliberately varies in the lateral and vertical direction. The lateral doping of the semiconductor material for the edge region and central region of the porous diaphragm is selected in such a way that mesopores (pores on the order of 5–50 nm) are formed in the edge region and macropores (pores > 50 nm and up to a few micrometers) are formed in the center region. This may be accomplished, for example, with an n-type doping to produce macropores in the center region, whereas the edge region of the diaphragm is provided with p^+ doping to obtain mesoporous Si. This makes it possible for the gases produced in etching to escape more easily through regions of the porous layer, which have a comparatively higher porosity, when producing the cavity underneath the porous layer. In the edge region of the diaphragm with the lower porosity, a good layer quality is possible, for example, for the subsequent epitaxial process, whereas in the central region of the diaphragm the epitaxial quality is comparatively lower as a result of higher-porosity sections. However, in the pressure sensor application, this is unimportant because the properties of the pressure sensor are not impaired. The semiconductor substrate is also doped differently in the region of the porous diaphragm layer and in the region of what will become the cavity in such a way that mesopores are produced in the semiconductor material of the diaphragm layer and nanopores (pores from 2–5 nm) are produced as a "precursor structure" in the cavity region. The production of a small-pore precursor structure prevents the formation of comparatively large air bubbles, which makes it possible to adequately remove the gas bubbles through the porous diaphragm layer. In this procedure, use is also made of the fact that the "nanostructure" has a considerably higher internal surface area than the "mesostructure" of the diaphragm region, which is usable in a subsequent process step for a shorter oxidation time. We learned above that the very reactive porous Si etches or oxidizes very rapidly. This makes it possible to subsequently produce a completely oxidized porous Si, which is then selectively removed, e.g., in a vapor etching process. The cavity may also be produced by rearranging the nanoporous layer in a high-temperature process step. Different porosities subjected to heat treatment at high temperatures in a reducing atmosphere induce a structural rearrangement, forming in this way a membrane with a thickness ranging from few tenths of micrometers to 1 µm, as well as the cavity under the membrane.

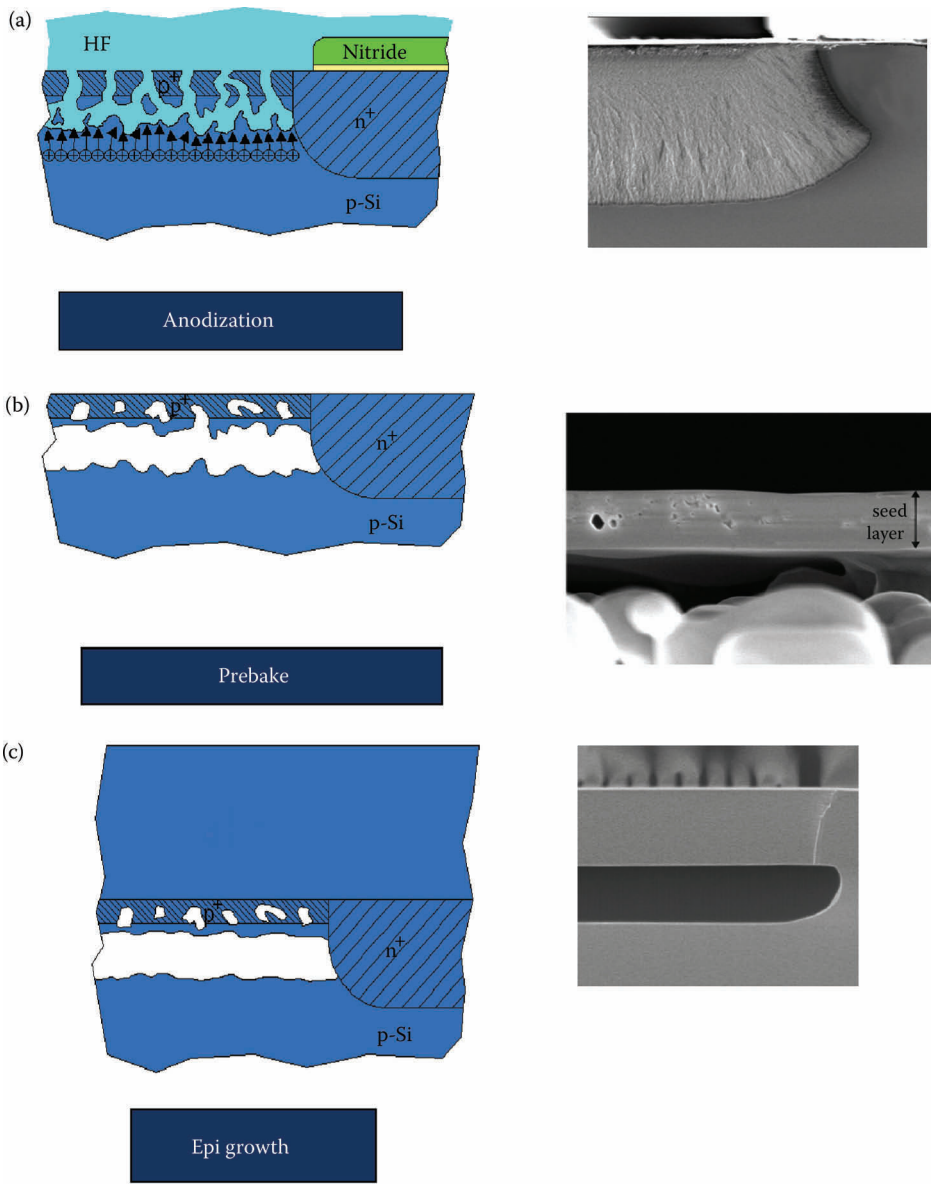

FIGURE 4.79 The Bosch porous Si-based APSM process. (From a Bosch presentation.) (a) Local anodic etching of layered porous Si with different porosities. (b) Thermal rearrangement of the porous Si. (c) Epitaxial growth of the Si membrane layer. (From a Bosch presentation.)

A third alternative procedure in forming the cavity structure involves directly dissolving the semiconductor material underneath the porous layer using electrolytic polishing, for example, at comparatively higher current densities and lower HF concentrations (see also page 287).

In contrast to conventional bulk micromachining, the new technology has the benefit of more design freedom because the shape/size of the monocrystalline silicon membrane only depends on the porous Si region. Except for the anodic etching, all process steps are part of a standard mixed signal IC production line. We may also compare the APSM process to a surface micromachined membrane pressure sensor. In surface micromachining, we learn in Chapter 7, to make a membrane sensor, a sacrificial layer is normally used, which is applied to the front of a carrier substrate before depositing the sensor diaphragm. The sacrificial layer is later removed from the front of the sensor through "dissolution openings" in the diaphragm, whereby an unsupported structure is obtained. The surface micromachining method is relatively complicated because of the need for separate sacrificial layers. Using APMS,

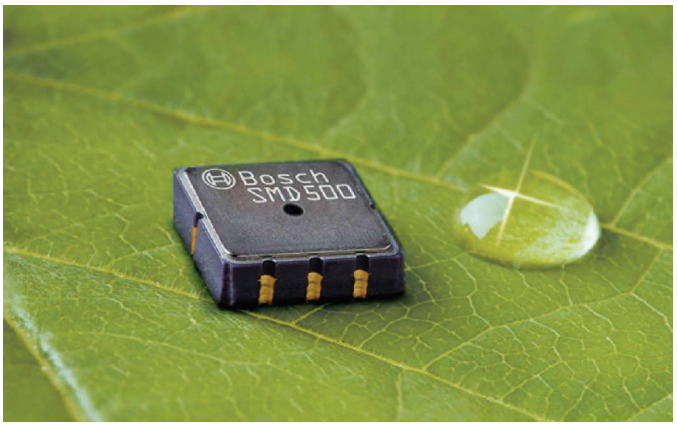

FIGURE 4.80 The Bosch SMD 500. The world's smallest digital pressure sensor! With a size of only 5 × 5 × 1.6 mm, the SMD 500 is the smallest pressure sensor for consumer electronics available. Manufactured using the new APSM technology (advanced porous Si membrane), it is much smaller compared with conventional bulk micromachined sensors. (From a Bosch presentation.)

it is possible to considerably simplify the manufacture of such component because no sacrificial layer needs to be additionally applied, and the sacrificial layer and the porous diaphragm are produced from the semiconductor material itself.

A piezoresistive pressure sensor (the SMD 500, the world's smallest digital pressure sensor) with integrated ASIC based on the new fabrication method is shown in Figure 4.80. The sensor that is shown here can measure pressure ranges from ±2.5 kPa (relative) up to 3.3 MPa (absolute). The sensor accuracy is 1.0% over the sensor lifetime, and its high robustness makes it ideal for applications like barometer, altimeter, weather forecast, health care, and fluid level measurements.

A good update on the chemistry of porous Si can be found at Sailor's web site: http://chem-faculty.ucsd.edu/sailor/research/porous_Si_intro.html.

Problems Associated with Wet Bulk Micromachining of Single-Crystal Silicon

Introduction

Despite the introduction of more controllable etch-stop techniques, bulk micromachining of Si remains a difficult industrial process to control. It is also not an applicable submicrometer technology because wet chemistry is not able to etch reliably on that scale. For submicrometer structure definition, dry etching is required (dry etching is also more environmentally safe). We will now look into some of the other problems associated with Si bulk micromachining, such as the extensive real estate consumption and difficulties in etching at convex corners, and detail current solutions to avoid, control, or alleviate them.

Problem: Extensive Real Estate Consumption

Introduction Bulk micromachining involves extensive real estate consumption. This quickly becomes a problem when making arrays of devices. Consider the diagram in Figure 4.81, illustrating two membranes created by etching through a <100> wafer from the back until an etch stop, e.g., a Si_3N_4 membrane, is reached. In creating two of these small membranes, a large amount of Si real estate is wasted, and the resulting device might become fragile.

Solution 1: Real Estate Gain by Etching from the Front One solution to limit the amount of Si real estate loss is to use thinner wafers, but this solution becomes impractical below 200 µm because such wafers often break during handling. A more elegant solution is to etch from the front rather than from the back. Anisotropic etchants will undercut a masking material by an amount dependent on the orientation of the wafer with respect to the mask. Such an etchant will etch any <100> silicon until a pyramidal pit is formed, as shown in Figure 4.82. These pits have sidewalls with a characteristic 54.7° angle with respect to the surface of a <100> silicon wafer because the delineated planes are {111} planes. This etch property makes it possible to form cantilever structures by etching from the front because the cantilevers will be undercut and eventually will be suspended over a pyramidal pit in the silicon. Once this pyramidal pit is completed, the etch rate of the {111} planes exposed is extremely slow and practically stops. Therefore, process sequences,

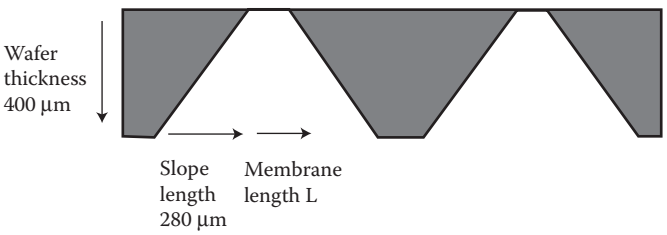

FIGURE 4.81 Two membranes formed in a <100>-oriented Si wafer.

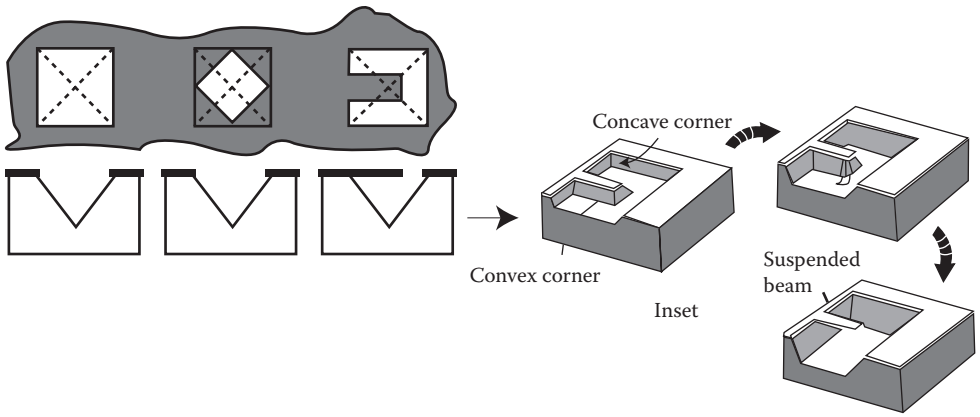

FIGURE 4.82 Three anisotropically etched pits etched from the front in a <100>-oriented silicon wafer. Inset, illustration of etching at convex corners for the formation of suspended beams.

which depend on achieving this type of a final structure, are very uniform across a wafer and very controllable. The top drawings in Figure 4.82 represent patterned holes in a masking material: a square, a diamond, and a square with a protruding tab. The drawings immediately below represent the etched pit in the silicon produced by anisotropic etching. Note in the first drawing that a square mask aligned with the <110> direction produces a four-sided pyramidal pit. In the second drawing, a similar mask shape oriented at 45° produces an etched pit that is oriented parallel to the pit etched in the first drawing independent of the mask orientation. In the second drawing, the corners of the diamond are undercut by the etchant as it produces the final etch pit. The third drawing illustrates that any protruding member is eventually undercut by the anisotropic etchant, leaving a cantilever structure suspended over an identical etch pit. The inset detailing the third drawing shows how undercutting at the convex corners of the cantilever, in pure KOH, is determined by {411} planes.[225]

Solution 2: Real Estate Gain by Using Silicon Fusion-Bonded Wafers Using silicon fusion-bonded (SFB) wafers rather than conventional wafers also makes it possible to fabricate much smaller microsensors and gain real estate. The process, introduced in the 1980s, is clarified in Figure 4.83 for the fabrication of a pressure sensor.[225] The bottom handle wafer has a standard thickness of 525 µm and is anisotropically etched with a square cavity pattern. Next, the etched handle wafer is fusion bonded to a top sensing wafer (the SFB process itself is detailed in Chapter 7, dealing with surface micromachining, and is also touched on in Volume III, Chapter 4, on packaging). The sensor wafer consists of a p-type substrate with an n-type epilayer corresponding to the required thickness of the pressure-transducing membrane. The sensing wafer is thinned all the way to the epilayer by electrochemical etching, and resistors are ion implanted. The handle wafer is ground and polished to the desired thickness. For gauge measurement, the anisotropically etched cavity is truncated by the polishing operation, exposing the back of the diaphragm (Figure 4.83a). For an absolute pressure sensor, the cavity is left enclosed (Figure 4.83b). With the same diaphragm dimensions and the same overall thickness of the chip, an SFB device, because of the inward sloping {111} walls, is almost 50% smaller than a conventional machined device (see Figure 4.84). For example, Lucas NovaSensor (Fremont, CA; now GE Novasensor, http://www.gesensing.com/novasensorproducts) manufactures a sensor that is 400 µm wide, 800 µm long, and 150 µm thick and fits inside the tip of a catheter.

Solution 3: Real Estate Gain by Using the Bosch Advanced Porous Silicon Membrane Process As we saw on page 293, the Bosch APSM process makes use of porous Si to form a cavity underneath the surface of a single-crystalline silicon membrane, which turns the traditional bulk micromachining process into a surface micromachining technology (see Figures 4.78–4.80). A piezoresistive pressure sensor made this way, the SMD 500, is the world's smallest digital pressure sensor (Figure 4.80).

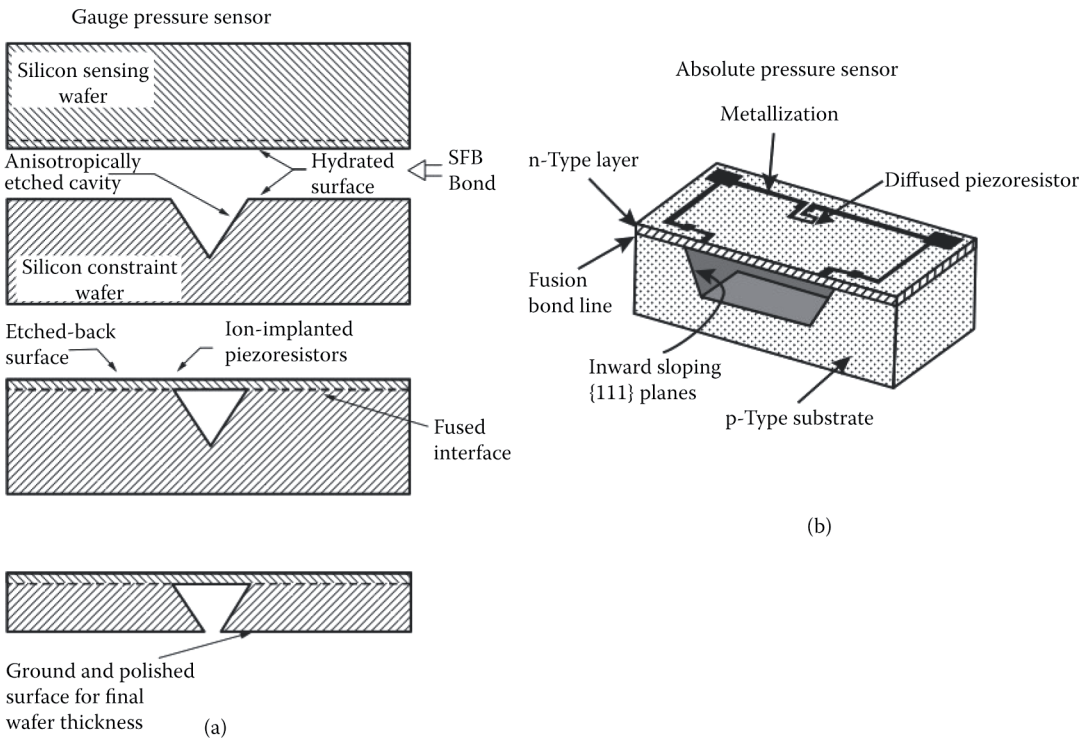

FIGURE 4.83 Fabrication process of SFB-bonded pressure sensors. (a) For gauge measurement, the anisotropically etched cavity is truncated by the polishing operation, exposing the back of the diaphragm. (b) For an absolute pressure sensor, the cavity is left enclosed. (From Bryzek, J., K. Petersen, J. R. Mallon, L. Christel, and F. Pourahmadi. 1990. *Silicon sensors and microstructures.* Fremont, CA: Novasensor. With permission.[226])

Problem: Underetching and Undercutting

Mask Underetching Underetching of a mask that contains no convex corners (that is, corners turning outside in) in principle stems from mask misalignment and/or from a finite etching of the {111} planes. Peeters measured the widening of {111}-walled V-grooves in a (100) Si wafer after etching in 7 M KOH at 80 ± 1° over 24 hours as 9 ± 0.5 µm.[126] The sidewall slopes of the V-groove are a well-defined 54.74°, and the etch rate R_{111} is related to the rate of V-groove widening R_v through:

$$R_{111} \frac{1}{2}\sin(54.74°)\, R_v \text{ or } R_{111} = 0.40R_v \qquad (4.13)$$

with R_{111} the etch rate of the (111) plane in nanometers per minute and R_v the groove widening, also in nanometers per minute. The V-groove widening experiment then results in an R_{111} of 2.55 ± 0.15 nm/min. In practice, this etch rate implies a mask underetching of only 0.9 µm for an etch depth of 360 µm. For a 1-mm-long V-groove and a 1° misalignment angle, a total underetching of 18 µm is theoretically expected, with 95% resulting from misalignment and only 5% caused by etching of the {111} sidewalls.[126] The total underetching will almost always be determined by misalignment rather than by etching of {111} walls.

Mask underetching with masks that include convex corners is much larger than the underetching

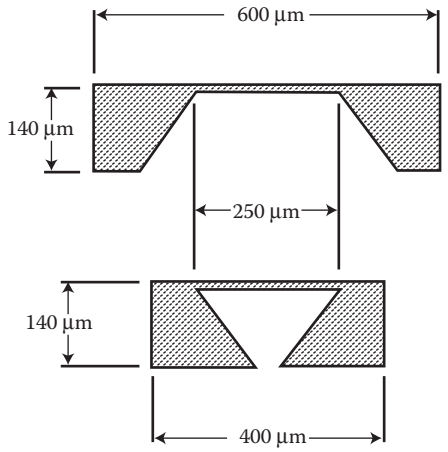

FIGURE 4.84 Comparison of conventional and SFB processes. The SFB process results in a chip that is at least 50% smaller than the conventional chip. (From Bryzek, J., K. Petersen, J. R. Mallon, L. Christel, and F. Pourahmadi. 1990. *Silicon sensors and microstructures.* Fremont, CA: Novasensor. With permission.[226])

just described because the etchant tends to circumscribe the mask opening with {111} walled cavities. This is usually called *undercutting* rather than underetching.

Undercutting—Convex Corner Attack It is advisable to avoid mask layouts with convex corners. However, mesa-type structures often are essential, and in that case there are two possible ways to reduce the undercutting. One is by chemical additives, reducing the undercut at the expense of a reduced ansiotropy ratio, and the other is by a special mask compensating the undercut at the expense of more lost real estate. When etching rectangular convex corners, deformation of the edges occurs because of undercutting. This is often an unwanted effect, especially in the fabrication of, e.g., acceleration sensors, where total symmetry and perfect 90° convex corners on the proof mass are mandatory for good device prediction and specification. The undercutting is a function of etch time and thus directly related to the desired etch depth. An undercut ratio is defined as the ratio of undercut to etch depth (δ/H).

Solutions: Additives and Corner Compensation Structures Saturating KOH solutions with isopropyl alcohol (IPA) reduces the convex corner undercutting; unfortunately, this happens at the cost of the anisotropy of the etchant. This additive also often causes the formation of pyramidical or cone-shaped hillocks.[126,141] Peeters claims that these hillocks are the result of carbonate contamination of the etchant, and he advises etching under inert atmosphere and stockpiling all etchant ingredients under an inert nitrogen atmosphere.[126]

Undercutting can also be reduced or even prevented by "corner compensation structures," which are added to the corners on the mask layout to be undercut during etching. Depending on the etching solution, different corner compensation schemes are used, among them square corner compensation (EDP or KOH) and rotated rectangle corner compensation (KOH) as illustrated in Figure 4.85.

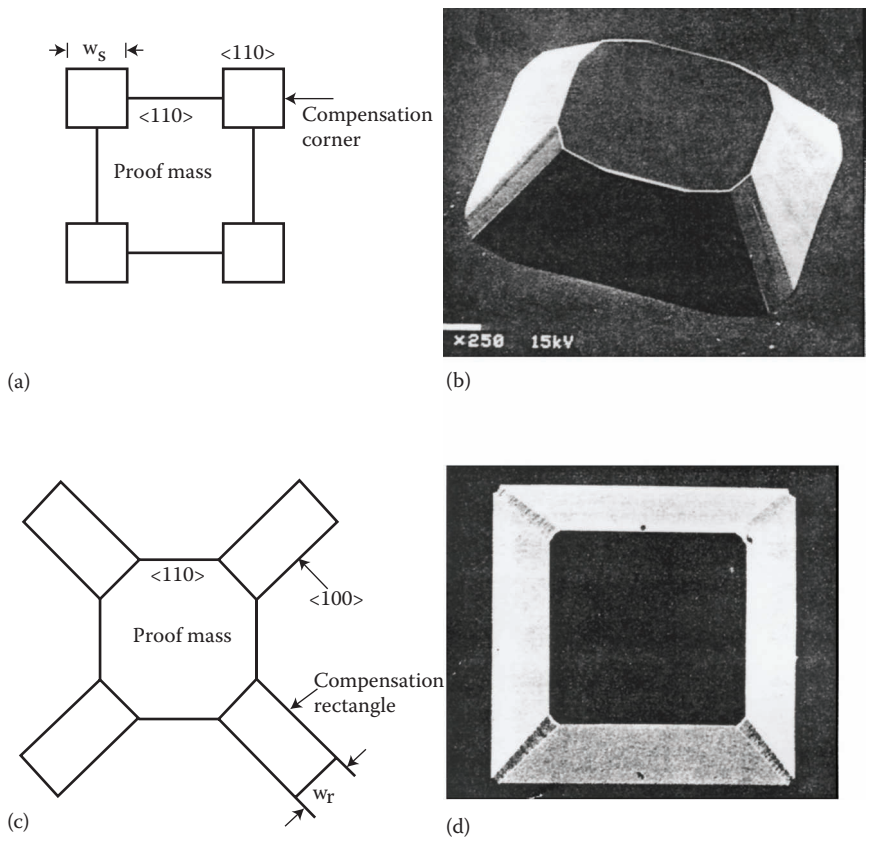

FIGURE 4.85 Formation of a proof mass by silicon bulk micromachining. (a and b) Square corner compensation method, using EDP as the etchant. (c and d) Rotated rectangle corner compensation method, using KOH as the etchant.

In square corner compensation, the square of SiO_2 in the mask, outlining the square proof mass feature for an accelerometer, is enhanced by adding an extra SiO_2 square to each corner (Figure 4.85a). Both the proof mass and the compensation squares are aligned with their sides parallel to the <110> direction. In this way, two concave corners are created at the convex corner to be protected. Thus, direct undercutting is prevented. The three "sacrificial" convex corners at the protective square are undercut laterally by the fast etching planes during the etch process. The dimension of the compensation square, w_s, depends on the depth of the required cavity; for example, for a 300-µm-deep cavity, a square with a side length of 300 µm is used. The resulting mesa structure after EDP or KOH etching is shown in Figure 4.85b. In rotated rectangle corner compensation, shown in Figure 4.85c, a properly scaled rectangle (w_r should be twice the depth of etching) is added to each of the mask corners. The four sides of the mesa square are still aligned along the <110> direction, but the compensation rectangles are rotated (45°) with their longer sides along the <100> directions. Using KOH as an etchant reveals the mesa shown in Figure 4.85d. A proof mass is frequently dislodged by simultaneously etching from the front and the back. Corner compensation requires a significant amount of real estate in the mask layout around the corners, making the design less compact, and the method is often only applicable for simple geometries.

Different groups using different corner compensation schemes all claim to have optimized spatial requirements. For an introduction to corner compensation, refer to Puers et al.[227] Sandmaier et al.[228] use <110>-oriented beams, <110>-oriented squares, and <010>-oriented bands for corner compensation during KOH etching. They found that spatial requirements for compensation structures could be reduced dramatically by combining several of these compensation structures. Figure 4.86 shows the mask layouts for some of the different compensation schemes they used. To understand the choice and dimensioning of these compensation structures, as well as those in Figure 4.85, we will first look at emerging planes at convex corners during KOH etching.

There is some disagreement in literature about the exact nature of planes that emerge at convex

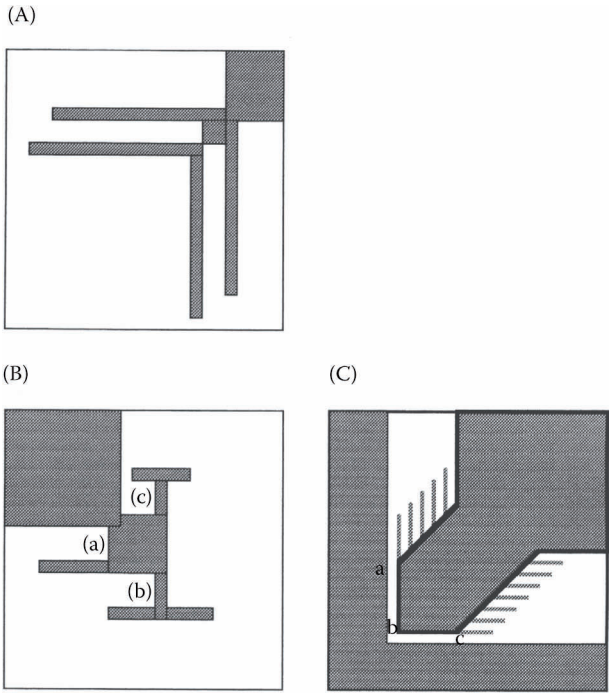

FIGURE 4.86 Mask layout for various convex corner compensation structures. (A) Splitting of the compensation beam creates concave corners, and by arranging two such double beams, a more symmetrical final structure is achieved. (B) Three convex corners of the compensation square are protected from undercutting by the added <110> beams. The side beam on corner b is made about 30% longer than the other two side beams. In this case, the corner is formed by the etch fronts starting at the corners a and b. (C) <010> bands that are added to convex corners in the <100> direction. (From Sandmaier, H., H. L. Offereins, K. Kuhl, and W. Lang. 1991. *Sixth international conference on solid-state sensors and actuators (Transducers '91).* San Francisco. With permission.[228])

corners as etching progresses. Long et al.[229] in their work assumed {310} to be the dominant etch plane. Mayer et al.[225] found that the undercutting of convex corners in pure KOH etch is determined exclusively by {411} planes. However, the {411} planes of the convex underetching corner, as shown in Figure 4.87, are not entirely laid free; rugged surfaces, where only fractions of the main planes can be detected, overlap the {411} planes under a diagonal line shown as AB in Figure 4.87b. The ratio of {411} to {100} etching does not depend on temperature between 60 and 100°C. The value decreases with increasing KOH concentration from about 1.6 at 15% KOH to 1.3 above 40%, where the curve flattens out.[225] Ideally one avoids rugged surfaces and searches for well-defined planes bounding the convex corner. Figure

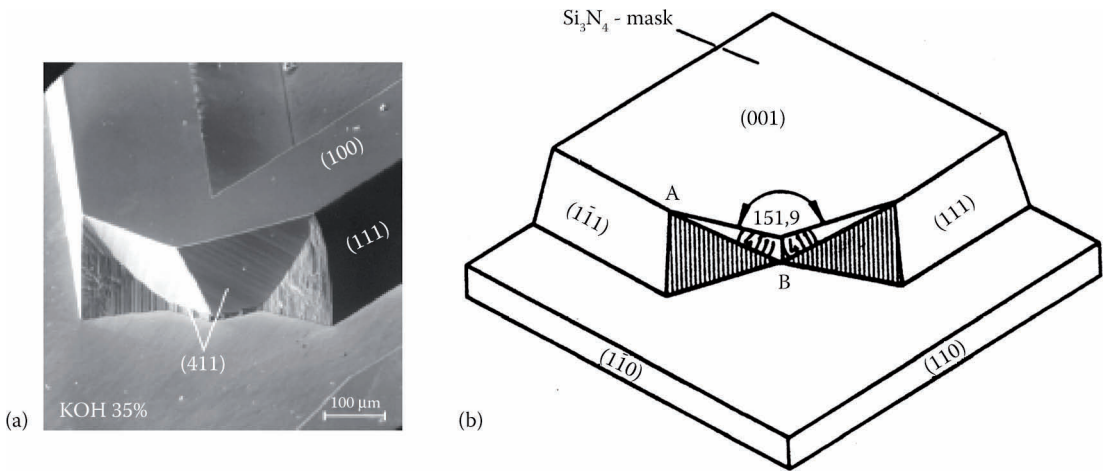

FIGURE 4.87 Planes occurring at convex corners during KOH etching of Si. (a) SEM picture. (b) Schematic. (From Mayer, G. K., H. L. Offereins, H. Sandmeier, and K. Kuhl. 1990. Fabrication of non-underetched convex corners in ansisotropic etching of (100)-silicon in aqueous KOH with respect to novel micromechanic elements. *J Electrochem Soc* 137:3947–51. With permission.[225])

4.88 shows how a <110> beam is added to the convex corner to be etched. Fast-etching {411} planes, starting at the two convex corners, laterally underetch a <110>-oriented beam (dashed lines in Figure 4.88). The longer this <110>-oriented beam is, the longer the convex corner will be protected from undercutting. It is essential that the beam disappear by the end of the etch to maintain a minimum of rugged surface at the convex edge. On the other hand, as is obvious from Figure 4.88, a complete disappearance of the beam leads to a beveling at the face of the convex corner. The dimensioning of the compensating <110> beam then works as follows: the length of the compensating beam is calculated primarily from the required etch depth (H) and the

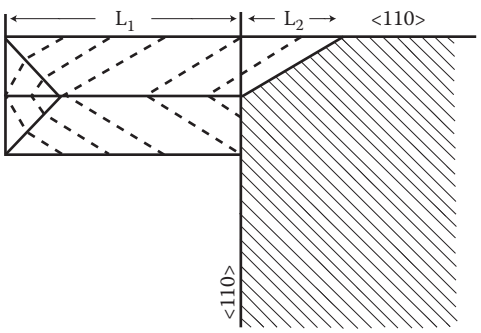

FIGURE 4.88 Dimensioning of the corner compensation structure with a <110>-oriented beam. (From Sandmaier, H., H. L. Offereins, K. Kuhl, and W. Lang. 1991. *Sixth international conference on solid-state sensors and actuators (Transducers '91).* San Francisco. With permission.[228])

etch rate ratio $R\{411\}/R\{100\}$ ($\approx\delta/H$) at the concentration of the KOH solution used:

$$L = L_1 - L_2 = 2H\frac{R\{411\}}{R\{100\}} - \frac{B_{<110>}}{2\tan(30.9°)} \qquad (4.14)$$

with H the etch depth, $B_{<110>}$ the width of the <110>-oriented beam, and tan (30.9°) the geometry factor.[225] The factor 2 in the first term of this equation results because the etch rate of the {411} plane is determined normal to the plane and has to be converted to the <110> direction. The second term in Equation 4.15 takes into account that the <110> beam needs to disappear completely by the time the convex corner is reached. How long does etching go in {110} direction when it goes down in {100} direction by a certain depth?

The resulting beveling in Figure 4.88 can be further reduced by altering the etch compensation structures. This is done by decelerating the etch front, which largely determines the corner undercutting. One way to accomplish this is by creating more concave shapes right before the convex corner is reached. In Figure 4.86a, splitting of the compensation beam creates such concave corners, and by arranging two such double beams, a more symmetrical final structure is achieved. By using these split beams, the beveling at the corner is reduced by a factor of 1.4–2 and leads to bevel angles less than 45°.

Corner compensation with <110>-oriented squares (as shown in Figure 4.85a) features

considerably higher spatial requirements than the <110>-oriented beams. Because these squares are again undercut by {411} planes that are linked to the rugged surfaces described above, the squares do not easily lead to sharp {111}-defined corners. Dimensioning of the compensation square is done by using Equation 4.15 again, where L_1 is half the side length of the square; for $B_{<110>}$, the side length is used. All fast-etching planes have to reach the convex corner at the same time. As before, the spatial requirements of this compensation structure can be reduced if it is combined with <110>-oriented beams. Such a combination is shown in Figure 4.86b. The three convex corners of the compensation square are protected from undercutting by the added <110> beams. During the first etch step, the <110>-oriented side beams are undercut by the etchant. Only after the added beams have been etched does the square itself compensate the convex corner etching. The dimensioning of this combination structure is carried out in two steps. First, the <110>-oriented square is selected with a size that is permitted by the geometry of the device to be etched. From these dimensions, the etch depth corresponding to this size is calculated from Equation 4.15. For the remaining etch depth, the <110>-oriented beams are dimensioned like any other <110>-oriented beam. If the side beam on corner b is made about 30% longer than the other two side beams, the quality of the convex corner can be further improved. In this case, the corner is formed by the etch fronts starting at the corners a and b (Figure 4.86b).

A drawback to all the above-proposed compensation schemes is the impossibility of obtaining a sharp corner in both the top and the bottom of a convex edge as a result of the rugged surfaces associated with {411} planes. Buser et al.[230] introduced a compensation scenario where a convex corner was formed by two {111} planes, which were well defined all the way from the mask to the etch bottom. No rugged, undefined planes show in this case. The mask layout to create such an ideal convex corner uses <010> bands that are added to convex corners in the <100> direction (see Figure 4.86c). These bands will be underetched by vertical {100} planes from both sides. With suitable dimensioning of such a band, a vertically oriented membrane results, thinning and eventually freeing the convex edge shortly before the final intended etch depth is reached. In contrast to compensation structures undercut by {411} planes, posing problems with undefined rugged surfaces (see above), this compensation structure is mainly undercut by {100} planes. For the temperature range of 50–100°C and KOH concentrations ranging from 25–50 wt%, no undefined surfaces could be detected in the case of structures undercut by {100} planes.[228] The width of these <010>-oriented compensation beams, which determines the minimum dimension of the structures to etch, has to be twice the etching depth. These beams can either connect two opposite corners and protect both from undercutting simultaneously or be added to the individual convex corners (open beam). With an open-beam approach (see Figure 4.89), it is extremely important that the {100} planes reach the corner faster than the {411} planes. For that purpose the beams have to be wide enough to avoid complete underetching by {411} planes moving in from the front before they are completely underetched by {100} planes moving in from the side. For example, in a 33% KOH etchant a ratio between beam length and width of at least 1.6 is required. To make these compensation structures smaller while at the same time maintaining {100} undercutting to define the final convex corner, Sandmaier et al.[228] remarked that the shaping {100} planes do not need to be present at

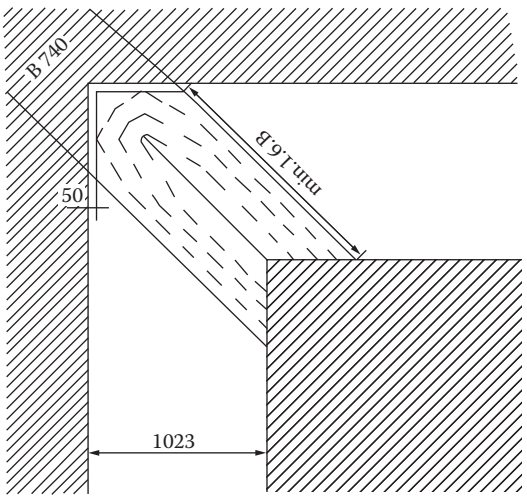

FIGURE 4.89 Beam structure open on one side. The beam is oriented in the <010> direction. The dimensions are in microns, and *B* is the width of the beam.

the beginning of the etching process. These authors implement delaying techniques by adding fan-like <110>-oriented side beams to a main <100>-oriented beam (see Figure 4.86c). As described above, these narrow beams are underetched by {411} planes and the rugged surfaces they entail until reaching the <100>-oriented beam. Then the {411} planes are decelerated in the concave corners between the side beams by the vertical {100} planes with slower etching characteristics. The length of the <110>-oriented side beams is calculated from:

$$L_{<110>} = \left(H - \frac{B_{<010>}}{2} \right) \frac{R\{411\}}{R\{100\}} \qquad (4.15)$$

with H being the etching depth at the deepest position of the device.

The width of the side beams does not influence the calculation of their required length. To avoid the rugged surfaces at the convex corner, the width of the side beams and the spaces between them should be kept as small as possible. For an etching depth of 500 µm, a beam width of 20 µm and a space width of 2 µm are optimal.[228] The biggest drawback of this compensation strategy is that the mask layout is rather complicated, and it takes a lot of time to generate the pattern to fabricate the masks themselves.

Modifications of the compensation scheme that uses <010> bands have been proposed to simplify the mask design. Zhang et al.[231] introduced a modified method that uses a <100> bar with a width greater than twice the etching depth, so that lateral etching would stop at <410> sidewalls, and improved results were obtained. Another novel structure was described by Enoksson[232] and involves a layout that consists of a <010> diagonal band connected to a concave corner on the opposite side of the groove (similar to the situation in Figure 4.89). The band has a slit in the middle of the concave corner, and according to Enoksson, this gives a near-perfect square corner.

Depending on the etchant, different planes are responsible for undercutting. From the above we learned that in pure KOH solutions, undercutting, according to Mayer et al.[225] and Sandmaier et al.,[228] mainly proceeds through {411} planes or {100} planes. That the {411} planes are the fastest undercutting planes was confirmed by Seidel.[233] At the wafer surface, the sectional line of a (411) and a (111) plane point in the <410> direction, forming an angle of 30.96° with the <110> direction, and it was in this direction that he found a maximum in the etch rate. In KOH and EDP etchants, Bean[131] identified the fast undercutting planes as {331} planes. For alkali/alcohol/water, Puers et al.[227] identified the fast underetching planes as {331} planes as well. Mayer et al.,[225] working with pure KOH, could not confirm the occurrence of such planes. Lee[112] indicated that in hydrazine/water, the fastest underetching planes are {211} planes. Abu-Zeid[234] reported that the main beveling planes are {212} planes in ethylenediamine-water solution (no added pyrocatechol). Wu et al.[235] found the main beveling planes at undercut corners to be {212} planes whether using KOH, hydrazine, or EPW solutions. In view of our earlier remarks on the sensitivity of etching rates of higher index rates to a wide variety of parameters (e.g., temperature, concentration, etching size, stirring, cation effect, alcohol addition, and complexing agent), these contradictory results are not too surprising. Along the same line, Wu et al.[236] and Puers et al.[227] have suggested triangles to compensate for underetching, but Mayer et al.[225] found them to lead to rugged surfaces at the convex corner. Combining a chemical etchant with more limited undercutting (IPA in KOH) with Sandmaier's reduced compensation structure schemes could further decrease the required size of the compensation features while retaining an acceptable anisotropy.

Corner compensation for <110>-oriented Si was explored by Ciarlo,[51] who comments that both corner compensation and corner rounding can be minimized by etching from both surfaces so as to minimize the etch time required to achieve the desired features. This requires accurate front-to-back alignment and double-sided polished wafers.

Using corner compensation offers access to completely new applications such as rectangular solids, orbiting V-grooves, truncated pyramids with low cross-sections on the wafer surface, bellow structures for decoupling mechanical stresses between micromechanical devices and their packaging, and so on.[228]

Some additional important references on corner compensation are Ted Hubbard's PhD thesis

(MEMS Design, Caltech 1994)[237] and references by Nikpour et al.[238] and Kim et al.[239]

Comparing Wet and Dry Etching of Si

For the construction of Si micromechanical devices, etching is a commonly used technique. Silicon can be etched in four principal ways: wet anisotropic, wet isotropic, dry anisotropic, and dry isotropic (see Figure 4.90). For wet anisotropic etching, aqueous KOH solutions are mostly used. Slow-etching (111) planes determine the shape of the etched structure. For dry etching, plasma etching machines are common tools. By varying the conditions, the shape of the channels can be varied from perfectly isotropic to exactly vertical. Positive or negative tapering is also possible.

In bulk micromachining, which requires more extreme topologies (more *z*-axis) than classical IC devices, wet etching of crystalline Si used to dominate the state of the art. The development of the newest fast etching, highly anisotropic DRIE equipment is changing this picture rapidly (see Chapter 3). Wet anisotropic etching of Si results in atomically smooth planes and atomically sharp edges, properties hard to achieve with dry etching. Wet etching also offers the advantage of low-cost batch fabrication—usually 20–25 wafers at a time. Some dry etching advantages include the elimination of handling of dangerous acids and solvents and the use of small amounts of chemicals that can provide both isotropic or anisotropic etch profiles, i.e., directional etching without relying on the crystal orientation of Si. Disadvantages of RIE etching are the fact that expensive equipment must be used, and the etching recipes are machine-dependent and also depend on the etching history of the machine. The walls of the etched structures are also rough compared with wet (electro)chemically etched structures.

Dry etching already is predominantly used in IC manufacture, and with higher-aspect-ratio devices and better materials selectivity being attained, the same is happening in micromachining. Besides selectivity and aspect ratio, problems with and concerns about the slow dry etch rate, mask erosion, and high sensitivity to operating parameters are being addressed. Etch rates as high as 6 μm/min have become possible, and the operation is much more automated. However, the equipment is still very specialized and expensive and requires very clean lines to bring the various gases into the vacuum chamber.

Environmental issues dictated a switch from wet to dry etching, but a recent concern in this context is the search for alternative chemistries because chlorofluorocarbon (CFC) production was banned. According to the Montreal Protocol, all ozone-depleting CFCs had to be eliminated by the year 2000. This included etchants such as $CFCl_3$, CCl_2F_2, CF_3Cl, C_2F_5Cl, and CF_3Br.[240] However, the most decisive reason for a switch to dry etching was the need for better CD control.

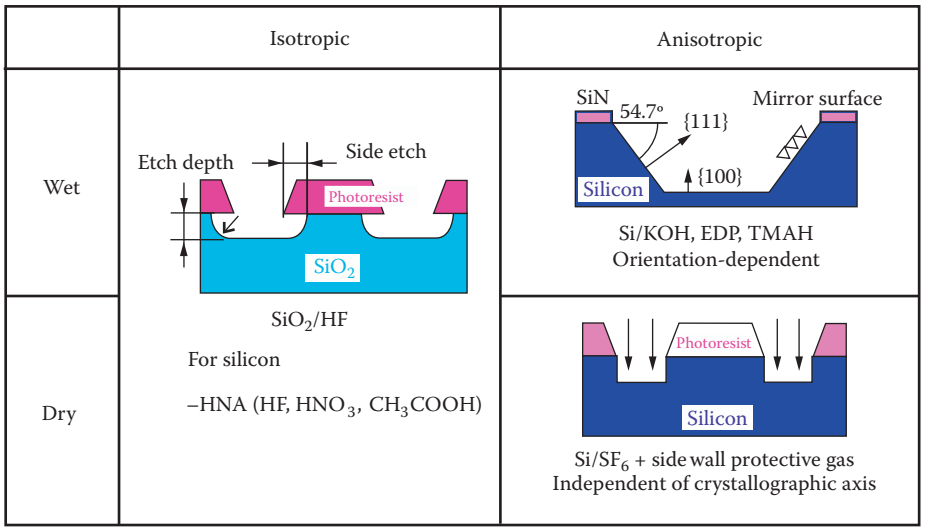

FIGURE 4.90 Different means for etching Si.

TABLE 4.13 Comparison of Wet versus Dry Etching Techniques

Parameter	Dry Etching	Wet Etching
Directionality	Can be highly directional with most materials (aspect ratio of 25 and above)	Only directional with single crystal materials (aspect ratio of 100 and above)
Production-line automation	Good ease of automation (e.g., cassette loading)	Poor
Environmental impact	Low but some gases are toxic and corrosive	High
Masking film adherence	Not as critical	Very critical
Cost chemicals	Low	High
Selectivity	Poor	Can be very good
Materials that can be etched	Only certain materials can be etched (e.g., not Fe, Ni, Co)	All
Radiation damage	Can be severe	None
Process scale-up	Difficult	Easy
Cleanliness	Good under the right operational conditions. Redeposition of nonvolatile compounds might occur.	Good to very good
CD control	Very good (<0.1 μm) Faithfully transfers lithographically defined photoresist patterns into underlying layers. High resolution. Less undercutting	Poor
Equipment cost	Need for specialized (expensive) equipment	Inexpensive
Submicron features	Applicable	Not applicable
Typical etch rate	Slow (0.1 μm/min)	Fast (1 μm/min, anis.)
Theory	Very complex, not well understood	Better understood (Volume I, Chapter 4)
Operating parameters	Many	Few
Control of etch rate	Good because of slow etching	Difficult

Surface micromachining (see Chapter 7) relies on both wet and dry etchants, with processes similar to the ones used in the IC industry. For example, wet etchants are used to etch away sacrificial layers (e.g., HF to etch CVD phosphosilicate glass), whereas dry etching helps to define polysilicon structural elements (e.g., in an NF_3-O_2 plasma). A combination of wet and dry techniques presently makes up the majority of Si micromachining work. Table 4.13 compares the characteristics of dry versus wet etching techniques.

Example 4.1: Dissolved Wafer Process

Figure 4.91 illustrates the dissolved wafer.[241] This process, used by Draper Laboratory for the fabrication of low-cost inertial sensors, involves a sandwich of a silicon sensor anodically bonded to a glass substrate.[242,243] The preparation of the silicon part requires only two masks and three processing steps. A recess is KOH-etched into a p-type (100) silicon wafer (step 1 with mask 1), followed by a high-temperature boron diffusion (step 2 with no mask). In step 1, reactive ion etching (RIE) may be used as well. Cho claims that by maintaining a high-temperature uniformity in the KOH etching bath (±0.1°C), the accuracy and absolute variation of the etch across the wafer, wafer-to-wafer and lot-to-lot, can be maintained to <0.1 μm using premixed, 45 wt% KOH.[241] Cho also uses low-defect oxidation techniques (e.g., nitrogen annealing and dry oxidation) to form

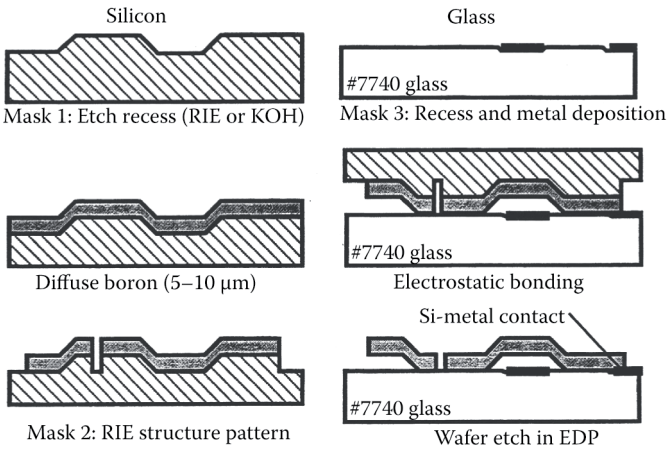

FIGURE 4.91 Dissolved wafer process. (From Greiff, P. 1995. *Micromachining and microfabrication process technology. Proceedings of the SPIE.* Austin, TX: SPIE. With permission.[242])

defect-free silicon surfaces. In the boron diffusion, the key is optimizing the oxygen content. In general, the optimal flow of oxygen is on the order of 3–5% of the nitrogen flow, in which case the doping uniformity is on the order of ±0.2 μm. Varying the KOH etch depth and the shallow boron diffusion time, a wide variety of operating ranges and sensitivities for sensors can be obtained. Next, the silicon is patterned for a RIE etch (step 3 with mask 2). Aspect ratios greater than 10 are accessible. Using some of the newest dry etching techniques, depths in excess of 500 μm at rates greater than 4 μm/min (with an SF_6 chemistry) are possible.[244] The glass substrate (#7740 Corning glass) preparation involves etching a recess, depositing, and, in a one-mask step, patterning a multimetal system of Ti/Pt/Au. The electrostatic bonding of glass to silicon takes place at 335°C with a potential of 1000 V applied between the two parts (electrostatic or anodic bonding is explained in detail in Volume III, Chapter 4). Commercial bonders have alignment accuracies on the order of <1 μm. The lightly doped silicon is dissolved in an EDP solution at 95°C. The keys to uniform EDP etching are temperature uniformity and suppression of etchant depletion through chemical aging or restricted flow (e.g., through bubbles). These effects can be minimized by techniques that optimize temperature control and reduce bubbling (e.g., proper wafer spacing, lower temperature, large bath). The structures are finally rinsed in deionized water and a hot methanol bath.

Draper Laboratory, although obtaining excellent device results with the dissolved wafer process, is now exploring an SOI process as an alternative. The latter yields an all-silicon device while preserving many of the dissolved wafer process advantages (see also Chapter 7 under "SOI Surface Micromachining").

Example 4.2: An Electrochemical Sensor Array Measuring pH, CO_2, and O_2 in a Dual Lumen Catheter

An electrochemical sensor array developed by the author is shown in Figure 4.92, packaged and ready for in vivo monitoring of blood pH, CO_2, and O_2. The linear electrochemical array fits inside a 20-gauge catheter (750 μm in diameter) without taking up so much space as to distort

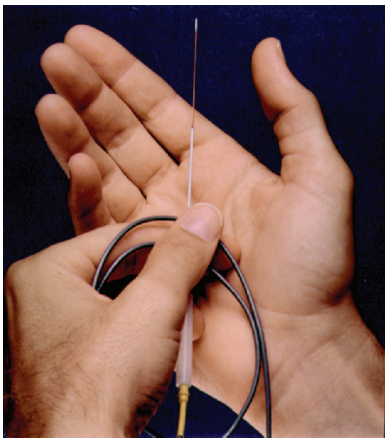

FIGURE 4.92 An in vivo pH, CO_2, and O_2 sensor based on a linear array of electrochemical cells.

the pressure signal monitored by a pressure sensor outside the catheter. A classical (macro) reference electrode, making ionic contact with the blood through the saline drip, was used for the pH signal, whereas the CO_2 and O_2 had their own internal reference electrodes. The high impedance of the small electrochemical probes makes a close integration of the electronics mandatory; otherwise, the high impedance connector leads, in a typical hospital setting, act as antennas for the surrounding electronic noise. As can be seen from the computer-aided design (CAD) picture in Figure 4.93, the thickness of the sensor comes from two silicon pieces: the top piece containing electrochemical cells and the bottom piece containing the active electronics. Each wafer is 250 μm thick. The individual electrochemical cells are etched anisotropically into the top

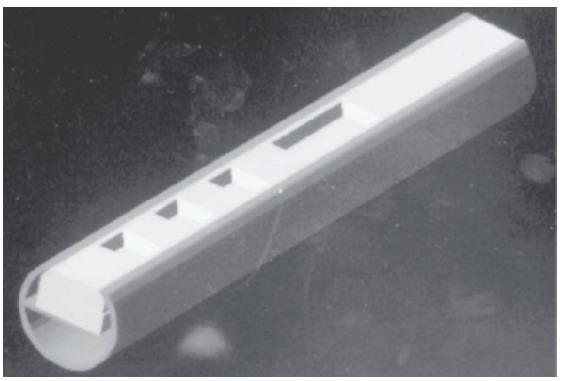

FIGURE 4.93 CAD of the electrochemical sensor array showing two pieces of silicon (each 250-μm thick) on top of each other, mounted in a dual-lumen catheter. The bottom part of the catheter is left open so pressure can be monitored and blood samples can be taken.

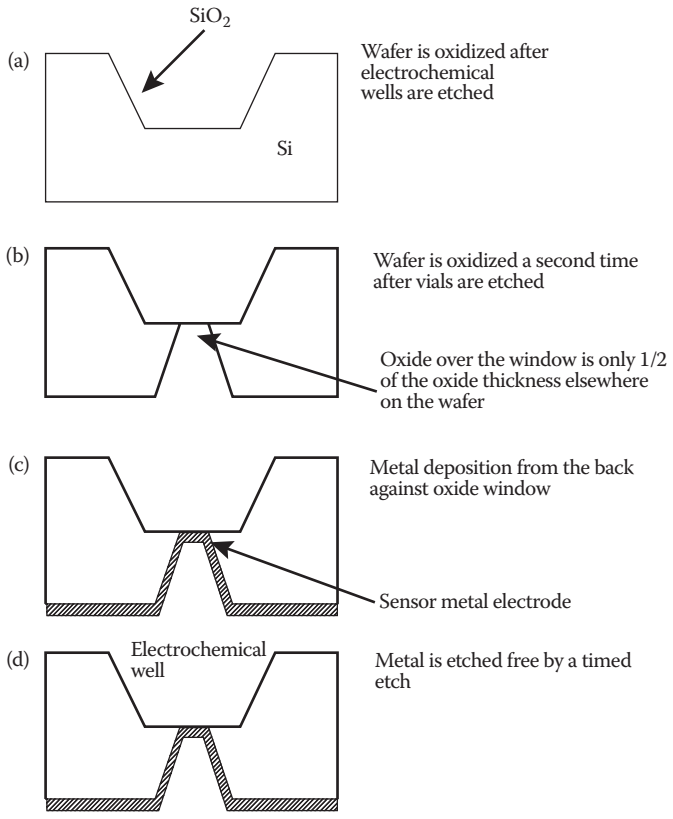

FIGURE 4.94 (a–d) Fabrication sequence for a generic electrochemical cell in Si. Depth of the electrochemical well, number of electrodes, and electrode materials can be varied.

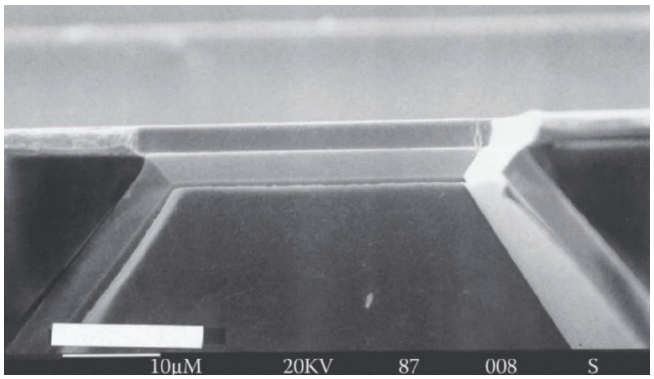

FIGURE 4.95 SEM micrograph illustrating process step (d) from Figure 4.94. A 30 × 30 μm Pt electrode is shown at the bottom of an electrochemical well. This Pt electrode is further contacted to the electronics from the back.

silicon wafer. The bottom piece is fabricated in a custom IC housing using standard IC processes. The process sequence to build a generic electrochemical cell in a 250-μm-thick silicon wafer with one or more electrodes at the bottom of each well is illustrated in Figure 4.94. Wells are etched from the front of the wafer, and after an oxidation step access cavities for the metal electrodes are etched from the back. The etching of the vias stops at the oxide-covered bottoms of the electrochemical wells (Figure 4.94a). Next, the wafers are oxidized a second time with the oxide thickness doubling everywhere except in the suspended window areas where no Si can feed further growth (Figure 4.94b). The desired electrode metal is subsequently deposited from the back of the wafer into the access cavities and against the oxide window (Figure 4.94c). Finally, a timed oxide etch removes the sacrificial oxide window from above the underlying metal, while preserving the thicker oxide layer in the other areas on the chip (Figure 4.94d).[245–247] An SEM micrograph demonstrating Figure 4.94d is shown in Figure 4.95. The electrodes in the electrochemical cells of the top wafer are further connected to the bottom wafer electronics by solder balls in the access vias of the top silicon wafer (see Figure 4.96). Separating the chemistry from the electronics in this way provides extra protection for the electronics from the electrolyte, as well as from the electronics, and chemical sensor manufacture can proceed independently. Depending on the type of sensor element, one or more electrodes are fabricated at the bottom of the electrochemical cells. For example, shown in Figure 4.97 is an almost completed (Severinghaus) CO_2 sensor with an Ag/AgCl electrode as the reference electrode (left in the figure) and an IrOx pH-sensitive electrode, both at the bottom of one electrochemical well. The metal electrodes are electrically isolated from each other by the SiO_2 passivation layer over the surface of the silicon wafer. To complete the CO_2 sensor, we silk-screen a hydrogel containing an electrolytic medium into the silicon sensor cavity and dip-coat the sensor into a silicone-polycarbonate rubber solution to form the gas-permeable membrane. For hydrogel inside the micromachined well, we use poly(2-hydroxyethyl)methacrylate or polyvinylalcohol.

The concept of putting the sensor chemistries and the electronics on opposite sides of a substrate is a very important design feature we decided on several years ago in view of the overwhelming problems encountered in building chemical sensors based on ion-sensitive field effect transistors or extended gate field effect transistors.[187]

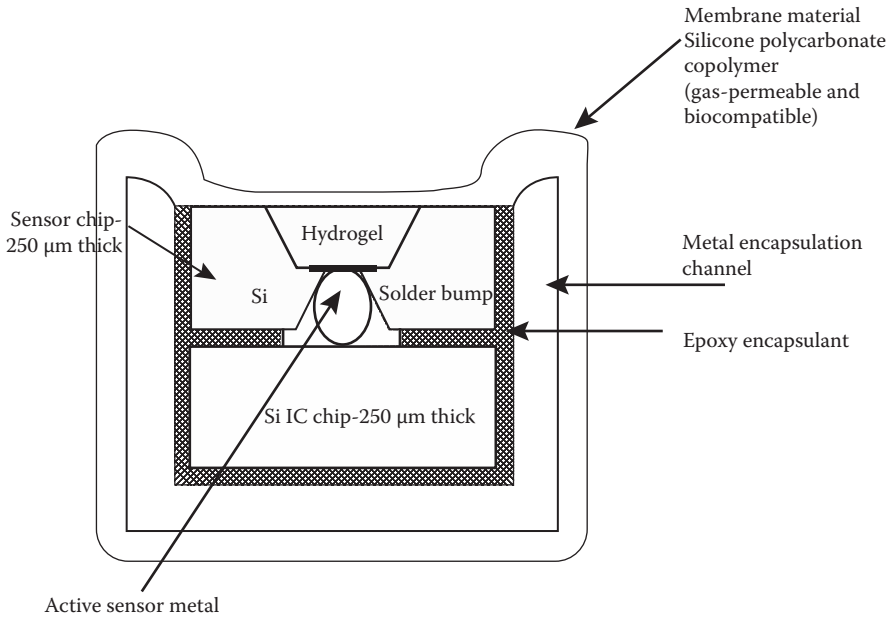

FIGURE 4.96 Schematic of the bonding scheme between sensor wafer and IC. The schematic is a cut-through of the catheter.

Example 4.3: Disposable Electrochemical Valves

One of the most difficult aspects of developing a microfluidic system is the miniaturization of valves. Most current MEMS valve technologies are still too complicated, too large, too power hungry, and too expensive for deployment in such applications as disposables (prohibitive cost) or implants (required power and size are too large). A more appropriate technology for a valve in a disposable such as a diagnostic panel for blood electrolytes or for an implantable drug delivery system may be a "sacrificial" or "use-once" valve. Such a valve could ensure device sterility, isolate reagents until they are required, and even entrap a vacuum to draw sample into the device (like a vacutainer blood-collection tube). Most current MEMS valves have moving parts, such as diaphragm valves that are micromachined in silicon, and are prone to malfunction through clogging. Valves without moving parts are obviously preferred, and some such valves have been incorporated in the electrokinetic and centrifugal fluidic platforms covered in Volume I, Chapter 6. These "valves" form a barrier for liquids but not for vapors. There is an even simpler valve, also without moving parts, which forms a barrier for both liquids and vapors. Creating a vapor barrier is essential if liquids are to be stored in small micromachined chambers for extended periods, e.g., for a diagnostic test incorporating different on-chip reagents. In the absence of such vapor barriers, liquid would be distributed over time driven by the gradients in vapor pressure above each individual chemical reservoir.

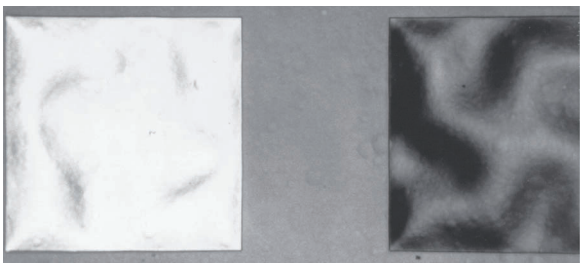

FIGURE 4.97 SEM micrograph of an Ag/AgCl (left) and IrO_x (right) electrode at the bottom of an anisotropically etched well in silicon. This electrochemical cell forms the basis for a Severinghaus CO_2 sensor.

In researching the structures described in Example 4.2 we discovered that a small current, applied between a counter electrode and a thin suspended metal electrode (see Figure 4.98), causes anodic dissolution of the metal or local electrolysis of water, depending on the nature of the valve metal. In both cases, the applied potential leads to bursting of the thin metal barriers. Thus, thin suspended metal membranes, such as silver or Au, can be burst open by passing a small current from the metal via a contacting electrolyte solution to a counter electrode. A Ag valve, for example, can be opened with an applied bias as low as 1–1.5 V. Although the "use-once"

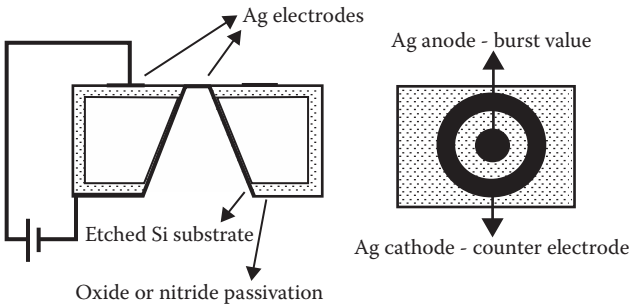

FIGURE 4.98 Disposable electrochemical valve: principle of operation.

microvalve in Figure 4.98 involves a Ag membrane suspended over an orifice, this patented electrochemical valve technology is generic, and a wide variety of metals may be used.[248] Small amounts of drugs can be kept in the Si micromachined chambers, and the chamber may be closed off using a polymeric laminate. The structure shown in Figure 4.98 has also been fabricated using a dry photoresist replacing the Si as structural material. Arrays of the element shown in Figure 4.98 can be made, and the individually addressable metal covers can then be opened electronically, releasing the drugs stored in the Si or polymer chambers. Different drugs can be released at different times, and by opening more "holes," the rate of drug delivery can be set. This is illustrated in Figure 4.99.[249]

One application for this type of valve is responsive drug delivery in a smart pill as sketched in Figure 4.100 (pharmacy-on-a-chip). In this type of implant, openings in a drug reservoir are regulated by a biological stimulus (e.g., the concentration of glucose sensed by a glucose biosensor); therefore, a patient receives only the amount of drug his/her body requires (e.g., the correct amount of insulin). A doctor may intervene via a telemetric link. This technology is currently being pursued by iGlyko (http://www.iglyko.com/iGlyko/Welcome_to_iGlyko.html).

Example 4.4: Self-Aligned Vertical Mirrors and V-Grooves for a Magnetic Micro-optical Matrix Switch

Hélin et al.[250] fabricated an elegant, monolithic magnetomechanical optical switch for dynamically reconfigurable dense wavelength division multiplexing networks. Arrays of optical switches allow for the rapid reconfiguration of optical

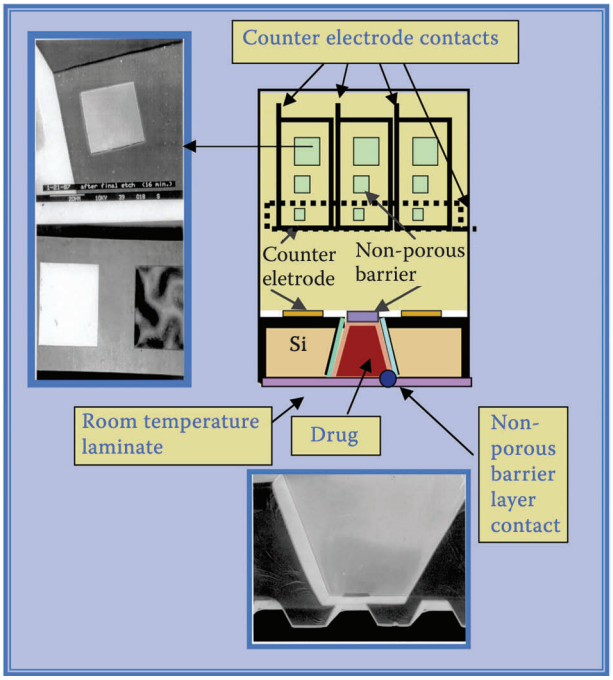

FIGURE 4.99 Metal electrodes are "blasted" open electrochemically. By making electrode arrays, the number of openings is selectable. The metal valve material may be Ag, Pt, Au, and so on. In the SEM picture on the left, we show a platinum electrode (top) and a set of an Ag/AgCl electrode and an IrO_x electrode (bottom). In the latter case the pH of the drug inside the reservoir can be monitored by measuring the voltage between the Ag/AgCl and IrO_x electrode.

networks by altering the light path in a system of intersecting fibers. A wavelength division multiplexer adds or deletes extra optical channels. A switch routing light from a single fiber into any of N output fibers is a $1 \times N$ switch. An $M \times N$ switch routes any one of M inputs to any one of N outputs. The $M \times N$ designation is the order of the optical switch. Commercially available optical switch arrays from companies such as JDS Uniphase Corp. (Milpitas, CA; http://www.jdsu.

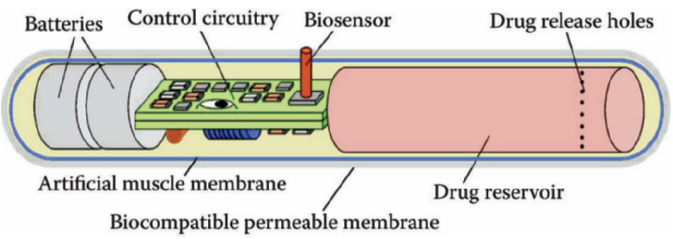

FIGURE 4.100 Model of responsive drug-delivery system (pharmacy-on-a-chip). Responsive drug-delivery pill-type configuration. A video on the operation of the device can be found at http://www.biomems.net/.

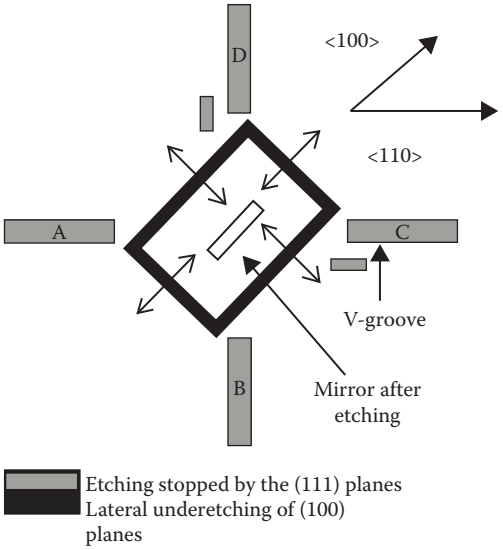

FIGURE 4.101 Principle of the self-aligned optical switch structure (arrows indicate the underetching).

com) and DiCon Fiberoptics, Inc. (Berkeley, CA; http://www.diconfiberoptics.com) are limited to 1×2 or 2×2.[251] Using MEMS, the prospect is to deliver 64×64 or even larger arrays in the case of Xros (bought by Nortel and then dissolved) (see also Volume III, Chapter 10 on IT applications of MEMS).

To make a low-cost, batch-machined switch, Hélin et al. use a simple, one-level mask process on a (100) silicon wafer, which allows for the simultaneous fabrication of (100) sidewalls for high quality mirrors and (111) V-grooves for self-alignment between V-grooves and mirrors. The etching principle, a nice illustration of the wet etching processes described in this chapter, is shown in Figure 4.101. The 45° angle between the <100> and <110> directions is used to self-align the vertical mirrors and V-grooves. As the

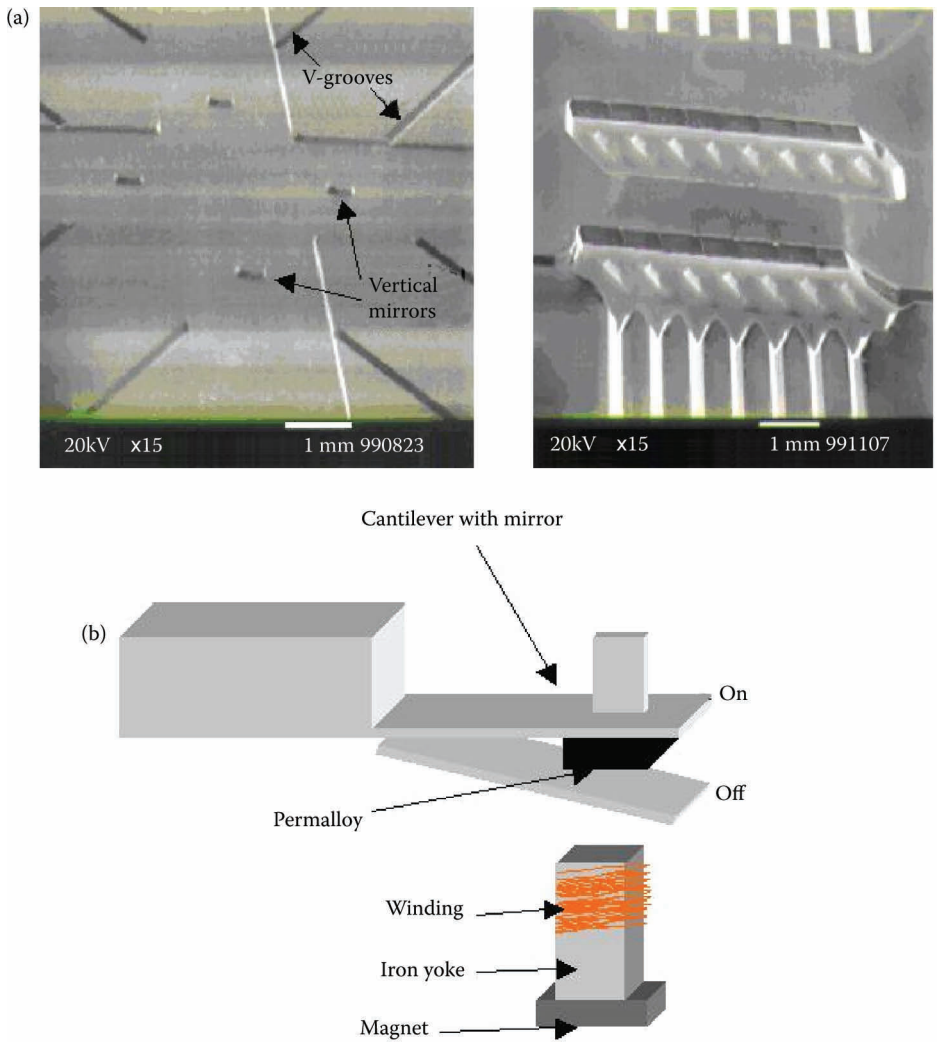

FIGURE 4.102 (a) Examples of optical switching structures for a self-aligned matrix switch; 2×2 bidirectional switch (left) and 1×8 (right). (b) Principle of switch operation with a self-latching system. (Courtesy of Dr. H. Fujita, University of Tokyo.)

bottom and sidewall planes are all from the same {100} family, the lateral underetch rate is equal to the vertical etch rate (see also Figure 4.102). Underetching in the <100> direction creates the upstanding mirror while at the same time V-grooves (A, B, C, and D) are formed in the <110> directions for optical fiber alignment. Contrary to DRIE-based processes, in which ripples etched in the vertical walls are inevitable, wet anisotropic etching fulfills the requirements of high surface quality mirrors, reducing optical losses. Because intersecting (111) planes stop the etching, the width of the V-groove in the mask layout fixes the position of the optical axis. The thickness of the mirror is determined by timing the etch. Cr/Au layers are deposited by vacuum evaporation to finish the mirror manufacture. The etching principle outlined in Figure 4.101 can be expanded to an $M \times N$ matrix switch as shown in Figure 4.102a for a 2×2 and 1×8 switch.

The front-side wafer etching process is preceded by a back-side etching of a cantilever beam, whose role is to support the mirror and allow it to move. The thickness of the cantilever support plate is determined by a timed etch, and the cantilever with mirror is actuated using electromagnetic actuation. The actuation principle is demonstrated in Figure 4.102b.

Questions

4.1: True or False. Give an explanation for your answer.
- (a) Sputtering technique yields a poor quality of SiO_2.
- (b) Etch selectivity of <110> over <111> for KOH is much higher than EDP.
- (c) EDP does not etch Si_3N_4.
- (d) KOH does not etch SiO_2.
- (e) Doping Si with high levels of boron provides a good etch stop for both EDP and KOH.
- (f) The lift-off technique is used mostly to pattern thick Si_3N_4 films.

4.2: A 0.6 μm film of silicon dioxide is to be etched with a buffered oxide etchant (BOE) with an etch rate of 750 Å/min. Process data show that the thickness may vary up to 10% and the etch rate may vary up to 15%.
- (a) Specify a time for the etch process.
- (b) Predict how much undercut will occur at the top of the film.

4.3: Using the isotropic etching diagram for silicon from H. Robbins and B. Schwartz, *J. Electrochem. Soc.*, 107, 108–11, 1960:
- (a) If HF: HNO_3: $HC_2H_3O_2$ = 70:10:20, what is the etch rate?
- (b) At this point, which component controls the etch rate?
- (c) If we use water (10%) instead of $HC_2H_3O_2$ (10%) as our diluent, the etch rate will be more sensitive to which components?
- (d) How can we significantly reduce the etch rate?

4.4: You are asked to build a 600 μm square, 25-μm thick diaphragm in an oxidized (100) silicon wafer. Given that the wafer thickness is 300 μm and that you will be using an anisotropic etching solution of KOH/water which attacks the (111) crystal plane 100 times slower than the (100) crystal direction, the etch rate of (100) silicon in this specific KOH/water solution is 10 μm/hr.
- (a) Find the etching time.
- (b) Find the dimensions of the mask opening you would use.

4.5: You are asked to make grooves 50 μm deep in an oxidized (100) silicon wafer. Use first a BOE etch to make an opening in the oxide layer and then an anisotropic etchant like KOH/water. What are the dimensions of the mask opening you would use to make this dimension insensitive to the amount of over-etch?

4.6: Write one paragraph on each of the Si etch stop techniques including electrochemical etch stop, p-n junction etch stop, and dopant-dependent etch stop, etc.

4.8: Explain in detail the various corner compensation schemes to reduce undercutting while etching anisotropically.

4.9: Which are the three orientations of silicon wafers most commonly employed in micromachining? Arrange them in order of most common usage and briefly describe their benefits and drawbacks.

4.10: Derive the relation that connects the size of an etched cavity with the size of the mask opening in the case of anisotropic etching of [100] silicon.

4.11: In a 4″ Si (100) wafer, with a thickness of 525 µm, 2 different etch features must be created. What should the mask opening be to create:

(a) A square orifice of width 200 µm that extends through the wafer?

(b) A V-groove that extends all the way through the wafer?

4.12: Compare the etching characteristics of (110)- and (100)-oriented silicon wafers. Which would you choose for the following applications and why?

(a) A diaphragm-based pressure sensor

(b) Closely spaced packed high-aspect-ratio comb actuators

4.13: Draw a mask with a convex and a concave corner and describe what happens when anisotropically etching with such a mask. What is the effect etch stop layer has on undercutting of a mask?

4.14: We are building a MEMS device using a <100>-oriented silicon substrate. The 4-inch wafer is p-type and 500 µm thick. There is a 200-nm-thick PECVD SiO_2 thin film deposited onto the surface. We use photolithography to pattern a 750-µm square onto the wafer backside, and while the photoresist is still in place, employ a 33% KOH bath at 70°C to etch the device (see also the figure below*).

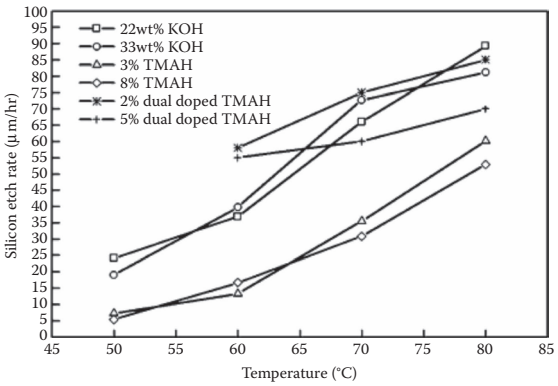
(a) What is the final size of the internal square projected onto the SiO_2 on the opposite side of the wafer?

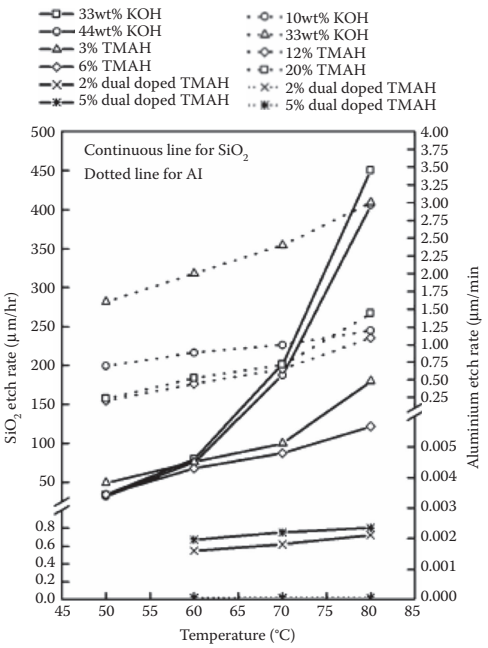
(b) What would have been the minimum photolithography square feature that will etch all the way through the wafer?

(c) How long will it take to etch through the SiO_2 layer (see also the figure below)?

(d) Once the SiO_2 layer is removed, how long will it take to etch through the Si layer?

(e) The etch rate of SiO_2 in buffered hydrofluoric acid (BHF) is 100 nm/min. How long will it take to etch the remaining oxide layers away from the device?





4.16: What wafer orientation would you select if you had to etch under a micro-bridge with a shallow V-groove crossing it at a 90° angle?

4.17: Compare wet and dry etching of Si.

4.18: Prepare a table with the most relevant design parameters for making a very sensitive

* Figures appearing under Question 4.14 reprinted from *Microelectronics Journal*, Volume 37, pp. 519–525, 2006. With kind permission from Elsevier.

piezoresistive Si cantilever to measure bending induced by differential surface stress.

4.19: With what you have learned so far, how would you make a very thin Si membrane in a Si frame and pattern a square Au electrode on that membrane inside the cavity? Where does your process differ from typical IC manufacture?

4.20: How would you make, using lift-off technology, an array of Pt electrodes at the bottom of a deep cavity and contact the Pt electrodes with leads extending over the cavity's edge?

4.21: Mark the wrong statements:

- The factors that affect the etching process are temperature, transport of reactant, reaction rate, diffusion rate, and so on.
- Acetic acid is more polar than water, which helps in achieving proper wetting of slightly hydrophobic Si wafers.
- Photon-pumped etching uses photogenerated electron-hole airs to supply oxidation sites for the etching process.
- Boron doped regions can be used as an etch stop layer.
- KOH etching is used for MOS and CMOS processing.

4.22: In the context of using piezoresistivity to sense strain, what are the advantages/disadvantages of using silicon vs. silicon nitride for pressure sensitive diaphragms? How does residual stress affect the sensitivity?

Introduction

In thermal removing processes, thermal energy, provided by a heat source, melts and/or vaporizes the volume of the material to be removed. Among thermal removal methods, electrical discharge machining (EDM) is the oldest and most widely used. Electron beam machining (EBM) and laser beam machining (LBM) are newer thermal techniques also widely accepted in industry today. Plasma arc cutting using a plasma arc torch is mostly used for cutting relatively thick materials in the range of 3–75 mm and is less pertinent to most miniaturization science applications. In thermal removal processes, a heat-affected zone (HAZ), sometimes called a *recast layer*, is always left on the work piece. In EBM, LBM, and arc machining, deposition and removal methods are available.

Additive thermal techniques involving EBM, LBM, and arc machining are covered in Chapter 9.

Historical Note

Among thermal methods, electrical discharge machining (EDM), using electrical sparks for cutting, is one of the oldest. In an "uncontrolled" fashion, EDM has existed ever since the first thunderstorm. The first widespread "controlled" application for shaping some of the toughest metals was developed during World War II. Although the EDM principle was discovered during the early 1940s, it was not until the early 1950s that the first practical EDM machine was designed. In the United States, during the 1960s, EDM machining was used to create features in the 75-µm range; even more precise EDM, using rotating spindles, was pioneered in Japan in the late 1980s (5-µm size range). There are two major types of EDM: wire EDM and sinker EDM. Sinker EDM is the older of the two. Wire EDM was introduced as a machining process in 1969. EDM, until 10 years ago, found limited application in micromachining[1]; given its very good accuracy, the method is now being investigated for a wide variety of miniaturization problems. Electron beam machining (EBM) and laser beam machining (LBM), two other examples of thermal techniques, were developed in the 1960s and 1980s, respectively. In EBM, high velocity electrons are used instead of sparks, and in LBM intense photon pulses are used. Some authors group EBM, LBM, and ion-beam machining together as high-energy beam machining. Ion-beam machining is a mechanical removing technique and as such is covered in Chapter 6 on mechanical energy-based removing techniques. We only touch briefly on plasma arc cutting because the method has only limited utility in miniaturization science.

Electrical Discharge Machining Introduction

Electrical discharge machining, more commonly known as EDM or spark machining, has traditionally been used to machine unusual designs in hard, brittle metals. Metal is removed by high-frequency electrical sparks, which are generated by pulsing a high voltage between the cathode tool and a work piece anode. The work piece and the tool are both submerged in a dielectric fluid as shown in Figure 5.1. Electrodes are usually made from graphite, copper, or silver. We cover two major types of EDM: wire EDM and sinker EDM.

Silicon-based machining often does not achieve the demands of applications like microsurgery, biotechnology, fluidics, or high temperature environments. As a consequence, EDM methods (including µ-EDM) are providing more and more solutions for application, such as fuel-injection nozzles for automobiles (regulations on environmental laws are forcing manufacturers to improve designs and making them smaller and more compact) and miniaturization of medical tools.

Sinker Electrical Discharge Machining

Sinker or cavity-type electrical discharge machining (EDM) is a thermal mass-reducing process that uses

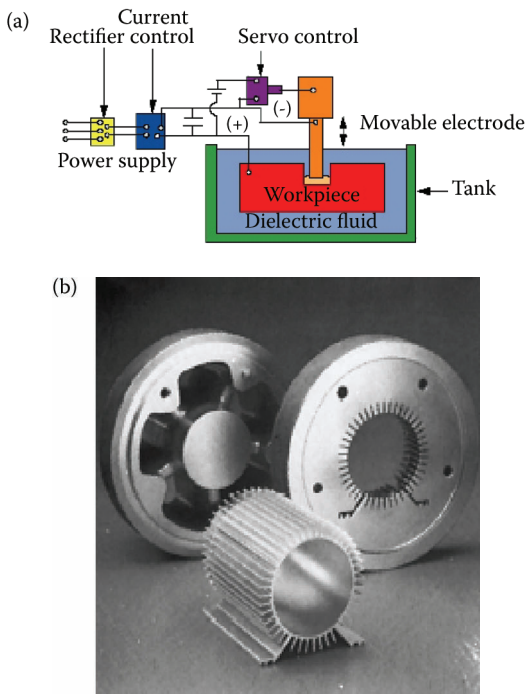

FIGURE 5.1 (a) Discharge machining. Schematic illustration of the electrical discharge machining (EDM) process. Process is based on erosion of metals by spark discharge. The cavity is formed by the shape of the electrode. (b) Examples of cavities produced by the EDM process using shaped electrodes. Two round parts (rear) are the set of dies for extruding the aluminum piece shown in front.

Table 5.1 Electrical Discharge Machining Characteristics

Typical Use	Hard, Machining of Brittle Metals, Tool Making
Tool	Carbon, zinc, brass, copper, silver-tungsten, or copper-tungsten
Dielectric medium	Distilled water (DI), petroleum oils, silicones, triethylene, glycol water mixtures
Aspect ratio of holes	As high as 100:1
Surface finish	1–3 μm but even 0.25 μm has been reported
Gap size/voltage	25 μm/80 V
Removal rate	0.001–0.1 cm^3/h
Work piece	Conductor

a shaped conductive tool (the cathode) to remove electrically conductive material (anode). It does this by means of rapid, controlled, repetitive spark discharges. A dielectric fluid is used to flush the removed particles, to regulate the discharge, and to keep the tool and work piece cool. With a gap between tool and work piece of about 25 μm and a voltage of, for example, 80 V, intense sparking occurs across the dielectric filled gap, melting and vaporizing metal from both pieces (ideally much more from the work piece than from the tool).

Resolidified small hollow spheres are washed away by the recirculating dielectric, for example, oil or deionized water (DI water). A servomechanism adjusts the work piece–tool gap, and DC current pulses produce sparks at a rate of up to 500,000/s. Each spark generates a localized high temperature on the order of 12,000°C in its immediate vicinity (the power concentration is 10^5–10^7 W/mm^2). The tool wear ratio, a measure of work piece material removal to tool material removal, varies from about 3:1 for metallic electrodes to about 70:1 for the better carbon electrodes. The tool wear can be reduced to 1% or less with an adequate selection of tool and work piece materials and appropriate generator settings.[2] Volumetric metal removal rates, ranging from 0.001–0.1 cm^3/h, are determined by thermal characteristics, such as conductivity and melting temperature of tool and work piece rather than hardness, and are small compared with more conventional machining methods. Metal removal rates increase as spark intensity (current) increases, but so does the surface roughness. Increasing the spark frequency, while keeping the other parameters constant, results in a decrease in surface roughness because the energy available is shared between more sparks, and smaller-sized surface craters are produced in the work piece. The frequency range of EDM machines is from 180 Hz, for rough cuts, to several hundred kilohertz, for fine finishing. Although sparks are effective for material removal, arcs result in bad surface quality. Arcs are created when the standby time is not long enough for the deionization of the dielectric to take place. Both short circuit and open circuit result in a stoppage of material removal. Thus, the goal of pulse control is to always create sparks and avoid arcs by optimizing the pulse width (on) and standby time (off). With carefully controlled conditions, it is possible to achieve tolerances as fine as 0.005 mm, but 0.02 mm is more typical. The accuracy of the process is closely related to the spark-gap width: the smaller the gap, the higher the accuracy, but a smaller gap results in a lower working voltage and a lower removal rate. A typical surface finish is in the 1–3-μm range. Two layers are of concern in EDM products. One is a layer of melted and resolidified material usually 0.0025–0.05-mm thick, known as *recast*, which is left on the surface produced by EDM. This layer tends to be very hard and brittle and may have to be removed if high levels of fatigue resistance are required (e.g., with shot peening*). A second layer is the so-called *heat-affected zone* (HAZ) that can be removed through electrochemical abrasion. In Table 5.1 some key EDM features are summarized.

With EDM, holes as small as 0.3 mm in materials 20 mm or more in thickness can be readily achieved. With efficient flushing, holes with an aspect ratio as high as 100:1 have been produced.[3]

* Shot peening is a process used as a decorative finish and/or to modify the mechanical properties of metals. It entails impacting a surface with shot (round metallic particles) with a force sufficient to create dimples and with enough shot so that those dimples overlap.

In general, EDM is one of the most widely used nonmechanical, noncontact machining processes in the industry today. Applications of this process include extrusion dies, fuel injector nozzles, aircraft engine turbine blades, and machining of difficult-to-machine materials like tool steel, tungsten carbide, and cemented carbides. EDM provides very good accuracy and repeatability; however, the tradeoff is a very low material removal rate (0.001–0.1 cm^3/h) for conductive and semiconductive materials only accompanied by thermal damage of the machined surface as a result of high heat generated during the discharge pulses (recast layer of 20–50 μm). Finally, the severe electrode wear affects machining accuracy, and the process poses some fume and skin hazards to operators.

An excellent starting point on the Internet for studying EDM in more detail is EDM Talk (http://www.edmmachining.com), the original EDM industry bulletin board and online forum. EDM equipment includes Fanuc's Robocut (http://www.fanuc.co.jp/en/product/robocut/index.html), Panasonic's MG-ED82W(http://www.panasonicfa.com/?id=MG-ED82W), and Agie's Agie® Mondo Star™ 50 CNC EDM (http://www.agie.com). Also check SmallTec International (http://www.smalltec.com) for sinker EDM and wire-cutting EDM (EDM-WC). A typical EDM machine may cost $350,000, and a typical service supplier is National Jet Company (Lavelle, MD), performing state-of-the-art micro-EDM (http://www.najet.com). The *EDM Handbook* by E. Bud Guitrau constitutes excellent further reading.[3]

A recent variant, EDM-WC, promises to make yet more impact on the future of microelectromechanical systems and is covered next.

Electrode Discharge Machining: Wire Cutting

One of the most interesting adaptations of EDM is the development of electrodischarge machining wire cutting (EDM-WC), also called *wire electrode discharge grinding* (WEDG), which can be used for cutting complex two- (2D) and three-dimensional (3D) shapes from electrically conducting materials.[4] EDM-WC, like EDM, is a thermal mass-reducing process that uses a continuously moving wire to remove material by means of rapid controlled repetitive spark discharges. In EDM-WC, the cutting electrode is a continuously moving thin copper or brass wire, 0.15–0.3 mm in diameter, or, for high-precision cutting, stronger molybdenum-steel wire (0.15–0.03 mm). The wire is pulled from a supply reel past two fixed sapphire or diamond guides, one located above and one below the work piece, as shown in Figure 5.2, and collected on a take-up reel. This continuously delivers fresh wire to the work area. As much as 50 hours of machining can be performed with one reel of wire, which is then discarded. Deionized water is used as dielectric and as a flushing fluid. Flushing is essential for achieving high accuracy and preventing short-circuiting between the wire and part. The main advantage of EDM-WC is that it can mill through metals four or five times faster than EDM. Moreover, no expensive, shaped EDM electrodes are required. Linear cutting rates are still relatively slow, especially for thick substrates: from 38–115 mm/h in 25-mm-thick steel.

Numerically controlled EDM-WC has revolutionized die making, particularly for plastic molders. EDM-WC is now common in tool-and-die shops. Shape accuracy in EDM-WC in a working environment with temperature variations of about 3°C is about 4 μm. If temperature control is within ±1°C,

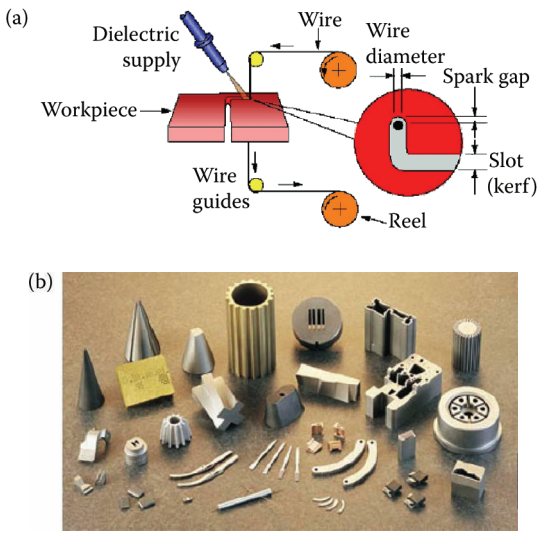

FIGURE 5.2 Electrical discharge machining, wire cutting (EDM-WC). (a) Schematic illustration of the wire EDM process. As much as 50 hours of machining can be performed with one reel of wire, which is then discarded. (b) Typical EDM-WC products.

the obtainable accuracy is closer to 1 µm.[5] No burrs are generated, and because no cutting forces are present, EDM-WC is ideal for delicate parts. No tooling is required, so delivery times are short. Pieces more than 16-in. thick can be machined. Tools and parts are machined after heat treatment; thus, dimensional accuracy is held and not affected by heat treat distortion.

Service and equipment providers in the EDM-WC arena include Small Tec International (http://www.smalltec.com), Reliable, EDM Inc. (http://www.reliableedm.com), and XACT (http://www.xactedm.com/index.html). Oki is a provider of brass wire for EDM-WC (OB wire) (http://www.okidensen.co.jp/english/e_home.htm). Equipment may be bought from companies such AGIE (http://www.agie.com), Fanuc (http://www.fanuc.co.jp/en/product/index.htm), and Panasonic (http://www.panasonicfa.com/?id=Micro%20EDM). For further reading also consult the *Wire EDM Handbook*.[6]

Microelectrical Discharge Machining

When referring to microelectrical discharge machining (µ-EDM) one refers either to working with a small EDM machine (see Figure 5.3 for a hand-held EDM at Panasonic) or to working with smaller than usual electrodes (in sinker EDM) or with thinner wires (in EDM-WC).

In die-sinking µ-EDM, an electrode with microfeatures is used to produce its mirror image in the work piece. The Matsushita Research Institute Tokyo, Inc. developed such a microsinker EDM machine.

FIGURE 5.3 Handheld µ-EDM at Panasonic.

This machine incorporates submicron movement resolution and uses a microtool (microelectrode).

The smallest microtools may be produced by the wire electrode discharge grinding method (see above) (http://www.panasonicfa.com/?id=Micro%20EDM). µ-EDM machining can produce a hole of 5–300 µm in diameter, with a depth three to five times the diameter, and at a precision of ± 0.5 µm on its circularity. Under the right conditions, the machine may result in a surface roughness of as little as 0.1 µm R_{max}. The latter is achieved by minimizing the electrical discharge energy to an extremely small amount. These microholes can be used as nozzles for ink-jet printers, flow control orifices, and pinholes for x-ray measurements. There are also more applications other than simply drilling microholes, such as microshafts, gears, springs, molds, dies, precision optics, and magnetic heads for digital video cameras.

In µ-EDM drilling, a microelectrode is used to "drill" microholes; a circular electrode is rotated at high speed (to help flushing of the liquid), and holes of 5 µm in diameter are reported. In µ-EDM milling, a simple-shaped electrode, rode or tube, is used to produce 3D cavities by adopting a contour motion.

The µ-EDM-WC technique can be used to make circular rods by rotating the work piece against the cutting wire as shown in Figure 5.4a, resulting in diameters as small as 5 µm and a surface roughness of 0.1 µm. The rods can have cross-sections such as triangular, rectangular, slit-type, and polygonal as well. The way to make a triangular shape is illustrated in Figure 5.4b.

Kuo et al.[7] used µ-EDM-WC to make micropipes with an inner diameter of 23 µm, an outer diameter of 186 µm, and a length of 3 mm. These micropipes came with a variety of micronozzle exit shapes and different sizes at the ends; slit openings of 100 × 10 µm, triangular openings with a base of 50 µm, and circular openings with a radius of 6 µm were demonstrated.[8] The manufacturing process of those micropipes is illustrated in Figure 5.5 (steps a–d). µ-EDM-WC is first used to machine a stainless steel rod (a); then electroforming is used to deposit a Ni coat (b); the Ni deposit is subsequently sized by µ-EDM-WC (c); and finally the stainless steel core is removed (d). To separate the core from the deposit

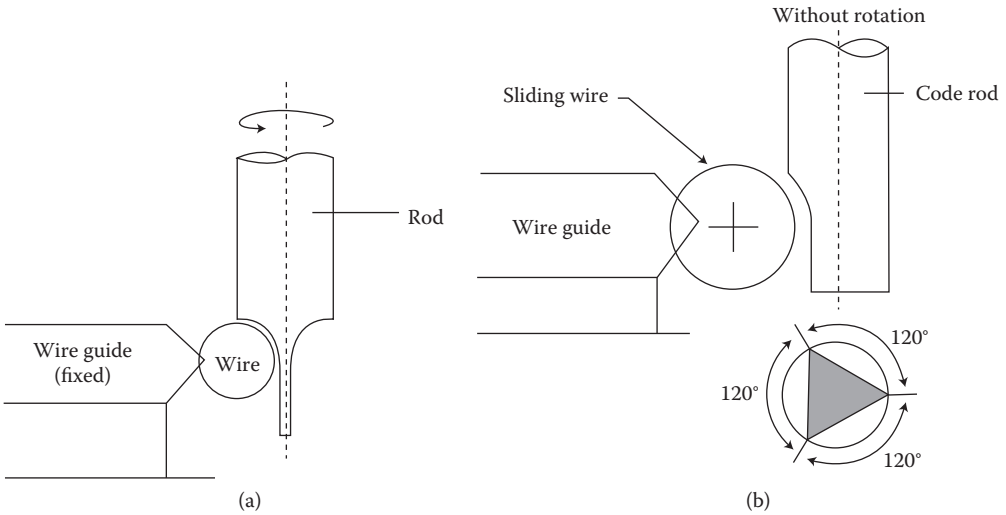

FIGURE 5.4 Microelectrical discharge machining, wire cutting (μ-EDM-WC) for a round rod profile (a) and for a triangular rod profile (b). (From Kuo, C.-L., T. Masuzawa, and M. Fujino. 1991. *Proceedings: IEEE micro electro mechanical systems (MEMS '91).* Nara, Japan; and Kuo, C.-L., T. Masuzawa, and M. Fujino. 1992. *Proceedings: IEEE micro electro mechanical systems (MEMS '92).* Travemunde, Germany. With permission.[7,8])

after plating, it is necessary to reduce the deposit tension stress as much as possible. A sulfamate nickel-plating solution with a plating temperature of 50°C and a pH of 4 was selected for this experiment because it can be operated with high current density and results in low residual stress. A schematic side view of a typical micropipe with a circular exit is shown in Figure 5.6. None of the lithography techniques discussed in the preceding chapters can produce this type of intricate pipe as easily as μ-EDM-WC. It is of great value for a micromachinist to recognize at a glance which shapes are better produced by a lithography-based method and which are better produced by a truly 3D lathe-based method. Microtools produced by EDM-WC may be used as sinker EDM electrodes to enable μ-EDM.

The use of microelectrode arrays enables one to use μ-EDM in batch mode as pioneered by Takahata.[9] Takahata used the LIGA process (Chapter 10) to make the microelectrode array shown in Figure 5.6. Using the setup shown here, 400 holes through 50-μm-thick stainless steel were made in

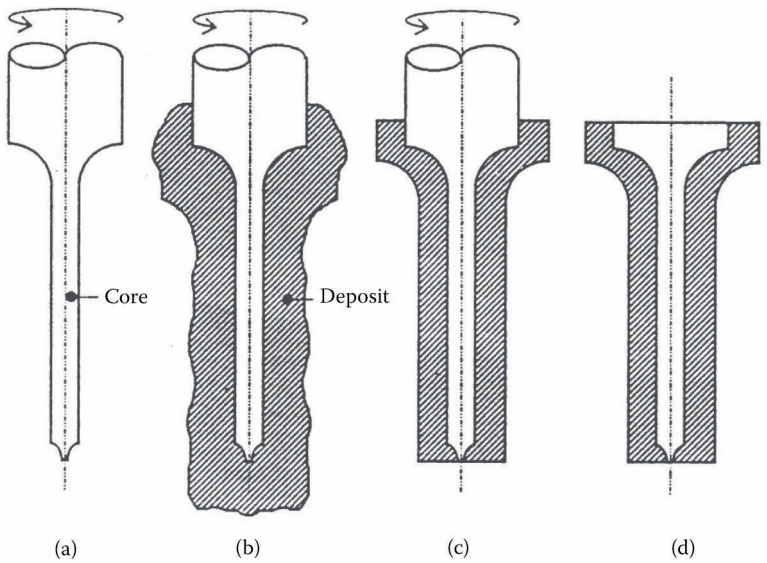

FIGURE 5.5 Micronozzle fabrication process with microelectrical discharge machining, wire cutting (μ-EDM-WC). For fabrication steps (a–d), see text.

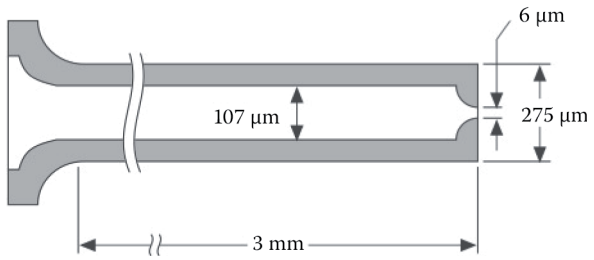

FIGURE 5.6 Schematic side view of micronozzle (see also Figure 5.5d). Schematic side view of a circular pipe with 6-mm exit hole. (From Kuo, C.-L., T. Masuzawa, and M. Fujino. 1992. *Proceedings: IEEE micro electro mechanical systems (MEMS '92).* Travemunde, Germany. With permission.[8])

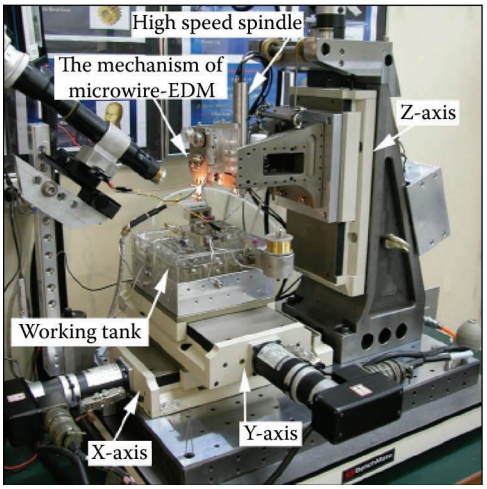

FIGURE 5.8 High precision four-axes multipurpose CNC machine for making microparts developed by Y. S. Liao et al. at the National Taiwan University. (Ehmann, K. F., D. Bourell, M. L. Culpepper, T. J. Hodgson, T. R. Kurfess, M. Madou, and K. Rajurkar. 2007. *Micromanufacturing: international research and development.* New York: Springer.[10])

5 minutes (20–30 times faster than serial machining with a single electrode). Other structures made with this hybrid LIGA-EDM method are also shown in Figure 5.7.

A desk-top high-precision four-axes computer numerical controlled (CNC) machine for making microparts was developed by Liao et al.[10] at the National Taiwan University. This multifunction high-precision machine (accuracy of 1 μm) does on-machine assembly and on-machine metrology (Figure 5.8). Parts in the size range of 0.1–2 mm can be produced, and all manufacturing processes are completed on the same machine without moving the work piece.

This hybrid desk-top machine is capable of performing the following four functions. 1) Milling with a low-speed (0–3,000 rpm), a middle-speed (1,000–10,000 rpm), and a high-speed (2,000–80,000 rpm) spindle. 2) μ-EDM with microelectrodes with a diameter as small as 8 μm and very high high-aspect ratios. These microelectrodes are made using the on-board μ-EDM-WC with a 0.02 mm ϕ brass wire (see next). 3) μ-EDM-WC that features microwire tension control and wire vibration suppression (Figure 5.9) and a novel mechanism that permits vertical, horizontal, and slanted wire cutting. 4) On-line measuring of the flatness, circularity, concentricity, dimensions, and geometric tolerances of the work piece.

The vertical, horizontal, and slanted cutting with the μ-EDM-WC tool has successfully fabricated complex features and parts. An example is the impressive Chinese pagoda (1.25 mm × 1.75 mm) shown in the

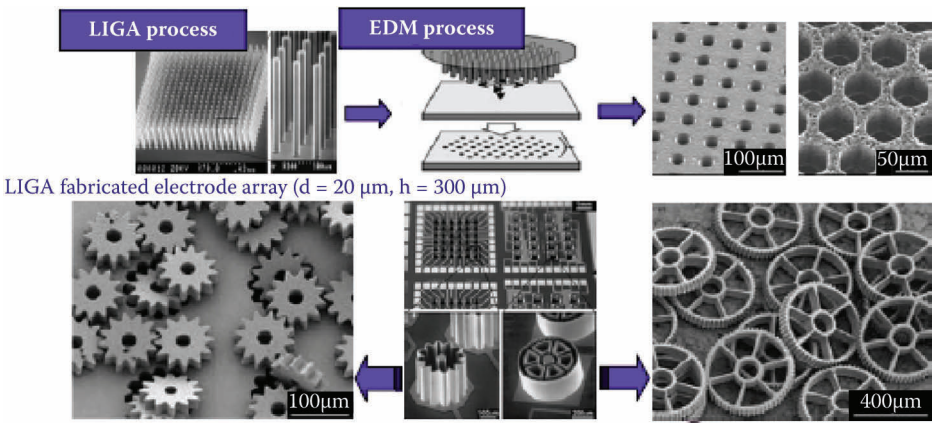

FIGURE 5.7 Microelectrode array fabricated using LIGA. This array toll enables the use μ-EDM in batch mode. (Takahata, K., and Y. B. Gianchandani. 2002. Batch mode micro-EDM for high-density and high-throughput micromachining. *IEEE/ASME J Microelectromechanical Systems* 11:102–110.[9]) Example products include copper electrode arrays and WC-Cu super hard gears.

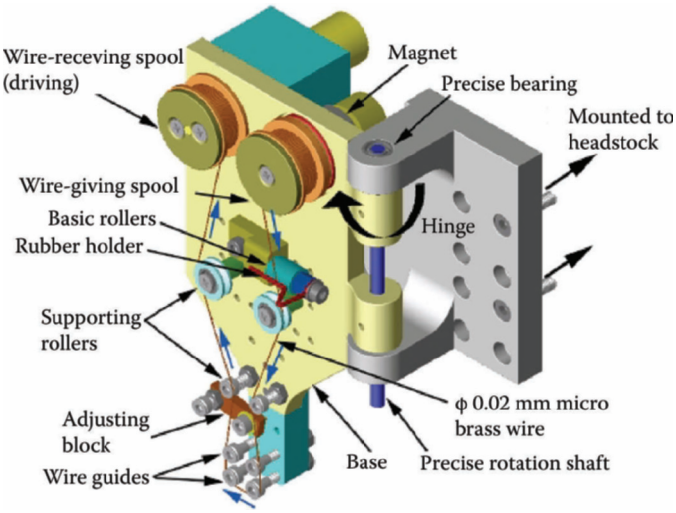

FIGURE 5.9 The μ-EDM-WC tool features microwire tension control and wire vibration suppression. The tool allows vertical, horizontal, and slanted wire cutting. μ-EDM-WC at the National Taiwan University (Prof. Y. S. Liao).

heading of this chapter. The vertical and horizontal μ-EDM-WC cuts to make this pagoda are shown in Figure 5.10.

High-speed micromilling with a single crystal diamond milling cutter is demonstrated in Figure 5.11. The depth of the cut is 0.03 mm; the rotational speed is 80,000 rpm; and the feed rate is 20 mm/min.

We conclude this section with a table comparing EDM with ECM, a chemical etching technique covered in Chapter 4, using conventional mechanical machining (CNC machining; see Chapter 6) as a reference point. In Table 5.2 we list metal removal rates (MRRs), tolerance, surface finish and damage depth, and required power.

The metal removal rate by ECM is much higher than that of the EDM, with a metal removal rate 0.3 that of CNC, whereas EDM is only a small fraction of the CNC material removal rate. Power requirements for ECM are comparatively high. The tolerance obtained by EDM and ECM is within the range of CNC machining, which means satisfactory dimensional accuracy can be maintained. All the processes obtain satisfactory surface finishes. Depth of surface damage is very small for ECM, whereas it is very high in the case of EDM. For this reason, ECM can be used for making dies and punches. Capital cost for ECM is very high when compared with conventional CNC machining, and

Table 5.2 Machining Characteristics of EDM and ECM

Process	MRR (mm^3/min)	Tolerance (μm)	Surface Finish (μm)	Damage Depth (μm)	Power (W)
ECM	15,000	50	0.1–2.5	5	100,000
EDM	800	15	0.2–1.2	125	2,700
CNC	50,000	50	0.5–5	25	3,000

MRR, metal removal rate; tolerance, tolerance maintained; surface finish, surface finish required; damage depth, depth of surface damage; ECM, electrochemical machining; EDM, electrical discharge machining; CNC, computer numerical control machining.

EDM has also a higher tooling cost than the other machining processes.

Laser Beam Machining

Introduction

The basic operating principle of the laser was put forth by Charles Townes and Arthur Schalow from Bell Telephone Laboratories in 1958, and the first laser, based on a pink ruby crystal, was demonstrated in 1960 by Theodore Maiman at Hughes Research Laboratories. Lasers are defined as narrow beams (a divergence angle might be about 1 mrad, i.e., 1 m spread over 1 km of travel length) of monochromatic and coherent light in the visible, infrared (IR), or ultraviolet (UV) ranges of the spectrum. The key components of a laser unit are the active medium (a gas, liquid, or solid in which the beam is generated), the power supply (which delivers energy to the laser medium in the form needed to stimulate its emission), and the optical cavity (where the beam characteristics are defined). Lasers can be run in continuous mode or in pulsed mode to enhance the irradiance. The word *laser*, we saw in Volume I, Chapter 5, stands for Light Amplification by Stimulated Emission of Radiation. In Volume I, Chapter 5 we explained the lasing action; here we detail laser use in subtractive manufacturing. In 1960, the laser was said to be a "solution waiting for a problem," but today lasers are used in a wide range of applications, and some laser types have even become commodity products (e.g., laser pointers). In Table 5.3 we show the operating mode, wavelength, power, and example applications of some popular lasers (the list of potential applications is far from complete).

The CO_2 laser is an example of a gas laser based on a mixture of helium (83%) and nitrogen (16%) with carbon dioxide (6%) as the lasing material. The CO_2 laser produces a collimated coherent beam in the IR region (10.6 μm) characteristic of the active material (CO_2). The wavelength is strongly absorbed by glasses or polymers; thus, either mirrors or ZnSe lenses with excellent IR transparency are used to handle the beam.

The neodymium-doped yttrium aluminum garnet (Nd:YAG) laser is a solid-state laser producing a collimated coherent beam in the near-IR region of wavelength 1.06 μm, and can be pulsed or continuous. In pulsed mode, peak power pulses of up to 20 kW are now available. The shorter wavelength allows the use of optical glasses to control the beam path.

Excimer (EXCIted diMER) lasers, invented in 1975, are a family of pulsed lasers with a fast electrical discharge in a high-pressure mixture of a rare gas (krypton, argon, and xenon) and a halogen gas (fluorine and hydrogen chloride) as the source of emission. The particular combination of rare gas and halogen determines the output wavelength. Excimer lasers cover a range of wavelengths in the UV range from 157 nm (F_2) to 353 nm (XeF) with 193 nm (ArF), 248 nm (KrF), and 308 nm (XeCl) being particularly useful intermediate wavelengths.* Peak powers typically range from 3 MW (F_2) to 50 MW (KrF or XeCl) in pulses lasting a few tens of nanoseconds.

Machining with laser beams, first introduced in the early 1970s, is now used routinely in many industries. Laser machining, with long or continuous wave (CW), short, and ultrashort pulses, includes the following applications:

- Heat treatment
- Welding (see Volume III, Chapter 4 on packaging)
- Ablation or cutting of plastics, glasses, ceramics, semiconductors, and metals (this chapter)

* Recently, the 308-nm xenon chloride laser has gained much attention as a very effective treatment modality in dermatological disorders.

Table 5.3 Laser Types with Characteristics and Applications

	Wavelength	Maximumm Power Output (W)	Operation Mode	Applications
Semiconductor lasers, also injection or junction laser				
Single diodes	Infrared to visible (0.33–40 μm)	0.6 W (CW) 100 W (P)	CW and pulsed	Compact discs, laser printers, bar code scanners, optical communications
Diode laser bars	Infrared to visible	Up to 100 W	CW and pulsed	Pumping light source for solid state lasers
Solid-state lasers				
Ti-sapphire	690–960		Tunable	
Nd:YAG	1.064 μm	1000 W (CW) 2 10^8 W (P)	CW and pulsed	Welding, hole piercing, cutting
Ruby	694.3 nm	Several MW	Pulsed	Measurement instrumentation, pulsed holography
Gas/liquid lasers				
CO_2 (gas)	9.6 μm, 10.6 μm	1 W–40 kW (CW) 100 MW(P)	CW and pulsed	Heat treatment, scribing, welding, cutting
Excimer laser (gas)	193 nm, 248 nm, 308 nm (and others)	1 kW–100 MW	Pulse mode, pulse length 10–100 ns	Micromachining such as flex circuit via drilling and wire stripping, laser chemistry, medicine
HeNe (gas)	632.8 nm (most prominent), 1.15 μm, 3.39 μm	0.0005–0.05 (CW)	CW	Measurement instrumentation, holography, line-of-sight communications
Argon ion laser (gas)	515–488 nm (several)	0.005–20 (CW)	CW	Printing technology, pumping laser for dye laser stimulation, surgery
Dye laser (liquid)	Continuous between infrared and UV (different dyes): 0.38–1.0 μm	0.01 (CW) and 1 10^6 (P)	CW and pulsed	Measurement instrumentation, spectroscopy, medicine, pollution detection

- Material deposition (see Chapter 9)
- Etching with chemical assist, i.e., laser-assisted chemical etching (LACE; this chapter)
- Laser-enhanced jet plating and etching (see Chapter 9 and this chapter, respectively)
- Lithography (see Chapters 1 and 2)
- Surgery (see Volume III, Chapter 10)
- Photopolymerization (e.g., μ-stereolithography described in Chapter 9)

From this list, it is clear that lasers can be used for removal and for additive processes. We only consider ablative or subtractive laser processes here, as illustrated in Figure 5.12; additive laser processes are reviewed in Chapter 9. Interestingly, the laser may also serve as its own process monitor. This multiuse, multirole, and in situ capability is not offered with any of the other advanced material processing techniques such as molecular beam epitaxy, chemical vapor deposition, deep reactive ion etching, and so on.[11]

Earlier uses of laser beam machining (LBM) were mostly scientific in nature, and industrial applications involved macroprocesses, like sheet metal cutting and welding for the automobile industry (Figure 5.13). Today, industrial lasers are also used in a wide variety of microfabrication tasks. R. Srinivasan and V. Mayne-Banton of IBM Research first reported micromachining with laser ablation in 1982.[12] Initial studies by Srinivasan and coworkers showed that pulsed UV laser radiation at 193 nm (an ArF excimer laser) can be used to etch organic polymers several micrometers in depth. To illustrate how fast laser machining has improved and how little yet is known of the fundamental underlying processes in this field, consider that it was only recently recognized that femtosecond laser pulses interact with matter in a manner that is totally different from traditional lasers with longer pulses. During machining with femtosecond lasers, much less heat dissipates in the substrate, and, as

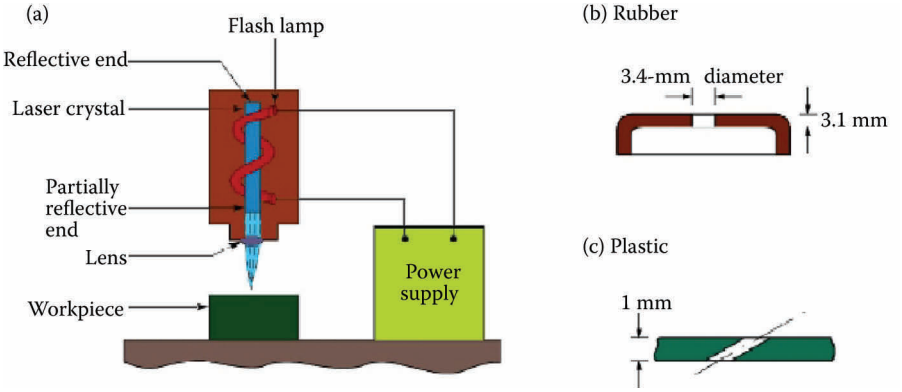

FIGURE 5.12 (a) Schematic illustration of the laser-beam machining process. (b and c) Examples of holes produced in nonmetallic parts by LBM.

a consequence, ultrafast lasers present the potential for micromachined products of superior quality (http://www.clark-mxr.com/industrial/handbook/index.htm).

Although the number of lasers delivered for strict micromachining applications has been low compared with others so far, it is predicted that the next 10 years will see a phenomenal market growth for this application.

Laser Parameters for Laser Material Removing—Laser Ablation

Introduction

Laser ablation is the process of removal of matter from a solid by means of an energy-induced transient disequilibrium in the lattice. The characteristics of the released atoms, molecules, clusters, and fragments (the dry aerosol) depend on the efficiency of the energy coupling to the sample structure, i.e., the material-specific absorbance of a certain wavelength, the velocity of energy delivery (laser pulse width), and the laser characteristics (beam energy profile, energy density or fluency, and the wavelength). Table 5.4 summarizes all the different laser parameters that can be controlled and their effect on materials processing.[13] More specifically for micromachining purposes, the wavelength, spot size [i.e., the minimum diameter of the focused laser beam, d_0 (Equation 5.9)], average laser beam intensity, depth of focus, laser pulse length, and shot-to-shot repeatability (stability and reliability in Table 5.4) are the six most important parameters to control. Additional parameters we will cover in the section below, not listed in Table 5.4, concern laser machining in a jet of water and laser-assisted chemical etching (LACE).

Like other thermal removing techniques, laser machining leaves a heat-affected zone (HAZ) on the work piece where molten material resolidified in situ or where material was sufficiently heated and cooled rapidly enough to result in embrittlement. This change in material properties can alter subsequent laser ablation and affect material performance.

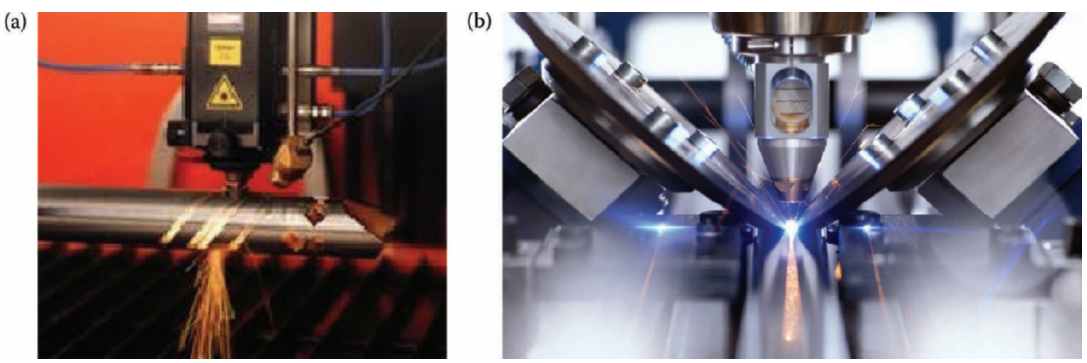

FIGURE 5.13 Laser manufacturing: (a) cutting; (b) welding.

Table 5.4 Laser Parameter and Related Processing Parameters

Laser Parameter	Influence on Material Processing
Power (average)	Temperature (steady state) Process throughput
Wavelength (μm)	Optical absorption, reflection, transmission, resolution, and photochemical effects
Spectral line width (nm)	Temporal coherence Chromatic aberration
Beam size (mm)	Focal spot size Depth of focus Intensity
Lasing modes	Intensity distribution Spatial uniformity Speckle Spatial coherence Modulation transfer function
Peak power (W)	Peak temperature Damage/induced stress Nonlinear effects
Pulse width (s)	Interaction time Transient processes
Stability (%)	Process latitude
Efficiency (%)	Cost
Reliability	Cost

Source: Liu, Y. S. 1989. *Laser microfabrication: thin film processes and lithography.* Eds. J. Y. Tsao, and D. J. Ehrlich. New York: Academic Press. With permission.[13]

The size of the HAZ is a function of the laser pulse duration and the thermal conductivity and specific heat of the work piece. The HAZ depends on the distance the heat is conducted within the material and varies with material and laser wavelength. The better the material conduction (thermal diffusivity), the greater the extent of the HAZ is. Associated with the HAZ are a recast layer and the formation of burrs. During the ablation process, the expulsion of material in the plasma jet creates a compressive force on the molten pool of material under the laser spot. This will cause a portion of the liquefied material to be forced out of the ablation zone, and it will deposit onto the surrounding region. Debris is also a related problem of the ablation process. Particulates redeposit onto the surface as solid fallout of higher boiling point second phases from the plume and as condensation of the primary material. Taken together, all the preceding effects reduce the quality of the ablated region.

Based on pulse length, there are three major laser machining operation modes: short, ultrashort, and long or CW. *Short* means that the pulse is longer than 10 ps. *Ultrafast* or *ultrashort* means that the laser pulse has a duration somewhat less than 10 ps, usually some fraction of a picosecond. *Long* or *continuous wave* lasers are lasers that are operated in a CW (pulse duration > 0.25 s) rather than a pulsed mode. Each operation mode has its own micromachining applications. Short pulses of coherent light replace electrons from the electron beam vacuum technology (EBM; see below) as the cutting tool by vaporizing the substrate (subtractive process). No vacuum is required, but the removal rate is much slower than in EBM. For "hard to drill" materials and when holes are smaller than 150 μm, mechanical drilling becomes less cost effective, and laser removing techniques become an attractive alternative. With ultrashort pulses, so much energy is deposited in the material at such a fast rate that the material is forced into a plasma state; the material goes from a solid to a gas phase without first going through a melt phase. This plasma then expands away from the material as a highly energetic gas, taking almost all the heat away with it. This newest operation mode avoids a lot of the problems associated with the HAZ and promises to open up a new universe of very accurate micromachined parts unavailable with long laser pulsing. Long-pulse or CW lasers can be used to melt the metal for welding (additive process).

Laser Wavelength

Laser wavelength has been identified as an important parameter influencing the efficiency of the energy transfer to the body of the irradiated sample (ablation characteristics). The selection of a wavelength with a minimum absorption depth helps ensure a high-energy deposition in a small volume for rapid and complete ablation. Several attempts have been made to describe the laser ablation phenomenon theoretically. It appears to be agreed now that, for very short wavelength radiation (~200 nm), direct photochemical bond breaking plays an important role in the ablation process. At that wavelength, photons have enough energy, and a one- or two-photon absorption by materials might cause direct bond cleavage in the solid, leading to rapid decomposition of the material into highly volatile molecular fragments. However, at longer wavelengths (>300 nm), the single-photon

energy is not sufficient for bond breaking; two-photon or multiphoton avalanche effect processes must be considered (see below). As mentioned above, a shorter absorption depth in the material to be machined means a higher laser energy density in metal.

The decay of the intensity of an electromagnetic wave with E along the *x*-axis and propagating in the *z*-direction in an absorbing material we derived in Volume I, Chapter 5 as:

$$I(z) = I_m e^{-\alpha z} \qquad \text{(Volume I, Equation 5.110)}$$

where $\alpha = \frac{4\pi n''}{\lambda}$ (with n'' the imaginary part of refractive index). Thus, the penetration depth d is given as [when d = z, then $I(z)/I_m = e$]:

$$d = 1/\alpha = \lambda / 4\pi n'' \qquad (5.1)$$

The surface condition also has some effect on the laser energy coupling. Rougher surface helps absorbing more, and special surface treatments can enhance the absorption.

Example 5.1

For copper the complex refractive index at 5893 Å is given as n = 0.62 + i2.57 and its reflectivity R = 0.73. For a λ = 100 Å one obtains a d = 6.2 Å and at a λ = 10μm, d = 62 Å.

Laser Spot Size

The laser beam spot size is another relevant factor influencing the efficiency and spatial resolution of laser ablation. Assuming cylindrical drilling, the ablated mass *M*, is given by:

$$M = \rho\pi L r^2 \qquad (5.2)$$

where ρ = the mass density
L = the ablation depth
r = the crater radius

This means that a variation of the spot size *r*, at constant ablation efficiency, leads to a quadratic variation of the signal intensity as a direct consequence of the ablated mass involved.

If the laser beam diameter is not of a controlled diameter, the ablation region may be larger than desired and result in excessive slope of the sidewalls.

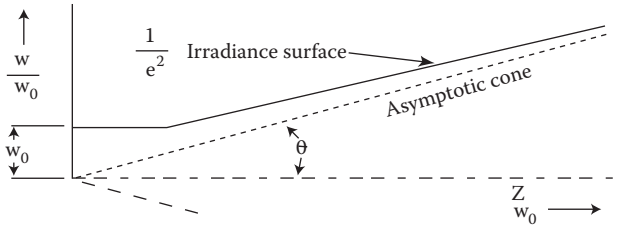

FIGURE 5.14 Growth in beam diameter as a function of distance from the beam waist for a Gaussian laser beam profile.

Diffraction causes light waves to spread transversely as they propagate; therefore, it is impossible to have a perfectly collimated beam. The spreading of a laser beam is in accord with the predictions of diffraction theory. If the objective is to create the smallest possible feature, it is important to be able to focus the laser beam to the smallest spot size. The latter depends on several factors, but crudely one can say that the smallest spot that one can create is about half the wavelength of the light used; if the wavelength of light is 1 μm, then the smallest spot one can create is about 0.5 μm (see Volume I, Equation 5.1 with NA = 1).

In a more rigorous description, we start from the irradiance distribution of a Gaussian TEM_{00}* laser beam (Figure 5.14):

$$I(r) = I_0 e^{-\frac{2r^2}{w(z)^2}} = \frac{2P}{\pi w(z)^2} e^{\frac{2r^2}{w(z)^2}} \qquad (5.3)$$

where r = the radial distance across the beam
P = total power in the beam in watts
w(z) = the radius or one-half the diameter of the $1/e^2$ irradiance contour after the wave has propagated a distance z

Gaussian beams propagate as Gaussians, and the expression for the spot size $w(z)$—the radius of the $1/e^2$ contour after the wave has propagated a distance z—is derived as:

$$w(z) = w_0\sqrt{1+\left(\frac{\lambda z}{\pi w_0^2}\right)^2} = w_0\sqrt{1+\left(\frac{z}{z_R}\right)^2} \qquad (5.4)$$

where λ = wavelength of light
w_0 = the waist radius of the $1/e^2$ irradiance contour at the plane where the wavefront is

* For the significance of the TEM_{00} laser beam designation, see Figure 5.19.

flat with all rays there moving in precisely parallel directions

z_R = *Rayleigh range* or *confocal parameter*, i.e., the distance over which the beam remains about the same size (or "collimated")

In Figure 5.14 we show this growth in beam diameter as a function of distance from the beam waist for a Gaussian laser beam profile. The point at z = 0 marks the location of a beam waist, or a place where the wavefront is flat.

The Raleigh range (z_R), also called the confocal parameter, defined as the distance over which the beam radius spreads by a factor of √2, is given by (see Figure 5.15):

$$z_R = \frac{\pi w_0^2}{\lambda} \tag{5.5}$$

Far from the waist ($z \gg z_R$), the laser beam asymptotically approaches the value:

$$w(z) = \frac{\lambda z}{\pi w_0} \tag{5.6}$$

From Figure 5.14 we see that a Gaussian beam does not diverge linearly; near the laser, the divergence θ angle is extremely small; far from the laser, half the divergence angle is given as θ ≈ tan (θ); thus, the $1/e^2$ irradiance contour asymptotically approaches a cone of angular radius:

$$\theta \approx \tan(\theta) = \frac{w(z)}{z} = \frac{\lambda}{\pi w_0} = 0.637\frac{\lambda}{w_0} = 1.27\frac{\lambda}{d_0} \tag{5.7}$$

This laser beam divergence is illustrated in Table 5.5, where we show the waist radius size w_0 of the beam and the collimation distances for two lasers, one at λ = 10.6 μm and one at λ = 0.633 μm.

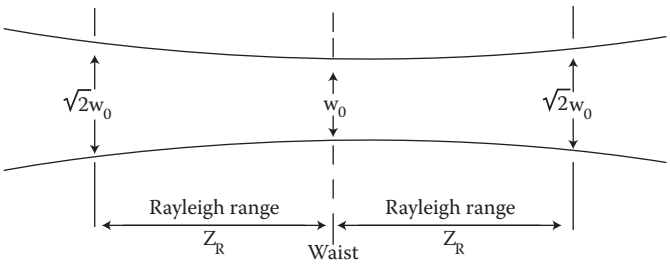

FIGURE 5.15 The Raleigh range (z_R), also called the confocal parameter.

TABLE 5.5 Waist Spot Size w_0 and Collimation Distances for Two Lasers at λ = 10.6 μm and λ = 0.633 μm

Waist Spot Size w_0	Collimation Distance λ = 10.6 μm	Collimation Distance λ = 0.633 μm
0.225 cm	0.003 km	0.045 km
2.25 cm	0.3 km	5 km
22.5 cm	30 km	500 km

We learn that tightly focused laser beams expand quickly and weakly focused beams expand less quickly, but still expand. As a result, it is very difficult to shoot down a missile with a laser. We also recognize that longer wavelengths expand faster than shorter ones.

Now let us focus this Gaussian laser beam using a lens (Figure 5.16) and calculate what its electric field will be one focal length *f* behind the lens. Gaussian beams focus as Gaussians.

If a "perfect" lens (no spherical aberration) is used to focus a collimated laser beam, the minimum spot size radius or the focused waist (w_0) is limited by diffraction only and is given by:

$$w_0 = \frac{\lambda f}{\pi w_{lens}} \tag{5.8}$$

where f = the focal length of the lens.

This is the same result as for a diffracting beam with z = f (Equation 5.6). Light being focused behaves just like diverging light, only reversed, and the divergence angle θ, given by Equation 5.7, is equally valid. With $d_0 = 1/e^2$ the diameter of the focus (= $2w_0$) and with the diameter of the lens $D_{lens} = 2w_{lens}$ (or the diameter of the laser beam at the lens—whatever is the smallest), we obtain:

$$d_0 = \frac{4\lambda f}{\pi D_{lens}} = \frac{1.27\lambda f}{D_{lens}} \tag{5.9}$$

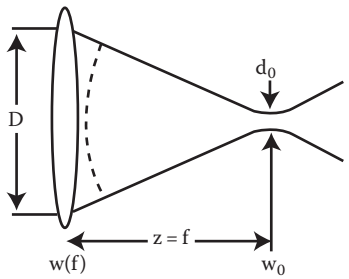

FIGURE 5.16 A Gaussian laser beam is focused using a lens.

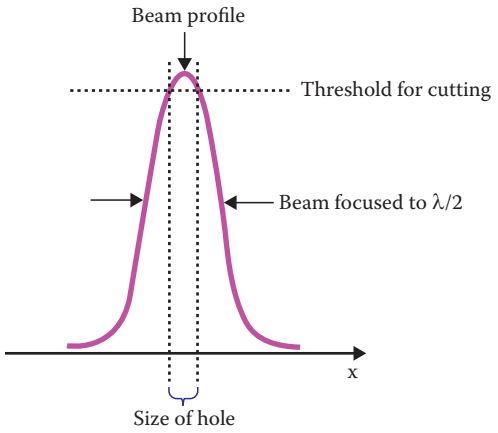

FIGURE 5.17 Size of hole cut with a laser can be substantially smaller than the beam size.

Thus, the principal way of increasing the resolution in laser machining, as in photolithography, is by reducing the wavelength, and the smallest focal spot will be achieved with a large-diameter beam entering a lens with a short focal length.

It is worth noting that ultrafast laser pulsing can create substantially smaller features than that of the central wavelength of the laser pulse itself. Because high-order nonlinear-optical processes are responsible for cutting, there is effectively a threshold for cutting (see Figure 5.17). This means that careful control of the intensity can yield a very small hole. By focusing the ultrafast laser pulse into a small spot with a Gaussian intensity profile, one can adjust the intensity of the laser spot on the surface of the material so that just the peak of the beam is above the ablation threshold; as a consequence, only material in that very limited area of the laser spot will be removed. That limited area can be as small as one-tenth the size of the spot itself; therefore, the unique combination of multiphoton absorption and saturated avalanche ionization provided by ultrafast laser pulses makes it possible to machine materials on dimensions much smaller than 1 μm: holes as small as 100 nm have been made.

Depth of Focus or Depth of Field

Twice the Raleigh range or 2 z_R is called the "depth of focus" because this is the total distance over which the beam remains relatively parallel, or "in focus" (see Figure 5.18). Or also, the depth of focus or depth of field (DOF) is the distance between the

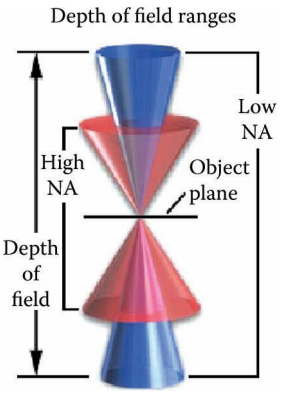

FIGURE 5.18 Depth of field (DOF) ranges.

values where the beam is √2 times larger than it is at the beam waist (see again Figure 5.18). Based on Equations 5.5, 5.8, and 5.9, we then obtain:

$$\mathrm{DOF} = 2z_R = \frac{2\pi w_0^2}{\lambda} = \left(\frac{8\lambda}{\pi}\right)\frac{f^2}{D_{lens}^2} \qquad (5.10)$$

The numerical aperture (NA) of a lens is given as $n\sin\theta$, and for small angles, one can derive that NA = D/2f with D the diameter of the lens and n the refractive index which in air = 1 (see Volume I, Chapter 5). Thus, we can recalculate the DOF also as:

$$\mathrm{DOF} = 1.27\lambda/\mathrm{NA}^2 \qquad (5.11)$$

Material processing with a very short depth of focus requires a very flat surface. If the surface has a corrugated topology, a servo loop connected with an interferometric auto-ranging device must be used.[11]

We want to contrast the results for resolution and depth of focus of laser beams obtained here with the resolution and depth of focus we calculated for other light sources in Volume I, Chapter 5 and in this volume, Chapter 1. In Volume I, Chapter 5 we saw that the Rayleigh criterion defines two incoherent light sources, separated by a distance d, as resolved when:

$$d = 1.22\frac{f\lambda}{D} \qquad \text{(Volume I, Equation 5.12)}$$

With an ideal lens system of focal length f, the Rayleigh criterion further yields a minimum spatial resolution as:

$$d = \frac{1.22\lambda}{2\mathrm{NA}} \qquad \text{(Volume I, Equation 5.13)}$$

TABLE 5.6 Comparing Standard Lens Parameters for Coherent and Incoherent Light

	Incoherent	Coherent (Gaussian Laser Beam)
Lens diameter	D	$D_{lens} = 2w_{lens}$
Focal spot radius size	$d = 1.22\frac{f\lambda}{D}$	$d_0 = \frac{4\lambda f}{\pi D_{lens}} = \frac{1.27\lambda f}{D_{lens}}$
Depth of focus	$DOF = 1.22\lambda\left(\frac{2f}{D}\right)^2 = 1.22\lambda/NA^2$	$DOF = 1.27\lambda\left(\frac{2f}{D_{lens}}\right)^2 = 1.27\lambda/NA^2$

In this expression d is the smallest object that the lens can resolve and also the radius of the smallest spot to which a collimated beam of light can be focused. From Equation 1.17 in Chapter 1 the DOF for an incoherent light source can be derived as:

$$DOF = 1.22\lambda\left(\frac{2f}{D}\right)^2 = 1.22\lambda/NA^2 \qquad (1.17)$$

We contrast these earlier results with those obtained for laser beams in Table 5.6. Whereas resolution is slightly worse for coherent light, its DOF is slightly better.

Laser beams can have any pattern, not just a Gaussian. The beam shape can even change with distance. Some beam shapes do not change with distance. These laser beam shapes are referred to as transverse electromagnetic (TEM) modes. Lasers can operate in various transverse modes as shown in Figure 5.19. Laser specifications will usually refer to the TEM_{00} mode. The 00 mode is the Gaussian beam. Higher-order modes involve multiplication of a Gaussian by a "Hermite polynomial." The TEM_{00} results in a single beam. The long narrow bore of a typical laser forces this mode of oscillation, and Equation 5.9 is only valid for this mode.

Laser Power

The laser power is also a critical parameter because it determines the damage impact on the irradiated solid. However, it must be considered in combination with the wavelength (see above). To clarify this, a distinction must be made between the optical penetration depth (Equation 5.1, wavelength-dependent) and the damage penetration depth (influenced by the power density as well). As we saw in Equation 5.1, the optical penetration depth is defined as the distance below the irradiated surface over which the laser energy is deposited. The fraction of this distance over which the irradiation exceeds the ablation threshold is defined as the damage penetration depth.

The laser intensity (W/cm^2) is given by the peak power (W) divided by the focal spot area (cm^2), and the peak power (W) is given as the pulse energy (J) divided by pulse duration (s). The intensity levels of a highly collimated, monochromatic, and coherent light beam at the work piece, which can be held in open air, may reach 10^6 W/mm^2, enough to melt any metal. The laser fluency or energy density (J/cm^2) equals the laser pulse energy (J) divided by focal spot area (cm^2). A typical 50-μJ output of a KrF laser

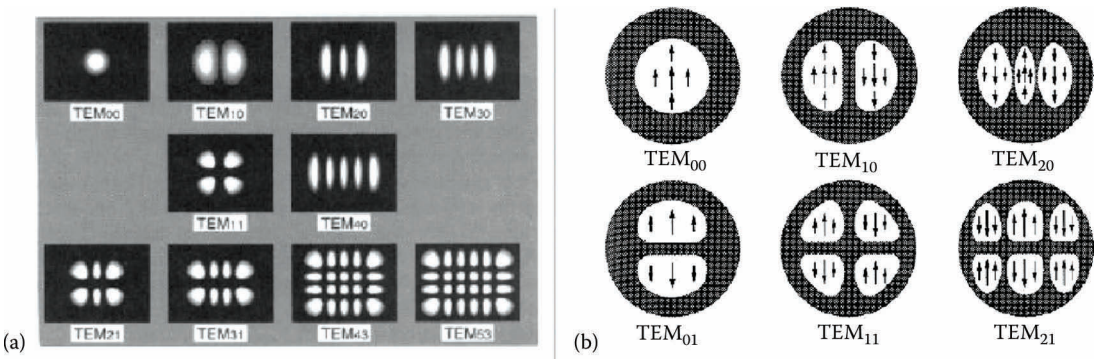

FIGURE 5.19 Some transverse electromagnetic (TEM) modes: (a) irradiance; (b) electric field.

focused by an optics system with NA of 0.5 will produce a focal spot of 15–20-µm diameter and a corresponding fluence of 10–20 J/cm^2.

The average on-axis laser beam intensity is related to the total laser power, *P* in watts, by:

$$I(r) = \frac{2P}{\pi w_0^2} \tag{5.12}$$

where P = the total power in watts

w_0 = the Gaussian beam radius—the radius at which the intensity has decreased to $1/e^2$ or 0.135 of its value on the axis

The average beam energy is of no use if it cannot be properly and efficiently delivered to the ablation region; thus, beam quality is not only measured by the brightness (energy) but also by its focusability and homogeneity.

Now we will have a look at a fifth important laser parameter influencing micromachining quality, that is, laser pulse length.

Laser Pulse Length

Long Pulses A further parameter with pulsed laser systems is the laser repetition rate, which expresses the number of pulses that are triggered per unit time. The laser pulse width determines the kinetics of the photon-induced disequilibrium on irradiated surfaces (for pulses longer than 100 ns the energy can be delocalized in thermal modes). It influences the role of the laser microplasma, too. The most fundamental feature of laser/material interaction in the long pulse regime (e.g., pulse duration 8 ns, energy 0.5 mJ) is that the heat deposited by the laser in the material diffuses away during the pulse duration; that is, the laser pulse duration is longer than the heat diffusion time. This may be desirable for laser welding, but for most micromachining jobs, heat diffusion into the surrounding material is undesirable and detrimental to the quality of the machining (http://www.clark-mxr.com). Here are a couple of reasons why one should avoid heat diffusion for precise micromachining:

- Heat diffusion reduces the efficiency of the micromachining process because it takes energy away from the work spot—energy that would otherwise go into removing work piece material. The higher the heat conductivity of the material, the more the machining efficiency is reduced.
- Heat diffusion reduces the temperature at the machining spot, pinning the working temperature to not much above the melting point of the material, which is removed by melting. Boiling of the substrate ejects globs of molten material away from the work zone. Those globs fall back onto the surface, contaminating the sample. The droplets can be rather large and retain a fair amount of residual heat so that they bind strongly to the sample surface. Removal of these contaminants is often difficult or impossible without damaging the work piece. An air jet is sometimes used to physically project the melt phase away from the work zone. This results in a cleaner-looking cut but contaminates the sample downstream.
- Heat diffusion reduces the accuracy of the micromachining operation. Heat diffuses away from the focal spot and melts an area that is much larger than the laser spot size. Therefore, it is difficult to do very fine machining; whereas the minimum laser spot size might be in the range of 1 µm or less, in many materials it is not possible to create features with dimensions much smaller than 10-µm diameter.
- Heat diffusion affects a large zone around the machining spot, a zone referred to as the *heat-affected zone* or HAZ. The heating (and subsequent cooling) waves propagating through the HAZ cause mechanical stress and may create microcracks (or in some cases, macrocracks) in the surrounding material. These defects are "frozen" in the structure when the material cools, and in subsequent routine use these cracks may propagate deep into the bulk of the material and cause premature device failure. A closely associated phenomenon is the formation of a recast layer of material around the machined feature. This resolidified material often has a physical and/or chemical structure that is very different from the unmelted material. This recast layer may be mechanically weaker and must often be removed.

- Heat diffusion is sometimes associated with the formation of surface shock waves. These shock waves can damage nearby device structures or delaminate multilayer materials. Whereas the amplitude of the shock waves varies with the material being processed, it is generally true that the more energy deposited in the micromachining process, the stronger the associated shock waves.

The various undesirable effects associated with long laser pulse etching are illustrated in Figure 5.20a and b.

Short Pulses We are particularly interested in femtosecond lasers with pulses more than 1 million times shorter than the several nanosecond-duration pulses used in traditional industrial laser micromachining systems (see above). Femtosecond lasers deliver an incredible amount of peak power, routinely up to 5–10 GW (this is more than the average power delivered by a large nuclear plant) (http://www.clark-mxr.com/industrial/handbook/introduction.htm). The laser intensity easily reaches the hundreds of terawatts per square centimeter at the work spot itself. No material can withstand the ablation forces at work at these power densities. This means that, with ultrafast laser pulses, very hard materials, such as diamond, as well as materials with extremely high melting points, such as molybdenum and rhenium, can be machined. The most fundamental feature of laser-matter interaction in the very fast pulse regime is that the heat deposited by the laser into the material does not have time to move away from the work spot during the time of the laser pulse. The duration of the laser pulse is shorter than the heat diffusion time. This regime has numerous advantages as listed below (http://www.clark-mxr.com/industrial/handbook/introduction.htm):

- Because the energy does not have the time to diffuse away, the efficiency of the machining process is high. Laser energy piles up at the level of the working spot, whose temperature increases instantly past the melting point of the material and keeps on climbing into what is called the *plasma* regime.
- After the ultrafast laser pulse creates the plasma at the surface of the work piece, the pressures created by the forces within it cause the material to expand outward from the surface in a highly energetic plume or gas. The internal forces that previously held the material together are vastly insufficient to contain this expansion of highly ionized atoms and electrons from the surface. Consequently, there are no droplets that condense onto the surrounding material. Additionally, because there is no melt phase, there is no splattering of material onto the surrounding surface.

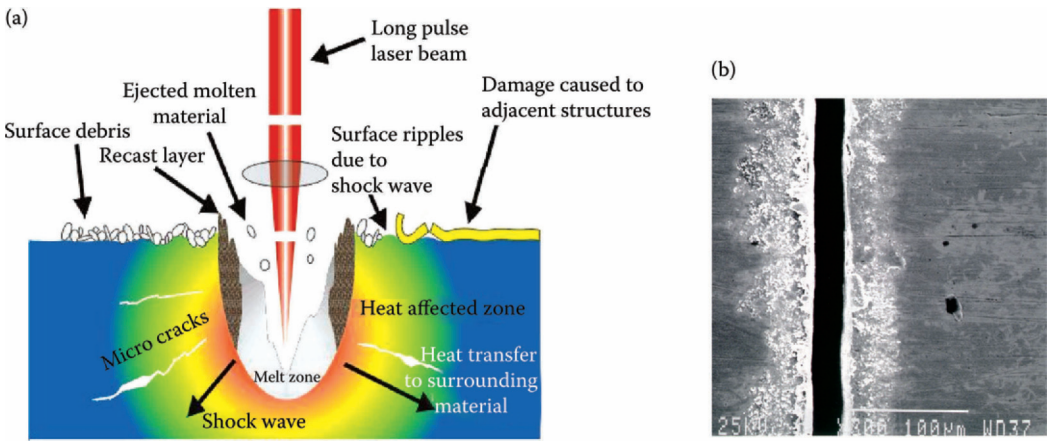

FIGURE 5.20 (a) Various undesirable effects associated with laser pulses that are too long, for example, pulse duration 8 ns, energy 0.5 mJ (http://www.clark-mxr.com). (b) Example of a 25-μm (1 mil) channel machined in 1-mm (40 mils) thick INVAR with a nanosecond laser. INVAR is often called for in the design of machinery that must be extremely stable. This sample was machined using a "long" pulse laser. The laser pulse parameters are pulse duration 8 ns, energy 0.5 mJ. A recast layer can be clearly seen near the edges of the channel. Large debris is also seen in the vicinity of the cut.

- Heating of the surrounding area is significantly reduced, and, consequently, all the negatives associated with a HAZ are no longer present—no melt zone, no microcracks, no shock wave that can delaminate multilayer materials, no stress that can damage adjacent structures, and no recast layer.

The many advantages associated with working in the femtosecond pulse range are illustrated in Figure 5.21a and b.

With ultrashort laser pulsing, it is possible to accurately control the depth of the cut by counting the number of pulses. Deep cuts (hundreds of microns) have been made this way, mostly by using an excimer laser, although it is now known that clean ablative etching, once the hallmark of excimer lasers, can also be achieved with pulsed laser sources at other wavelengths, including CO_2, copper vapor, and Nd:YAG and its harmonics. The latter lasers can be as effective for high-quality ablative micromachining provided laser photons are strongly absorbed in submicron depths at the surface of the material on time scales that are less than the time it takes for heat to diffuse away from the irradiated region. Lasers providing ultrafast pulse durations of less than 10 ps have, in recent years, demonstrated remarkably clean micromachining of many materials.

Ultrashort laser pulses have opened up many new possibilities in laser-matter interaction and materials processing. The extremely short pulse width makes it easy to achieve very high peak laser intensity with low pulse energies. The laser intensity can reach 10^{14}–10^{15} W/cm^2 with a pulse <1 mJ when a subpicosecond pulse is focused to a spot size of a few tens of micrometers. The extremely high intensity and short laser/matter interaction times lead to a highly nonequilibrium plasma state in the material under irradiation, where electrons are driven to much higher temperatures than ions. The short duration means that the hydrodynamic motion of the matter under laser irradiation can be ignored, and there is essentially no fluid dynamics to consider during the laser/matter interaction. The catch with ultrafast laser ablation is that throughput is low because the rate of removal of material is dependent on average power. The technology that makes these ultrafast laser pulses does not produce high average power. Additionally, the technology is very expensive (a system specifically tailored to an application can cost in the six- to seven-figure range), and the covered areas are very small.

In the past two decades lasers have become a precise, fast, wearless, flexible tool used for cutting, drilling, marking, and welding. Many of today's production processes are unimaginable without the laser.

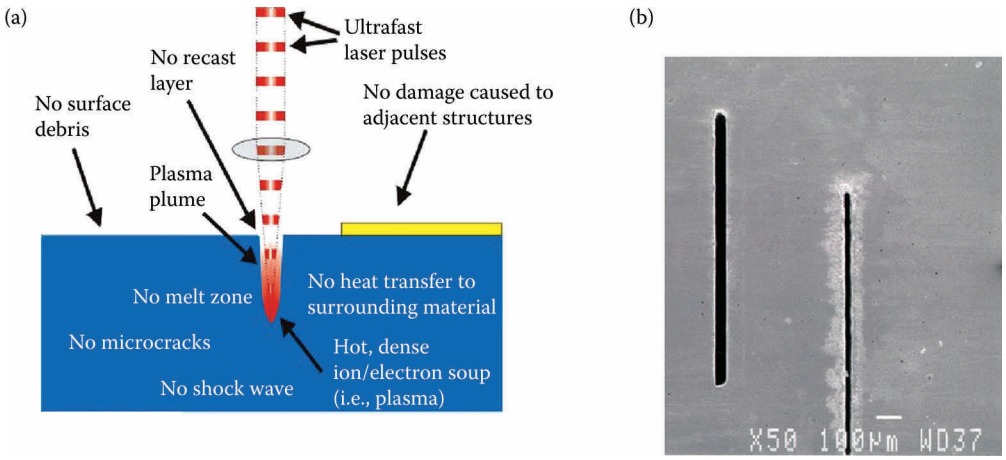

FIGURE 5.21 (a) Advantages associated with working with very short laser pulses (<10 ps). (b) A channel machined in 1-mm-thick INVAR, nickel/iron alloy under the same experimental conditions as the long pulse channel in Figure 5.20b, but with ultrafast pulses. The channel on the left was machined with 200-fs pulses, 0.5 mJ energy per pulse. It is obvious that the channel machined with femtosecond pulses is cleaner than the sample machined with nanosecond pulses (channel on the right). Note also the absence of a recast layer on the left channel. It is also clear that the machining process was more efficient—the channel is larger. The edges are straighter. Overall the quality of the micromachining is much higher.

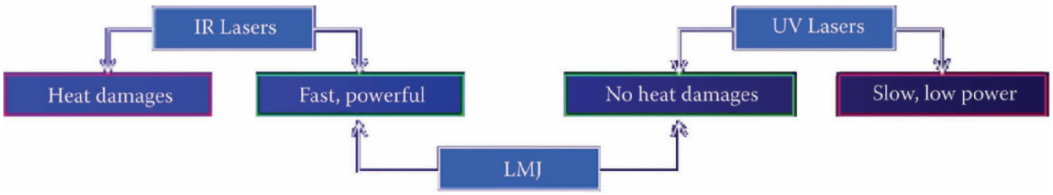

FIGURE 5.22 The laser dilemma. According to Synova, S.A., their water jet-guided laser, the Laser-Microjet (LMJ) (see also Figure 5.23), promises a solution.

Nevertheless, in some applications, as for example in the electronic or medical field, the laser is still too imprecise, too slow, or unacceptable because of material damages. High-power IR lasers, widely used in industrial material processing, are too "hot," creating heat damage and debris; meanwhile, shorter wavelengths found in UV lasers create less heat and debris but lack power for efficient material processing. This dilemma is summarized in Figure 5.22. According to some, water jet-guided laser machining, discussed below, might provide the solution for this dilemma.

Shot-to-Shot Repeatability

The process of laser ablation requires threshold fluency, and, as we have seen above, fluency is the laser pulse energy per unit area, and it can be changed either by changing the laser pulse energy or by changing the ablation area. At fluencies below the threshold, only miniscule etching (<0.05 μm/laser pulse) is observed, if any at all. However, when laser fluency is above the threshold, the etch depth per pulse increases rapidly with increasing laser fluency. The threshold fluency depends mainly on the target material structure and target absorption coefficients at the laser wavelengths. Absorption of laser radiation leads to a temperature increase in the target material. When laser pulse fluency is below the ablation threshold, the temperature increase is directly proportional to the laser pulse fluency, whereas when laser pulse fluency rises above the threshold, the temperature increases considerably more slowly. The absence of free electrons in a given substrate prevents the avalanche process from significantly starting and ultimately hinders the material ablation. In metals, there are always plenty of free electrons, and the avalanche process starts immediately, leading to reproducible machining (as we have seen, there may be other problems associated with heat diffusion). In semiconductors or insulators, there are naturally very few free electrons. The avalanche process may start right away or may not, depending on the presence or absence of a free electron in the beam path. This variability, which is inherent to the physical process, leads to unstable machining rates. The laser may be perfectly stable, and the beam spot size and amount of energy in the pulse may be precisely the same from shot to shot, yet the material ablation can vary significantly. Using lasers working in the UV range, or using ultrafast lasers, the electromagnetic field is so high that "bound" electrons are knocked free so that a large quantity of free electrons can start the avalanche ionization process immediately, reliably, and reproducibly. The latter ensures an excellent shot-to-shot reliability independent of the material.

Water Jet-Guided Laser Machining

In water jet-guided laser machining, a thin jet of high-pressure water (the diameter of the jet is between 40 and 100 μm, and the water pressure is between 20 and 500 bars) is forced through a nozzle (made of diamond or sapphire). The laser beam is focused through a water chamber (the water is deionized and filtered) into a nozzle as shown in Figure 5.23.

Leaving the nozzle, the laser beam is guided inside the water jet by total reflection at the water-air interface and is directed onto the work piece where it is absorbed by the material. The laser beam melts or vaporizes the material, and the water jet expels the molten debris. At the end of each laser pulse, the plasma disappears, and only the water jet remains in contact with the surface. Before the next pulse is emitted, the water jet removes any heat induced in the material during the laser ablation. Thus, the pulsed mode of the laser ensures continuous alternation of

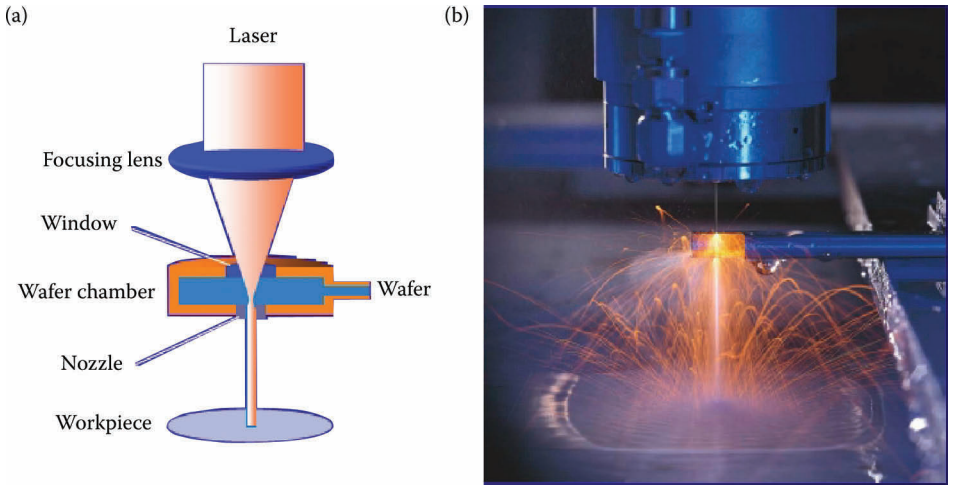

FIGURE 5.23 (a) Schematic water jet-guided laser machining setup. See text. (b) Water jet-guided setup from Synova, S.A., the Laser-Microjet®.

heating (during laser pulse) and cooling (between laser pulses). The water pressure value (20–500 bars) depends on the application, but the resulting force acting on the work piece is always very small, smaller than the force as a result of the cutting gas of conventional lasers. Thus, the water jet is obviously not abrasive in this case (as it is in mechanical water jet machining described in Chapter 6); the material is solely ablated by the laser (thermally). The high speed of the water, up to 300 m/s at 500 bars, ensures fast removal of debris. Water jet-guided laser etching prevents the problem of heat damage (microcracks, structural changes) inherent in any laser ablation process. The result is a heat damage-free material ablation.

The laser dilemma of high-power IR lasers that are too "hot," creating heat damage and debris, and the shorter wavelengths UV lasers that create less heat and debris, but lack power for efficient material processing, was summarized in Figure 5.22. Water jet-guided laser machining discussed here might provide a solution for this dilemma because it transforms a "hot" IR laser into a "cool" laser, avoiding heat damage. Water jet-guided machining combines high ablation efficiency, speed, and precision while avoiding material damage as demonstrated in Figure 5.24, where we compare laser ablation in Si using a conventional laser (Figure 5.24a) with jet-guided laser machining using the Laser-Microjet from Synova (Figure 5.24b). The Laser-Microjet was conceived in 1993 by scientists at the Institute of Applied Optics of the Swiss Federal Institute of Technology in Lausanne, Switzerland. Ten years later, this technology has proven its efficiency and reliability in many applications, especially of the semiconductor and microelectronics industries. The water jet-guided laser has indisputable advantages over the classical methods. The conventional laser kerv in Si exhibits typical heat damage with burrs and deposits, whereas the Laser-Microjet result exhibits neither burrs nor deposits.

Laser Etching with Chemical Assist

We just saw how water jet-guided laser machining helps keep a work piece clean; an air jet also may help to physically project the melt phase away from the work zone. This again results in a cleaner-looking cut but may contaminate the sample downstream. A third way to keep the work piece clean is the use of laser-assisted chemical etching (LACE).

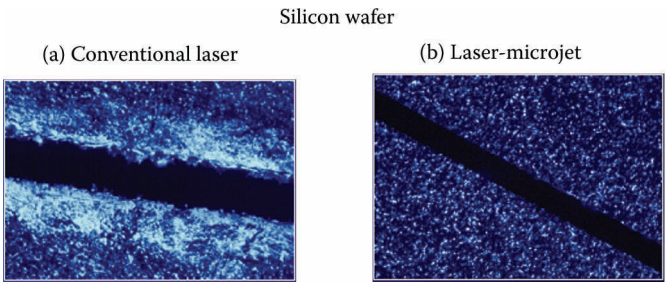

FIGURE 5.24 Silicon wafer laser machining. (a) With a conventional laser and (b) with a Laser-Microjet. The conventional laser kerv in silicon shows burrs and deposits, whereas the Laser-Microjet result has neither burrs nor deposits.

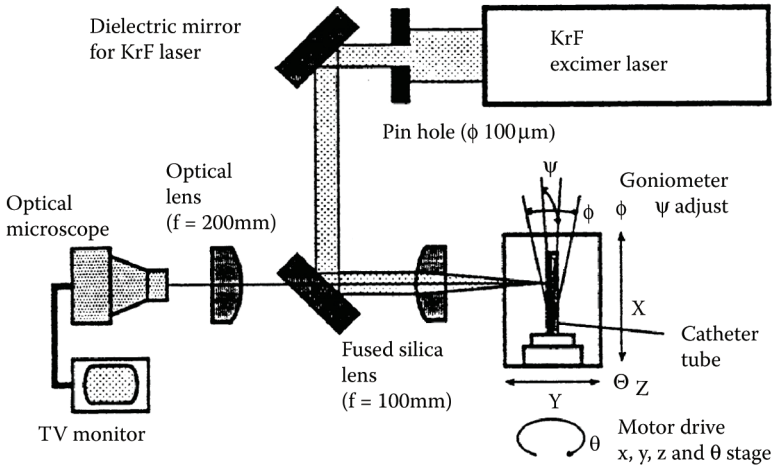

FIGURE 5.25 Laser microetching experimental setup: laser-assisted chemical etching (LACE). Etching/ablation of a catheter tube.

The laser cutting action can be assisted by dry or wet chemical etchants for building of higher-quality complex 3D micromachines. The process is also called *laser-induced chemical etching*, in which, for example, chlorine is used as the etchant and is photodissociated to react with the substrate.[14,15] If laser etching is performed in chlorine gas instead of open air, the silicon vapor and droplets leaving the work area combine with the chlorine to form $SiCl_4$ gas and are carried away from the work area. Silicon, when heated to its melting point, reacts nearly at the gas transport-limited rate with chlorine, enabling removal rates exceeding 10^5 μm³/s.[16] The resulting hole is cleaner and more sharply defined, and debris does not splatter on the surface of the substrate; thus, an excellent spatial resolution results (1 μm *x*,*y*-resolution at a removal rate of 2.10^4 μm³/s).[16,17] The latter removal rate is several orders of magnitude faster than with electrical discharge machining (EDM) methods.

Flexible laser machining setups as shown in Figure 5.25 can be used for the machining of 3D parts by using highly localized laser microchemical reactions and an accurate computer-controlled *x*, *y*, *z* and θ translation table. This same type of setup can accommodate additive processes (see Chapter 8), but it is more convenient to build separate, dedicated equipment, as illustrated in Figures 5.25.[18]

Remember LACE is not a parallel process and not fast enough for most manufacturing applications. The technique may have utility in specialty micromachining or for making molds.

At the Massachusetts Institute of Technology Lincoln Laboratories, scanning of the laser beam at a rate of 7500 μm/s is used to remove Si layers in a Cl_2 etchant. After a plane of 1 μm is removed, the focusing objective is lowered 1 μm, and a new pattern is etched. With this technique, it is very easy to produce multilevel-type structures. Some example devices made this way are shown in Figure 5.26. The Lincoln group also demonstrated that structures as shown can be replicated by using simple hot embossing molding techniques.[16]

In addition to Cl_2, reagents such as Br_2, HCl, XeF_2, KOH, and so on can also be used as the etchant in the laser photochemical etching of silicon. Table 5.7 summarizes several kinds of substrates etched by laser processes with different etchants and laser wavelengths.[11,20]

Laser Machining Applications

Overview

Advantages of laser cutting over mechanical cutting vary according to the situation, but important factors are lack of physical contact (because there is no cutting edge that can become contaminated by the material or contaminate the material) and, to some extent, precision (because there is no wear on the laser). There is also a reduced chance of warping the material that is being cut because laser systems have a small heat-affected zone (HAZ). Some materials are also very difficult or impossible to cut by more traditional means. The laser has other distinct

The dish has an upper radius of 80 µm and a lower radius of 35 µm with a radius curvature of 82 µm and spacer layers extending 8 µm inward. The clipped cone has an upper radius of 4 µm and lower radius of 16 µm. The laser was swept in a circular scan in each plane. The white bar is a 10-µm marker. (Courtesy of Dr. D. Ehrlich, Revise, Inc.)

advantages: aspect ratios for hole diameter to depth on the order of 1:50 are possible, and holes can be drilled in hard-to-reach areas and at difficult angles (e.g., 10° to the surface). A laser-based scribe can make narrower trenches than a mechanical diamond stylus. Disadvantages of laser cutting may include the high energy required. Also, when hundreds of holes all at the same angle are to be drilled, the job is better handled by an electron beam machine (EBM). However, if holes have to be drilled at many

angles, the laser may be the most cost-effective method. Lasers are most cost-effective for drilling holes between 0.01 and 1.5 mm. For larger holes, the cost of the large laser oscillator needed to produce the energy for vaporization becomes prohibitive, and because of the large amounts of material being vaporized, the hole produced suffers in terms of quality and controllable tolerance. With the very small holes, the high-power focusing lenses required to withstand the energies necessary for drilling holes smaller than 0.01 mm are limiting factors. The requirement for even smaller features necessitates the use of EBM (a thermal technique, see below), focused ion beam (FIB, a mechanical technique; see Chapter 6), or ultrafast laser pulsing (see above).

Both solid-state and gas lasers are commercially available and are touted for traditional machining operations in electronics such as postassembly processing, where site-specific action is necessary, for example, for drilling via holes, repair of embedded interconnects, and thick/thin film resistor and capacitor trimming. The most popular lasers for cutting materials are CO_2 and Nd:YAG, although semiconductor lasers are gaining prominence because of their higher efficiency. Because laser micromachining or direct ablation needs high laser intensity or fluence, usually only excimer lasers are used, especially for hard materials.

In recent years, excimer lasers, providing ultrafast durations of < 10 ps (10^{-11} s) based on diode-pumped solid-state gain media, have demonstrated remarkably clean micromachining of many materials. Despite initially gaining a poor reputation for reliability, during the past 25 years, excimer lasers have developed into mature industrial tools. For laser ablation of polymers, argon ion lasers, a kind of continuous laser, can also be used, and they can be modulated into different pulse widths, frequencies, and wavelengths. However, the excimer laser has several distinct advantages, even for the dry etching of polymers, over the CO_2 and Nd:YAG lasers. For example, the wavelengths are more compatible with the chemical bond energies in organic compounds and tend to produce less thermal damage. Excimer lasers, as we ascertained in Chapter 1, are also used in the newest lithography processes. A visual illustration is obtained comparing the hole-drilling capabilities of mechanical twist drill bits and excimer lasers in Figure 5.27. Here we compare 100-μm-diameter holes drilled in 75-μm-thick high-density polyethylene with a drill bit and a KrF excimer laser. Although mechanically the hole is close to the minimum size that can be drilled, the improved quality of this and much smaller holes drilled by excimer lasers is obvious.

Laser machining with chemical assist takes care of some of the problems associated with long laser pulse operation, but, as we have already seen, ultrashort laser pulsing takes care of most of them. Laser cutting machines have been used extensively in industry for cutting complex profiles in sheet and plate materials. Hard materials such as diamond, tungsten, and titanium can be cut without problems of tool wear because there is no contact between tool and work piece. For many applications, laser micromachining offers the advantage of more rapid prototyping as compared to, e.g., FIB machining or lithography techniques.

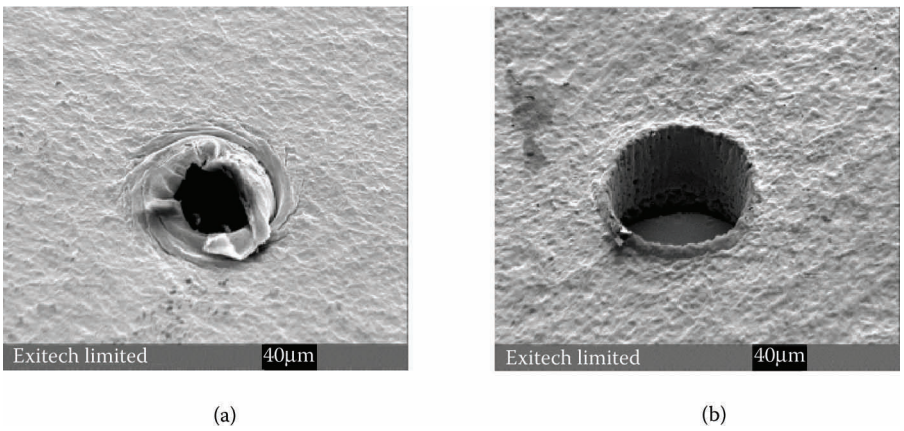

FIGURE 5.27 Holes drilled with twist drill bit (a) and KrF laser (b). (From Exitech.)

For a particular micromachining application the choice of laser type is now judged as much by criteria such as process speed, part throughput, reliability, service intervals, capital and operating costs of the overall machine tool rather than solely by the quality of the processed part.

Long Laser Pulse Machining Applications

A simple example of long laser pulse machining is a hole, laser drilled through glass or Si, that can be used as a high-aspect-ratio, through-the-wafer via.[21,22] This is illustrated for the electrical contact via of a solid-state capacitive pressure sensor in Figure 5.28.[21] This compact pressure sensor incorporates electrically conducting vias drilled through the glass cap by a CO_2 laser. In contrast, the through-the-wafer via connection fabricated by anisotropic etching has a large opening angle (54.7°) associated with the slow etching crystallographic planes of the Si substrate. Typically, the closest spacing for vias that are wet etched in a 300-µm-thick wafer is approximately 425 µm, thus limiting this method to a low density of via holes (different means of making vias are discussed in Volume III, Chapter 4).

When holes as shown in Figure 5.28 are laser drilled in a substrate, the expelled material solidifies into dust; therefore, a moving protective tape is used in front of the laser lens to keep it clean. Debris also collects around the perimeter of the openings in, e.g., a silicon substrate, when drilling, scribing, or trenching is done in air or an inert atmosphere.

To avoid the identified problems associated with long laser pulses, two methods can be used. One is to use laser-assisted chemical etching (LACE), as described above, which takes care of some of the mentioned problems; the other approach, taking care of most of the mentioned problems, is to use femtosecond laser pulses. The latter technique, as we have explained above, results in superior micromachining.

Short Laser Pulse or Excimer Laser Applications

Introduction Energy-deposition time with ultrafast excimer lasers is short compared with the electron-phonon time (a few picoseconds); thus, thermal conduction and hydrodynamic motion are generally negligible, and ejected material carries away most of the deposited energy. As a result, there is minimal collateral damage to remaining material. In metals, laser energy is deposited over the skin depth rather than spread over a thermal conduction length, yielding very high energy densities, temperatures (10 eV), and pressures (Mbar) during the pulse that are not that different from those in the sun (Figure 5.29). In Figure 5.29 we compare existence domains for various types of plasmas as a function of temperature and density. In dielectrics, electrons that are produced by nonlinear light absorption initiate the breakdown, and full breakdown is achieved during each pulse.

Excimer laser materials processing, by providing solutions to critical problems in manufacturing of integrated circuits, hard disks, displays, interconnects, desktop printers, and telecommunication

devices, has become a key enabling technology for the current revolution in information technology.

Ink-Jet Printers, Microvias, Catheters, and DVDs

Excimer lasers on production lines in Asia, Europe, and the United States now drill nozzle-hole arrays for most ink-jet printers. Earlier 300-dpi printers consisted of a 100-nozzle row of 50-µm-diameter holes made by electroforming thin nickel foil. Trying to fabricate more holes with smaller diameters reduced the already low 70–85% production yield even further. Increased printer quality is achieved by simultaneously reducing the nozzle diameter and decreasing the hole pitch. Modern printers like Hewlett Packard's (Palo Alto, CA) DeskJet 800C and 1600C have nozzles with 28-µm diameters, which provide resolution of 600 dpi. Laser drilling of nozzle arrays allows average yields greater than 99%. Excimer laser tools with appropriate CNC programming can readily engineer custom-designed reverse-tapered, $2\frac{1}{2D}$ and 3D structures. Some applications need a rifled, tapered hole to spin the droplet and optimize its accuracy of trajectory. Most of the ink-jet printer heads being currently sold (e.g., by Hewlett Packard and Canon) are excimer laser drilled on production lines in the United States and Asia. Figure 5.30 shows an excimer laser-drilled nozzle array in a modern print head.

Another example application of excimer lasers is drilling of microvia much smaller than the ones depicted in Figure 5.30. Packages on which chips are mounted for connection to other devices have to keep pace with the rapid advances made in ICs, so that speed, power, and area (real estate) do not become compromised. In multilayer sandwiches, blind via holes provide high-speed connections between surface-mounted components on the board and underlying power and signal planes while minimizing valuable real estate occupation. The cost of drilling these vias on such high-density packages can represent 30% of the overall cost of the board. The process was first applied to volume production when the Nixdorf computer plant of Siemens introduced polyimide ablative drilling of 80-µm-diameter vias in multichip modules. Other mainframe computer manufacturers such as IBM rapidly followed suit and installed their own production lines for this application. Trillions of vias have now been drilled with excimer lasers at

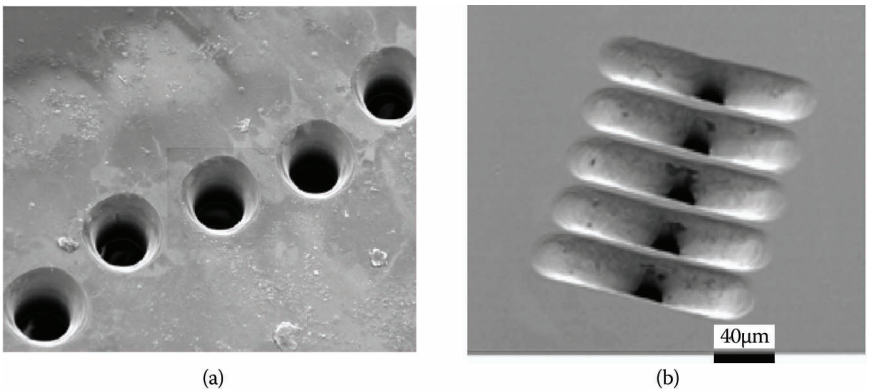

FIGURE 5.30 KrF laser-drilled ink-jet printer nozzles in polyimide. (a) 30-µm diameter nozzle array. (b) Nozzles with nonlinear tapers to aid the laminar flow of the droplet through the orifice. (From Excitech.)

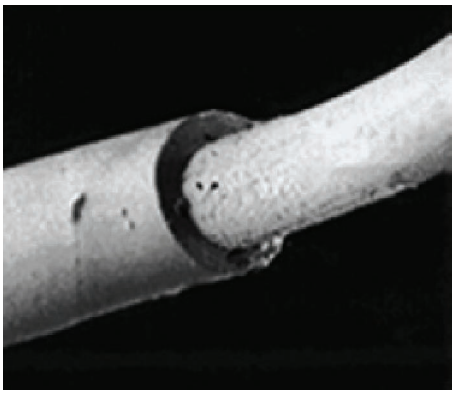

FIGURE 5.31 Stripping of wires with excimer lasers.

yields greater than 99.99% and mean time between failure at greater than 1000 hours.

Preferential excimer laser etching of plastics against metals is illustrated by the stripping of insulation from insulation sleeving of wires with widespread use in preparing connection wires to computer hard-disk reader heads (see Figure 5.31).

In the biomedical industry, the drive for increased miniaturization with improved device functionality is crucial to rapid progress, for example, in novel catheter-based sensors and actuators. Precision microdrilling with excimer lasers is routine when making delicate catheter-based probes. Here we explore, as a futuristic example, a fiberoptic-based sensor for analyzing arterial blood gases (ABGs) and pH. The use of fiberoptic sensors for ABG analysis provides clinical diagnostics at the patient's bedside without the need for taking blood samples or doing an analysis in the blood gas laboratory (except for a much less frequent calibration of the in vivo sensors). Envision one lumen of a bilumen catheter for blood drawing and one for the sensing optical fiber as shown in Figure 5.32.

The hole at the side of a polyvinyl chloride bilumen sleeving tube through which blood is drawn (to collect blood for the blood gas lab for calibration of the in vivo sensor) is machined using a krypton fluoride (KrF) laser. The clean-cutting capability of the laser provides the catheter with the necessary rigidity that prevents kinking and blockage of the tube when inserted into the artery. The other important components of this in vivo catheter are the oxygen, CO_2 sensors, and pH sensors on the side of a fiberoptic cable placed in the other lumen. These consist of ~50 × 15-μm rectangular holes machined in a 100-μm-diameter acrylic [poly(methylmethacrylate) (PMMA)] optical fiber with an argon fluoride (ArF) laser. The holes are filled with reagents whose optical transmission depends on the O_2, CO_2, and pH levels of the surrounding blood.

For an alternative ABG and pH sensor made with Si bulk micromachining, see Figure 4.92 depicting an electrochemical ABG and pH sensor.

Another typical application of laser micromachining is to increase the density of optical storage media such as DVDs. Currently, the track spacing on a DVD is 400 nm, yielding approximately 6 GB of data storage space. The initial target spacing for the next generation of laser micromachining systems is 100 nm, resulting in 25-GB storage capacity on a DVD.

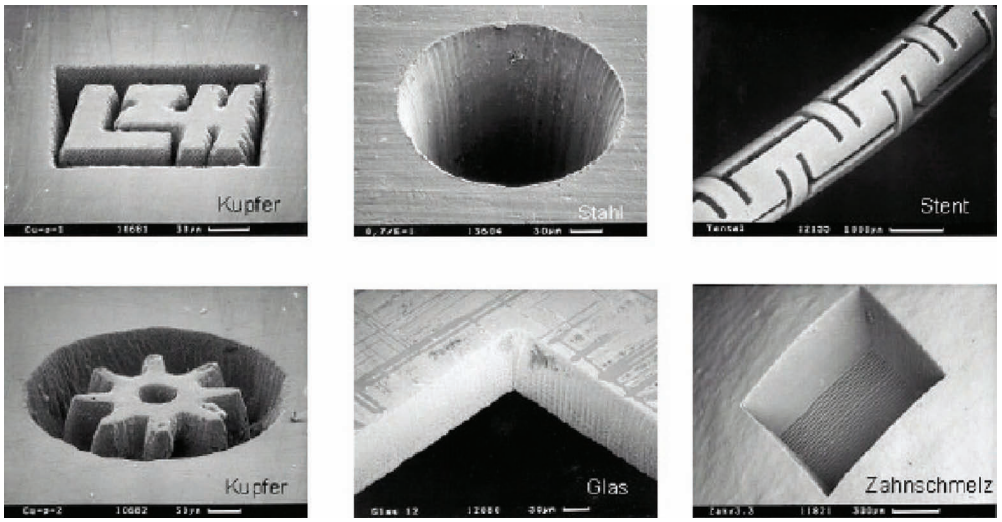

FIGURE 5.33 From the Laser Centrum at Hannover, Germany (LZH): laser machining in a wide variety of materials.

The excimer laser also has brought more accuracy to corneal surgery and vision correction than ever before. One pulse of the excimer laser removes 0.25 µm of tissue. To put this into perspective, a typical human hair is 70 µm in thickness. Surgeons have never had a device as accurate as the excimer laser in eye surgery.

At the Laser Centrum in Hannover (LZH), Germany, researchers use femtosecond lasers for hole drilling with pulse durations shorter than 100 fs and pulse peak powers in the gigawatt range.[10] Grooves of only 200-nm thickness can be cut. Some demonstration pieces are shown in Figures 5.33 and 5.34.

Machining inside Transparent Materials Ultrafast laser pulsing enables machining inside transparent bulk materials. A material such as a glass is transparent and does not absorb visible light—provided the intensity stays below the threshold for multiphoton absorption. One can exceed that threshold by focusing ultrafast laser pulses to a spot inside the material. When the intensity exceeds the threshold for plasma formation, very localized absorption occurs at the focal spot, and, as before, the plasma expands, but this time it is confined by the surrounding material. The effect of the expansion is to create a void within a very dense shell of material—a cavity within the glass itself. The process is not limited to glass. Pits can be created in any material by focusing an ultrafast laser pulse inside the material, whether it is amorphous or crystalline.

Based on the above properties of femtosecond lasers, one can manufacture single-mode waveguides in glasses. Glass is transparent to incident, ultrafast laser pulses at 775 nm, enabling the local melting of the glass via confined multiphoton absorption and avalanche ionization. The glass then resolidifies, changing its physical properties. The result is an index gradient that acts like a waveguide. Only ultrafast lasers are capable of producing this effect in transparent materials; with longer pulse lasers (nanoseconds), the glass incurs damage before the intensity reaches the threshold at which guides are formed. Femtosecond laser pulses can be used to induce localized refractive index increase in a wide variety of glasses, and this way optical waveguides have been produced in silicate, borosilicate, chalcogenide, and fluoride glasses.

		IC repair		

Summary: Laser Machining Applications and Comparisons

Subtractive and additive laser machining (see Chapter 9) present several application opportunities in micromachining because of their versatility, site-specific operation, and rapid prototyping capability. Ultrafast laser machining, when lasers become less expensive, will make laser micromachining yet more attractive. There are some obvious drawbacks with these direct write techniques: they are serial processes, and the deposition or removal rates limit the speed of the micromanufacture. However, for rapid prototyping, mold fabrication, and site-specific manufacturing, laser machining has a very bright future, and, as we have remarked before, many microsystems might carry a bigger price tag than an IC, making a more expensive manufacturing technology acceptable.

In Table 5.8 we list typical laser applications in different fields, and in Table 5.9 we compare laser micromachining with some other typical competing machining technologies.

A good further introduction to laser machining can be found in *Laser Machining: Theory and Practice* by George Chryssolouris[23] and in an excellent chapter by Henry Helvajian, "Laser Material Processing: A Multifunctional in situ Processing Tool for Microinstrument Development."[11] A very informative laser handbook on the Internet can be found at http://www.clark-mxr.com/industrial/handbook/introduction.htm. An excellent tutorial on the Internet is by Dieter Schuöcker, Chair of Nonconventional Processing, Forming, and Laser Technology at the TU Vienna, Austria, in cooperation with Arnold Braunsteiner, at http://www.argelas.org/files/tutorium/tutorium.htm. Laser tutorials may also befound at http://www.ilt.fraunhofer.de/eng/100048.html by Fraunhofer Institut Lasertechnik, http://www.coherentinc.com/Literature/ by Coherent, and http://www.colemaneye.com/fundamentals/laser.htm by Aldrich Computers & Consultants.

Also Rami Arieli's "The Laser Adventure" at http://stwww.weizmann.ac.il/lasers/laserweb/index.htm is a good laser introduction. A service

Electron Beam Machining

Electron beam removal of materials is another fast-growing thermal technique. Instead of electrical sparks, this method uses a stream of focused, high-velocity electrons from an electron gun to melt and vaporize the work piece material.[24] In EBM, electrons are accelerated to a velocity of 200,000 km/s or nearly three-fourths that of light. As shown in Figure 5.35, the process is performed in a vacuum chamber to reduce the scattering of electrons by gas molecules in the atmosphere. The stream of electrons is directed against a precisely limited area of the work piece; on impact, the kinetic energy of the electrons is converted into thermal energy that melts and vaporizes the material to be removed, forming holes or cuts. Originally, in the early 1960s, the method was used for welding and annealing, but today it is also used for many IC and micromachining tasks. EBM equipment now is commonly used by the electronics industry to aid in the etching of masks and the fabrication of circuits in microprocessors; today, scanning electron beam lithography remains one of the best-demonstrated methods for microfabrication in the sub-100-nm regime (see Part I). We will not repeat the electron beam lithography aspects of electron beam machines here but rather emphasize other machining applications. An electromagnetic coil or lens focuses the diverging electron beam to a power density of about 6500 GW/mm^2, high enough to vaporize the work piece material. A typical cross-sectional diameter of the beam is 10–200 μm at the point of impact on the work piece. A bias electrode switches the electron beam energy from the cathode (electron gun) on and off for pulsed drilling operations. The bias electrode also controls beam intensity. With additional coils, the beam can be deflected in any direction. With mechanical means, holes of a diameter of 0.8 mm are difficult to drill, and those less than 0.1 mm are nearly impossible. In contrast, EBM works well for deep holes of diameters less than 0.1 mm and is generally effective with a diameter-to-depth ratio of 1:10 in hard-to-machine materials. A hole in a sheet 1.25-mm thick up to 125 μm in diameter can be cut almost instantly with a taper of 2–4°. With multiple pulses, diameter-to-depth ratios can reach 1:100. For example, hole diameters of 0.1 mm can be drilled in materials up to 10-mm thick.

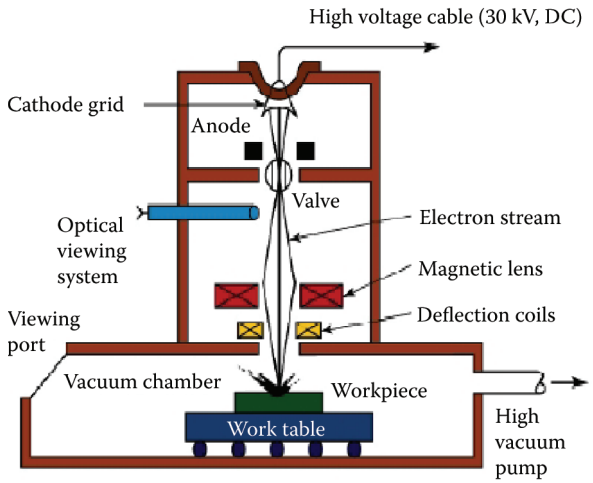

FIGURE 5.35 Schematic illustration of the electron beam machining process. Unlike LBM, this process requires a vacuum; therefore, work piece size is limited to the size of the vacuum chamber.

Once the vacuum is established (10^{-4} mm Hg), EBM can be extremely fast. The material removal rate is about 0.1 mg/s; hence drilling rates of 2000 holes/s are routine with EBM. Typical tolerances are about 10% of the hole's diameter (e.g., 0.005 mm on a 0.05-mm hole). The most suitable application is for work pieces requiring large numbers of simple small holes to be drilled or for drilling holes in materials that are hard and difficult to machine with other processes. The equipment is very expensive, and the need to operate in vacuum adds considerably to the machining time. The cost of an EBM facility ranges from $75,000 to $1.5 million.

Plasma Beam Machining

Plasma arc cutting (also plasma arc machining) is mainly used for cutting thick sections of electrically conductive materials (Figure 5.36). A high-temperature plasma stream (up to 60,000°F)

FIGURE 5.36 Plasma arc cutting.

interacts with the work piece, causing rapid melting. A typical plasma torch is constructed in such a way that the plasma is confined in a narrow column about 1 mm in diameter. The electrically conductive work piece is positively charged, and the electrode is negatively charged. Relatively large cutting speeds can be obtained: for example, 380 mm/min for a stainless steel plate 75-mm thick at an arc current of 800 A. Tolerances of ±0.8 mm can be achieved in materials of thicknesses less than 25 mm, and tolerances of ±3 mm are obtained for greater thicknesses. The HAZ for plasma arc cutting varies between 0.7 and 5 mm in thickness, and the method is used primarily for ferrous and nonferrous metals. The inert gas to form plasma also serves as a shielding gas. The torch and sometimes the work piece require cooling, and the process produces high noise levels. The technique is of marginal use in micromachining, except perhaps to cut the plasma arc-coated sensor substrates discussed in Chapter 9.

For a detailed history of plasma cutting, visit http://www.hypertherm.com/technology/plasma_history.htm. A detailed analysis of the quality of the cut of a plasma arc is presented at http://archive.metalformingmagazine.com/1998/05/plasma/plasma.htm.

Questions

Questions by Mr. Chuan Zhang, UC Irvine

5.1: In the electrical discharge machining (EDM) process, the spark-gap width is an important parameter in determining the accuracy of the process. Discuss the pros and cons of a very small spark-gap width.

5.2: What are the merits and drawbacks of electrical discharge machining? List some applications of EDM.

5.3: Sketch a way to make a 300-μm-diameter Ni rod with a polygonal cross-section using electro discharge machining wire cutting.

5.4: Draw two shapes that are better produced by lithography, and two shapes that are better made by wire cutting discharge machining (WC-EDM).

5.5: How can we perform μ-EDM in batch mode by relying on LIGA?

5.6: Explain why the metal removal rate in EDM is much slower than that of ECM.

5.7: Explain the energy conversion process in laser beam machining (LBM). How can we thermally remove materials by consuming electrical power?

5.8: Why is the mechanism of laser ablation different for different laser light wavelengths?

5.9: Why is a laser more efficient in machining than visible light? List the common applications of laser machining.

5.10: How can the quality of the ablated region be improved in the laser ablation process? Which factors affect the thickness of the heat-affected zone (HAZ)?

5.11: What are the important factors influencing the efficiency and spatial resolution of laser ablation? Explain why.

5.12: What is the difference between optical penetration depth and damage penetration depth in laser machining?

5.13: How does the laser pulse length affect laser beam machining? Compare long laser pulse etching and short laser pulse etching.

5.14: How can water jet guided laser machining keep a workpiece clean? How does it work?

5.15: What are the merits of laser etching with chemical assist (LACE)? What are the technical barriers for applying this technique in most manufacturing fields?

5.16: Laser machining offers advantages compared to methods such as EDM, ECM, chemical etching, or stamping. A laser can easily cut complex parts with high tolerances. Excessively hard, pressure- and force-sensitive, or very thin materials can be cut with a small focused beam. In many cases, laser cutting is preferred over stamping due to its high flexibility and noncontact characteristics. Lasers also enable low-temperature deposition processes, rapid prototyping, mold fabrication, and site-specific manufacturing. It also has obvious drawbacks. What are they?

Introduction

In mechanical subtractive machining, physical removal of unwanted material is achieved by mechanical energy applied at the work piece. In the ultraprecision range, the two major categories of mechanical material-removing technologies we detail in this chapter are single-point machining and abrasive machining (basically multipoint machining). Abrasive machining is a process that removes small amounts of material from a work piece in the form of tiny chips through the contact of small, hard, sharp, nonmetallic particles. In abrasive machining we review abrasive wheel machining, in particular electrolytic in-process dressing (ELID), ultrasonic machining (USM), water jet, abrasive water jet (AWJ), and abrasive jet machining (AJM). We also consider briefly two energetic beam mechanical machining methods, i.e., focused ion beam (FIB) and fast atom beam (FAB) machining. We also cover the miniaturization of mechanical machining equipment in a section on "desk-top factories." The fact that it often takes a two-ton machine tool to fabricate microparts, where cutting forces are in the milli- to micro-Newton range, is a clear indication that a complete machine tool redesign is required for the fabrication of micromachines.

Whereas primary manufacturing processes involve casting and molding, secondary manufacturing processes constitute the main mechanical removing techniques involving turning, drilling, and milling. Abrasive processes to superfinish a work piece are called tertiary manufacturing processes.

History of Mechanical Machining

Tool making for mechanical machining began perhaps when humans learned to walk erectly and had their hands free to grasp objects of wood or stone and to shape them. Although tool-making hominids probably emerged millions of years earlier, we can only trace tool-making history back 2 million years to the oldest surviving and recognizable flint hand axes.[1] Stronger, longer lasting tools resulted when metals such as copper and iron replaced wood and stone. Humans have been cutting metals for thousands of years to make the myriad tools, machines, and other devices that civilization demands.

The birth of more precise mechanical machining dates back to the invention of the lathe, attributed to Anacharis the Scythian and first depicted in an Egyptian low relief about 300 B.C. (Figure 6.1).[1] Hipparchus, in the second century B.C., and Ptolemy, in 150 A.D., used graduated instruments for astronomy and sailing. Ptolemy's astrolabe became the basic tool for observers of the skies for the next thousand years; the Arabs perfected it in the ninth century, and it remained in use for another 700 years (Figure 6.2).[2] Precision machining with a hand-operated lathe got a boost in the mid-1600s from demands for more precision in building better instruments for time measurement.[3] Ruling engines for the control of diffraction gratings have driven state-of-the-art precision machine tool design since the late 1700s. More than a century ago, Rowland at the John Hopkins University built ruling engines with part-per-million accuracy.[4,5] Today, the mechanical technology on which photolithographic alignment systems are based is still grounded in the same ruling engine design. An American astronomer, David Rittenhouse, made the first diffraction grating in 1785, when he fabricated a half-inch-wide grating with 53 apertures.[6] It is difficult to identify another single device that has provided more important experimental information to every field of science than the diffraction grating.[6] Rowland not only constructed sophisticated ruling engines, but he also invented

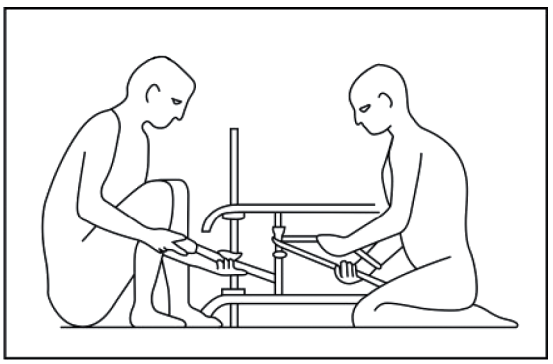

FIGURE 6.1 First lathe as depicted in an Egyptian bas relief, about 300 B.C. Shown here in a line drawing. The man at left is holding the cutting tool. The man at right is making the work piece rotate back and forth by pulling on a cord or thong.

FIGURE 6.2 Ptolemy's astrolabe; front view (a) and back view (b).

the concave grating, a device of spectacular value to modern spectroscopists.

Tools driven by mechanical power brought on the machine age in the late 1700s.[7] Diamond as a cutting tool was apparently first used in 1779 for making threads in hardened steel. The significance of diamond tools in precision machining was realized in the 1850s. By 1920, the Lord's Prayer had been engraved with a diamond tool into an area of 100 μm × 40 μm. In the 1930s, watchmakers used diamond turning to make watch dial components with excellent surface finishes. In the 1940s, Moore Special Tool Company designed a jig grinder that allowed toolmakers to work with accuracies that were not achievable by any of the existing methods (http://www.mooretool.com).

In modern times, precision engineering was initially pushed by nuclear programs and eventually by semiconductor manufacturing. By the 1960s demands from electronics, defense, and energy applications led to pioneering work on diamond turning from Lawrence Livermore National Laboratory and Oak Ridge National Lab. In the 1970s, the need for large optics in space telescopes and "defense" systems triggered the application of precision machining to complex optical components.

Norio Taniguchi started working on processing of materials to nanoscale precision as early as 1940 and worked on achieving precision finishes of quartz crystals, silicon, and other hard and brittle materials by using ultrasonic machining (USM). Taniguchi coined the term *nanotechnology* and in 1974 used the term to define ultraprecision machining. According to Taniguchi, ultraprecision machining is "the process by which the highest possible dimensional accuracy is achieved at a given point in time." In an ultraprecision manufacturing system, all the material processing methods used in a conventional manufacturing system, like removal, addition, joining, surface treatment, and assembly, are scaled down by orders of magnitude. The machine tool capabilities, metrology, and instrumentation used in these processes range in the orders of micrometers to nanometers.

Figure 6.3 includes the machine accuracy capabilities Norio Taniguchi predicted along with the processes or tools used to achieve it.

In the past 25 years, great progress has been made in building machines that can be operated and controlled automatically.

By 1977, highly precise instruments such as servomotors, feedback devices, and computers were implemented, paving the way for computer numerical control (CNC) machining, which is now standard in many types of machine tools. At the start, the smallest movement these machines could reproducibly make was 0.5 μm.

A crucial development came in the 1980s, when advanced machine tools became equipped with precision metrology and control tools. These machines used laser interferometer and capacitance probe feedback controls, temperature control, and hydrostatic

FIGURE 6.3 Progress of accuracy in machining. The development of achievable machining accuracy during the past 100 years is shown in this figure under the generalized classification of normal machining, precision machining, and ultraprecision machining. (a) Left ordinate, achievable manufacturing accuracy over time based on Taniguchi. (Taniguchi, N. 1983. Current status in, and future trends of, ultraprecision machining and ultrafine materials processing. *Annals CIRP* 32:S573–82.[8]) Right ordinate, increase in transistor density over time according to Moore's Law. (Gibbs, W. W. 1997. *Scientific American* September 22.[9]) (b) Machines, processing equipment, and metrology equipment by which the indicated resolution can be achieved and checked. By "ultraprecision machining," Taniguchi means those processes/machines by which the highest possible dimensional accuracy is or has been achieved at a given point in time.

bearings and featured accuracies better than 0.1 μm. Precision manufacturing methods were extended for industrial use for cutting aluminum, which was used for making components for scanners, photocopying machines, and computer memory disks. Also in the 1980s, cutting with very small diamond tools (e.g., 22-μm diameter) was developed in Japan.

In the 1990s, precision manufacturing became accepted as another advanced tool in manufacturing systems with some machining stations even allowing freeform machining. Large-scale adaptation of CNC machining also occurred during this period as a result of the surge of the electronics and computer industries.

By 1993, 0.05 μm became possible, and today there is equipment available featuring 0.01 μm and even nanometer step resolution (http://www.fanuc.co.jp/eindex.htm).[10]

This evolution closely follows the predictions sketched in Figure 6.3, where the Taniguchi curves show a machining accuracy for ultraprecision machining of subnanometer resolution for 2008. The resolution of the steps a machine can make, of course, is a determining factor for the manufacturing accuracy of the work piece.

Historically important milestones in new machining concepts include the introduction of ultrasonic techniques, focused ion beam, and desktop factories (DTFs).

The roots of ultrasonic technology can be traced back to research on the piezoelectric effect conducted by Pierre Curie around 1880. He found that asymmetrical crystals such as quartz and Rochelle salt (potassium sodium titrate) generate an electric charge when mechanical pressure is applied. Conversely, mechanical vibrations are obtained by applying electrical oscillations to the same crystals. This led to the discovery of SONAR (sound navigating and ranging). In USM, the tool, made of softer material than that of the work piece, is oscillated at a frequency of about 20 kHz with an amplitude of about 25.4 μm.

A liquid metal ion source used in focused ion beam machining (FIBM) was demonstrated between 1978 and 1980. The latter technique, although very slow and expensive, represents the latest and most accurate means of mechanical precision machining.

FIGURE 6.4 An example of a desktop factory at AIST, Japan.

In this case, a powerful, very thin beam of ions replaces the familiar mechanical tool. A variation of FIBM is fast-atom beam (FAB) machining, pioneered by Hatamura et al.[11] in the early 1990s. In FAB, ionized atoms, accelerated to about 100 km/s, are neutralized and used as the mechanical cutting tool.

Desktop factories (DTFs) constitute a rather interesting new manufacturing philosophy involving flexible and modular table top-sized automated factories that feature minimal human participation in the manufacturing process. An example of such a factory is shown in Figure 6.4. Since the early 1990s progress has been made toward making such DTFs a reality. A DTF as shown here has the potential of becoming the factory of the future: a totally self-contained, robotic, desktop-size machine tool that only requires materials, power, and water as outside inputs, and out come the finished machined products. The first DTFs in research and development incorporated lathes, cleaning, gluing, punching, and drilling stations. The work piece is transported between these different machining functions by a "cart" moving from station to station. A first commercial manufacturing unit by Sankyo Seiki is shown as the inset in the header of this chapter. Sankyo Seiki Mfg. Co. Ltd. believes that DTFs might help manufacturing survive in Japan.[12]

Absolute and Relative Tolerances in Manufacturing

The application ranges of normal, precision, and ultraprecision mechanical machining, according to Norio Taniguchi, are shown in Figure 6.3. The Taniguchi curves, which dramatically illustrate improvement in mechanical manufacturing accuracies achieved in the second half of the twentieth century (left coordinate) are compared with Moore's Law (right coordinate), which demonstrates the logarithmic progress in density of transistors on a chip during the past few decades. Mechanical machining and integrated circuit (IC) technology-based machining methods, as well as appropriate metrology tools, are listed in the table on the right side of this figure (see also Evans[13]). As illustrated, ultraprecision diamond machining reached a manufacturing accuracy of better than 1 nm in the year 2000. In Chapter 2 we mentioned that the mirrors for an extreme ultraviolet camera are machined flat with an accuracy of 0.25 nm rms or better. At the same time, lithography methods only reached critical dimensions of 0.18 μm. However, this comparison is a bit misleading because the accuracy for mechanical machining, which is truly 3D, pertains to the product surface finish, whereas for lithography-based methods, it is based on the accuracy of carving out very small features (e.g., 0.18 μm) in the *x,y*-plane. Photolithography-based IC methods are limited to 2–2.5D shapes (projected shapes), and although the dimensions along the *z*-axis can also be controlled to the nanometer and subnanometer range, in the *x,y*-plane, the accuracy, which is mostly determined by the alignment accuracy of a large number of photomasks, is considerably less. In terms of attaining the smallest absolute sizes, mechanical machining is considerably inferior to lithography-based methods because the writing tool in mechanical machining is crude compared with writing with light or electrons—the smallest diamond styluses are still about 22 μm in diameter! In mechanical machining (for example, polishing of a mirror), the size of the grinding tool does not influence the resulting accuracy in the *z*-direction.

The discrepancy between the progress in tolerances predicted by the Taniguchi and Moore plots and the tolerances that are being achieved in practice have been increasing, i.e., progress is slowing down (see also Part I on lithography). Progress in mechanical machining is in large part based on continued improvement in positioning stages and

computer control. Because positioning stages for lithography and ultraprecision machining are the same, the fact that the progress is slowing for both is not that surprising. Reasons for the slowdown of IC technology are a bit more complicated, however. In lithography, subsequent layers need to be aligned, an operation not needed when diamond milling, e.g., a high-precision lens. The alignment operation in lithography may be checked by laser interferometer-controlled stages to an absolute positioning accuracy of <10 nm, thereby allowing the registration of successive layers to a similar precision. The reasons for the slowdown in electronic device miniaturization are obviously not because of lack of appropriate metrology equipment, but rather hinge on securing more mechanical stability in the positioning stages and even more so on manufacturing cost and the fact that transistors are becoming too leaky at less than 30 nm, where quantum effects start playing a role.

To further extend manufacturing accuracy in electronics, one has to look beyond current manufacturing technologies and consider both top-down and bottom-up manufacturing methods or perhaps hybrid approaches. Bottom-up methods, such as molecular engineering, and top-down methods, such as e-beam nanofabrication of quantum devices, are bound to lead the way beyond the current limitations dictated by the Moore and Taniguchi curves. Micromachining of special manufacturing tools will play a pivotal role for both those new bottom-up and top-down techniques. For example, the scanning tunneling microscope, based on micromachining ultrasharp tips on Si cantilevers, creates machining opportunities with accuracies on the atomic level, well beyond the predictions of the Taniguchi and Moore curves.

For mechanical structures, operation in the micro- and nanodomain imposes barriers other than those described for electronic devices. New design philosophies that are more error-insensitive with simpler mechanisms, smaller numbers of parts, and, wherever possible, flexible members rather than rigid ones must be adopted. Also here bottom-up machining methods will play an important role (see Volume III, Chapter 3).

In Figure 6.5, we show, in a most generalized fashion, human manufactured objects (from an IC fabrication to a house) in terms of absolute size and relative tolerances (feature tolerance/object size). Mechanical machining is typically used to machine the bigger objects, e.g., a lens of an absolute size of 10 cm or a parabolic astronomic mirror with a diameter of several meters.[3] Mechanical engineers define precision machining as machining in which the relative accuracy (tolerance/object size) is 10^{-4} or less

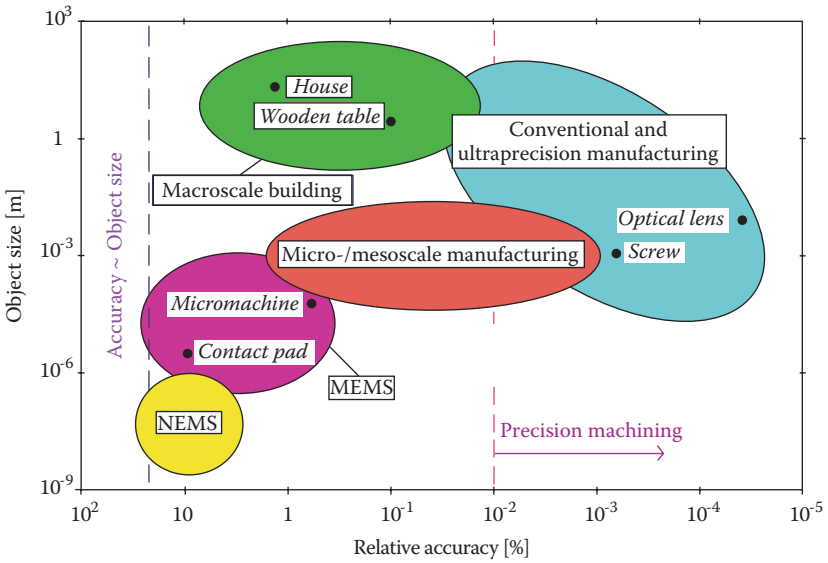

FIGURE 6.5 Various examples of human-engineered objects as a function of their relative (tolerance/object size) and absolute tolerance (size). The application field for precision machining at relative tolerances of 10^{-4} and less is also indicated. Object size versus relative accuracy for MEMS, NEMS, micro-/mesoscale manufacturing, and conventional/ultraprecision engineering.

of a feature/part size (see dividing line in Figure 6.5 at a relative accuracy of 10^{-2}%).[4,5] For comparison, a relative accuracy of 10^{-3} in the construction of a house is considered excellent. It is important to realize that, although IC techniques and silicon micro- and nanomachining (MEMS and NEMS) can achieve excellent absolute tolerances, relative tolerances here are rather poor compared with those achieved by most mechanical machining techniques. The decrease in manufacturing accuracy with decreasing size is rarely mentioned in discussions of Si micromachines; this probably is because Si micromachining originated from electrical engineering practice rather than mechanical engineering. The contrast is striking; in mechanical machining, relative tolerances of 10^{-6} (ppm) are becoming standard, whereas in the IC industry, a 10^{-2} relative tolerance is considered good. The definition of precision machining, with relative tolerances of 10^{-4}, excludes micromachining! To describe micromachining with the same terminology, it must be expanded to cover all machining methods where the relative accuracies are at least 10^{-4} or where absolute size in one or more dimensions is in the micrometer range.

In Figure 6.5 we also show the domains covered by the various machining options such as MEMS, NEMS, micro-/mesoscale manufacturing, and conventional/ultraprecision engineering. We see that IC, MEMS, and NEMS processes cover smaller absolute sizes, whereas their relative accuracies remain poor compared with those of conventional and ultraprecision manufacturing. IC-based machining in the relatively poor 10^{-1} to 10^{-2} relative accuracy range is also restricted in the types of engineering materials that can be used (Si, SiO_2, Si_3N_4, Al, …). There is an important micro-/mesoscale machining size range for applications with sizes between 10 µm and 1 mm, bridging the gap between silicon-based IC manufacturing and MEMS/NEMS and conventional miniature machining (Figure 6.6). This is a difficult size range to conquer: too large for IC manufacturing techniques and too small for traditional machining. It forms the needed hand-shake technology between the micro- and the macroworld. The bandwidth of sizes that can be attained with ultraprecision machining makes it an attractive candidate for this application range. Ultrahigh-precision techniques cover a wide range of materials, and they are—in contrast to IC methods—truly 3D and may even produce freeform surfaces. A freeform surface is a kind of complex, irregular, asymmetric aspherical surface. Generally, it cannot be described with an equation but usually only by a series of digital points. Unfortunately, whereas microscale technologies are well established in the microelectronics industry, the same cannot be said for mesoscale products involving complex 3D geometry and high relative accuracies in a range of nonsilicon materials. Thus, there is need for a strong focus on mesoscale manufacturing methods because our NEMS and MEMS devices would be rendered worthless if we cannot contact or package them.

"Precision machining," when used by mechanical engineers, has typically been reserved for removal processes only, whereas "micromachining," as used to describe IC, MEMS, and NEMS fabrication technology, covers both removal and forming processes. Precision machining and IC, MEMS, and NEMS are

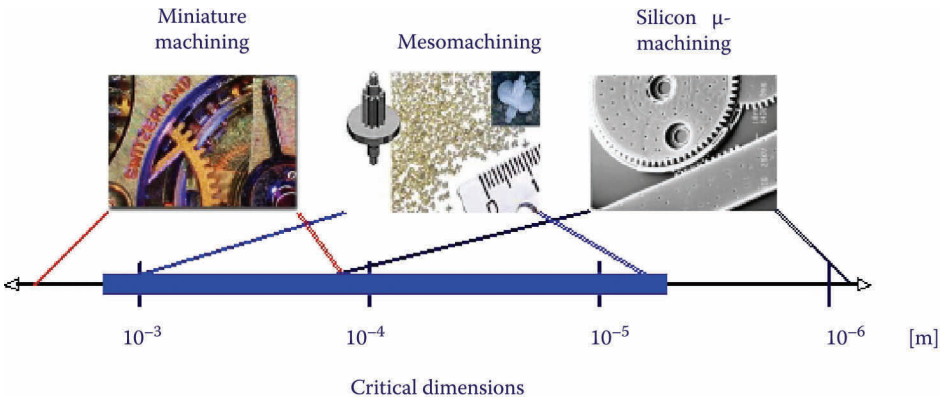

FIGURE 6.6 Mesoscale machining.

complementary; all strive to improve absolute and relative tolerances, with IC-, MEMS-, and NEMS-based technology better at obtaining smaller features (absolute tolerance) and traditional methods better at obtaining tighter relative tolerances. In this book, precision and ultraprecision machining encompasses removal and forming processes, with MEMS and NEMS as one of its newest disciplines.

The adjectives *nontraditional* and *nonconventional* have been in use by mechanical engineers for at least the past 30 years to describe nonmechanical machining methods such as thermal, electrochemical, and chemical machining of high strength and corrosion- and wear-resistant materials. However, the name *nontraditional* has become obsolete because "nonconventional" machining methods have found a wide range of commercial applications even with more readily machined materials.[14] In this book we refer to all top-down, non-IC manufacturing techniques as *traditional* machining techniques. In our nomenclature, IC-, MEMS-, and NEMS-based micromachining techniques are the nontraditional machining methods of our day. In making a manufacturing decision, it is not so much a question of which manufacturing technique is better or newer (very often, since the 1960s, silicon was the answer, sometimes independent of the question), but more which one is appropriate to use for the problem at hand.

Ultraprecision machining is significantly more expensive than normal machining and precision machining, especially when many abrasive machining steps are involved. Abrasive processes are finishing processes that are used to remove surplus material from the work piece surface. It is usually used on almost any surface that has been previously rough machined and is among the most expensive processes because it is generally slow in removing material. However, as we will learn, they can machine extremely hard surfaces and can be used on materials that are beyond the limits of virtually all other mechanical machining processes. In Table 6.1 available mechanical, electronic, and optical products are listed and categorized according to their tolerance band.

In general, to obtain the best possible accuracies with a given technique, materials such as wood or brick cannot be used; form-stable and workable materials such as aluminum, stainless steel, ceramics, or glasses must be used. In other words, material properties and machining accuracy are intertwined.

Ultraprecision Mechanical Machining

Introduction

In mechanical removal processes, stresses induced by a tool overcome the strength of the material. The process can produce complex 3D shapes, with very good dimensional control and good surface finishes. The method tends to be wasteful of material and expensive in terms of labor and capital. How well a part made from a given material holds its shape with time and stress is referred to as the *dimensional stability* of the part and the material. To maximize dimensional stability, the machine design engineer tries to minimize the ratios of applied and residual stress to yield strength of the material. A good rule of thumb is to keep the static stress less than 10–20% of yield. Increased heat at the work piece causes uneven dimensional changes in the part being machined, making it difficult to control its dimensional accuracy and tolerances. Thermal errors are often the dominant type of error in a precision machine, and thermal characteristics such as thermal expansion coefficient and thermal conductivity deserve special attention.[5]

Mechanical removal processes can be broken down into four commonly recognized categories: turning, milling, drilling, and grinding. *Turning* operations involve rotating a part and bringing it into contact with a fixed cutting tool. Mostly, turning makes parts that have a round cross-section such as screws, shafts, and pistons. *Mills* are used on a variety of materials, ranging from wood to metals, to shape a part. A mill's working feature is its revolving armature that can have a number of different tool-bit shapes. These shapes are used to cut out the different features of a part. A "block" of bulk material (e.g., steel) or a rough casting is secured to the mill, and either a manual operator or program (CNC) operates the machine, maintaining the cutting processes until the final milled product is produced. Machine *drilling* is normally done with a drill

Table 6.1 Tolerances of Components of Some Commonly Available Products

	Tolerance Band (±)	Mechanical	Electronic	Optical
Normal machining	200 μm	Normal domestic appliances and automotive fittings, etc.	General purpose electric parts, e.g., switches	Camera, telescope, and binocular bodies
	50 μm	General purpose mechanical parts for typewriters, engines, etc.	Transistors, diodes, magnetic heads for tape recorders	Camera shutters, lens holders for cameras and microscopes
Precision machining	5 μm	Mechanical watch parts, machine tool bearings, gears, ball screws, rotary compressor parts	Electrical relays, resistors, condensers, silicon wafers TV color masks	Lenses, prisms, optical fiber and connectors (multimode)
	0.5 μm	Ball and roller bearings, precision drawing wire, hydraulic servo-valves, aerostatic bearings, ink jet nozzles, aerodynamic gyro bearings	Magnetic scales, CCD (charged-coupled device), quartz oscillators, magnetic memory bubbles, magnetron, IC line width, thin film pressure transducers, thermal printer heads, thin film head discs	Precision lenses, optical scales, IC exposure masks (photo, x-ray), laser polygon mirrors, x-ray mirrors, monomode optical fiber and connectors
Ultraprecision machining	0.05 μm	Gauge blocks, diamond indenter tip radius, microtome cutter edge radius, ultraprecision *x-y* tables	IC memories, electronic video discs, LSI	Optical flats, precision Fresnel lenses, optical diffraction gratings, optical video discs
	0.005 μm		VLSI, superlattice thin films	Ultraprecision diffraction gratings

press or a boring machine. Tools that are used to produce holes are called bits. They are held in place in the drill press by clamping them in a chuck or by inserting them into a tapered sleeve. *Grinding* is a finishing process that is used to remove surplus material from the work piece surface. It is usually used on almost any surface that has been previously rough machined and is among the most expensive processes because it is generally slow in removing material. These four processes are characterized by the fact that each process generates chips, and each of these process categories has unique characteristics such as available materials, acceptable tolerance ranges, surface finish, part, and tooling costs.*

A lathe is a machine for shaping a piece of material, such as wood or metal, by rotating it rapidly along its axis while pressing a fixed cutting or abrading tool against it. Lathes are among the more versatile of the machine shop tools. They have the capability of generating true round surfaces, flat surfaces, and also screw threads. The various operations of the lathe include turning, facing, boring, drilling, parting, and threading.

Given that we are mostly interested in micro- and nanomachines, we focus our attention here on ultraprecision single-point machining and abrasive machining for finishing a product. The former is a type of ultraprecision machining where submicrometer form accuracy and nanometer-level surface finish are achieved by using high-precision, high-stiffness machine tools and single-point cutting tools. The latter is a process that removes small amounts of material from a work piece in the form of tiny chips through the contact of small, hard, sharp,

* A useful glossary for terms used in metal removal and manufacturing processes in general can be found at http://instruct1.cit.cornell.edu/courses/orie310/mfgproc/mfgprocsummary.html, and an introduction to machine tools can be found at http://me.mit.edu/2.70/machine/outline.html and at http://engide.bizland.com/mfg-5-machine.htm.

nonmetallic particles. In the abrasive machining section we review abrasive wheel machining, in particular electrolytic in-process dressing (ELID), ultrasonic machining (USM), water jet, abrasive water jet (AWJ), and abrasive jet machining (AJM).

Single-Point Mechanical Machining

In mechanical single-point machining, various factors such as deformation of the work piece and tool, vibration, thermal deformation, inaccuracies of machine tools, and so on affect the machining accuracy. Tools for single-point machining include the following materials: carbon and medium alloy steels, high-speed steels, cast-cobalt alloys, carbides, coated tools, alumina-based ceramics, cubic boron nitride, silicon-nitride-base ceramics, diamond, and whisker-reinforced materials. Single-point machining falls into these four types of machining: 1) straight turning, 2) cutting off, 3) slab milling, and 4) end milling as illustrated in Figure 6.7.

The types of chip formation in these mechanical single-point machining processes are continuous, discontinuous, built-up edge, and oblique cutting. Most machining operations involve oblique cutting and lead to the familiar rolled-up chips. Built-up edges affect the performance of a cutting tool because of their hardness and the perceived dulling of the tool. Chip breakers are used to prevent discontinuous chips from forming (see Figure 6.8).

As in all metalworking processes where plastic deformation is involved, the energy dissipated in cutting is converted into heat that in turn increases

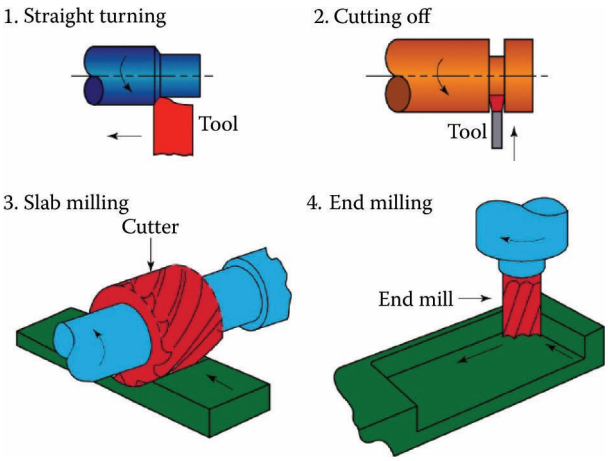

FIGURE 6.7 Single-point mechanical machining types.

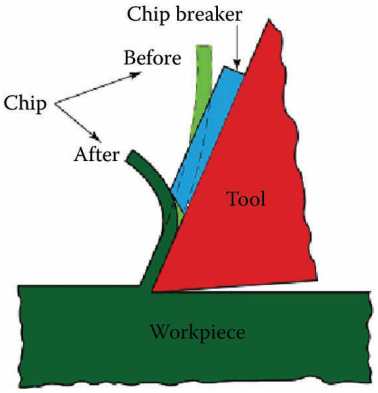

FIGURE 6.8 Chip formation during diamond milling.

the temperature in the cutting zone. Excessive heat decreases the strength, hardness, stiffness, and wear resistance of the cutting tool; tools also may soften and undergo plastic deformation, and thus the tool shape is altered.

Ultrahigh-precision machines with sharp single-crystal diamond tools have made submicrometer precision machining possible. Single-point diamond turning is less labor intensive than grinding and polishing (see "Abrasive Machining" below). A well-defined single-point tool is more predictable than a multipoint grinding wheel. Diamond-turned optical components have surfaces with a better metallurgical structure compared with the ones made from polishing and lapping. The time required to make optical quality mirrors and spheres using polishing and lapping methods is in the range of weeks, whereas the same or better quality parts can be completely fabricated from blanks using diamond turning in a few days.

A desktop high-precision four-axes CNC machine (four degrees of freedom)* for making microparts using milling and μ-EDM in a desktop machine was introduced in Chapter 5 (Figure 5.8). The single-crystal diamond cutter of this hybrid desktop machine was featured in Figure 5.11. In Figure 6.9a, we show a scanning electron microscope (SEM) photograph of a single-crystal diamond tool bit. The

* The degrees of freedom (DOF) of a machine refers to the number of independent axes along which one can obtain relative motion between the tool and the work piece. One can achieve this either by moving the tool or moving the work piece. The DOF does not include the spindle rotation or tool translation that is responsible for the cutting action. More than three DOF generally allows one to rotate the table or the work piece to achieve the correct angular relationship between the work piece and the cutter. This can help to reduce the number of separate fixturing steps and achieve smoother contours.

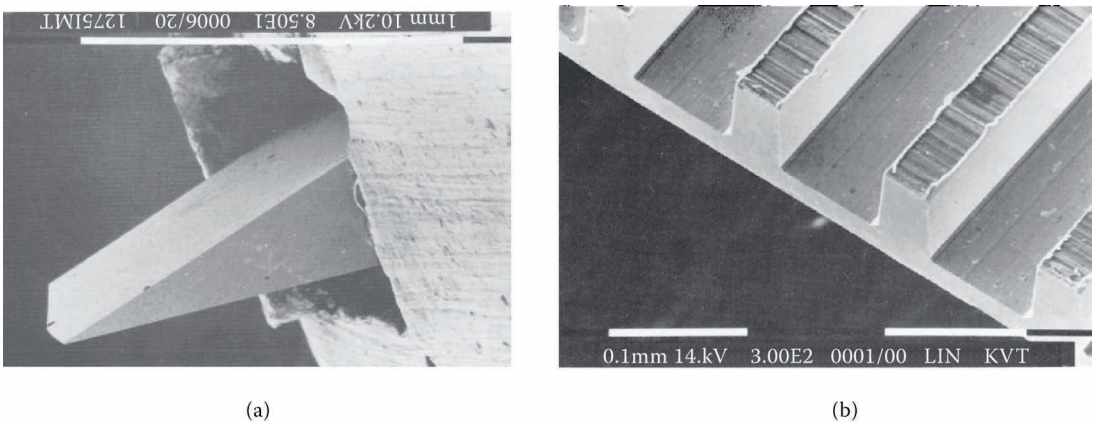

FIGURE 6.9 Diamond ultrahigh-precision tools. (a) Single-crystal diamond tool. Angle of tool is 20°. Maximum depth of cut is 500 mm. (b) Microgroove produced by diamond machining a 100-mm-thick Al foil. Width is 85 mm and depth is 70 mm.

radius of the edge on this bit is estimated at less than 0.05 μm; with such a tool, submicrometer grooves equivalent to those produced by silicon micromachining can be generated (Figure 6.9b).[16] The single hard point on the lathe in Figure 6.10 may be made from natural or synthetic diamond. Synthetic diamonds are preferred because natural diamonds have flaws that at times make them unpredictable. Ultraprecision cutting tools need to be hard and sharp, as well as have enhanced thermal properties to maintain their size and shape while cutting. High hot hardness means higher speeds and feed rates (higher production rates and lower costs). Advantages offered by diamond, the hardest material known today, include:

- Crystalline structure with a well-maintained sharp cutting edge
- High thermal conductivity, the highest of any material at room temperature
- Ability to retain high strength at high temperature
- High elastic and shear moduli, which reduce deformation during machining
- High wear resistance
- Low friction
- Produces a very accurate cut and good surface finish
- Most effective in light uninterrupted finishing cuts

However, diamond is chemically attacked by ferrous materials at high temperatures and is generally unsuitable for the machining of steels and nickel alloys. This is because of the very high wear rate of the diamond, resulting in nonviable tool costs for those applications. Diamond bits can be applied to most nonferrous metals, polymers, and crystals. Boron nitride in the forms of single-crystal cubic boron nitride (CBN) and microcrystalline cubic boron nitride (MCBN) under trade names such as Borazon or Borpax is used for precision cutting of hardened ferrous metals and high-temperature alloys.

Diamond machining is used for machining of nonferrous metals such as aluminum and copper, which are difficult materials on which to obtain a mirror surface by grinding, lapping, or polishing. This is because these metals are relatively soft, and the abrasive processes scratch the finished surface and, furthermore, are unable to produce

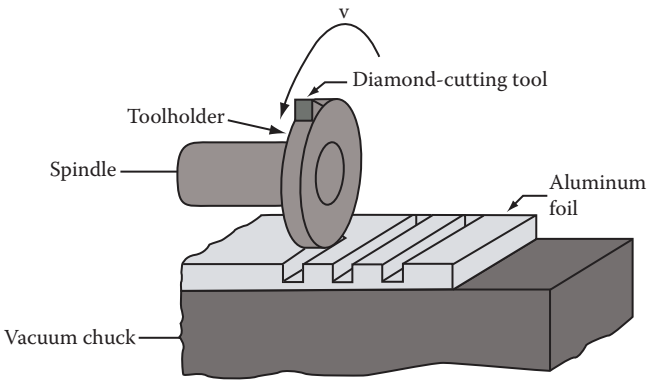

FIGURE 6.10 Diamond tool on a lathe for precision mechanical machining. Ultrahigh-precision milling of grooves in aluminum foil. The aluminum foil is 100 μm thick, and the grooves are 85 μm wide and 70 mm deep.

high levels of flatness at the edges of the machined surface.

The single-crystal diamond tool refinements are not the only reason for the high precision achieved today; submicrometer precision is also achieved through high-stiffness machine beds, air bearings (air bearings with a rotational precision of 0.01 µm and better are available), and measurement systems such as laser interferometry. Furthermore, highly precise instruments such as servomotors, feedback devices, and computers have been implemented, and many types of machine tools are now equipped for computer numerical control (CNC), further improving precision and reproducibility of the manufactured parts.

In mechanical micromachining processes, the effects of scaling on the process mechanism—including chip formation, cutting forces, vibration, process stability, and the surface integrity of the machined components—are some of the important issues that are not fully understood. The impact of work piece size on factors such as minimum chip thickness, surface quality, burr formation, built-up edge formation, and microstructure effects has been reported as summarized in Ehmann et al.[12] These reports reveal that ploughing and elastic recovery of the work piece plays a more significant role the more closely the chip thickness approaches the cutting edge radius of the cutting tool.

Various modeling techniques—including molecular dynamics (MD) simulation, finite element method (FEM), multiscale simulation modeling, and mechanistic modeling—have been attempted to characterize micromachining processes better. Simulation technologies for mahining processes such as FEM simulation of cutting, kinematical simulation of grinding, computational fluid dynamics (CFD) simulation of abrasive flow machining, and CFD simulation of electrical discharge machining (EDM) have been used for machining at the microscale level. These methods expand the process know-how and help to control development costs and define process limits. Using a diamond tip and numerical control (NC), rice grain-sized cars were machined at Nippondenso. One of these cars was 4.785 mm long, 1.73 mm wide, and 1.736 mm tall as shown in Figure 6.11.[17] In 1995, the Guinness Book of Records awarded a world record certificate to Nippondenso Co., Ltd. (now DENSO Corporation) for the development of this world's smallest motorized car. The DENSO Micro-Car is a miniature version of Toyota's first passenger car, the 1936 Model AA sedan. Its size is astounding: 1/1000th the size of the original car, or about the size of a grain of rice.

The Micro-Car has 24 parts that come in 13 different types, including body, tires, spare tire, wheels, axle, bearings, headlights, rear lights, front bumper, rear bumper, step, number plate, and emblem. The shell of the car was made by the sacrificial mold technique. A piece of aluminum was NC-machined and plated with 30-µm-thick electroless Ni; after cutting off the lower part of the body with EDM, the Al was removed by KOH etching. Finally, the Ni

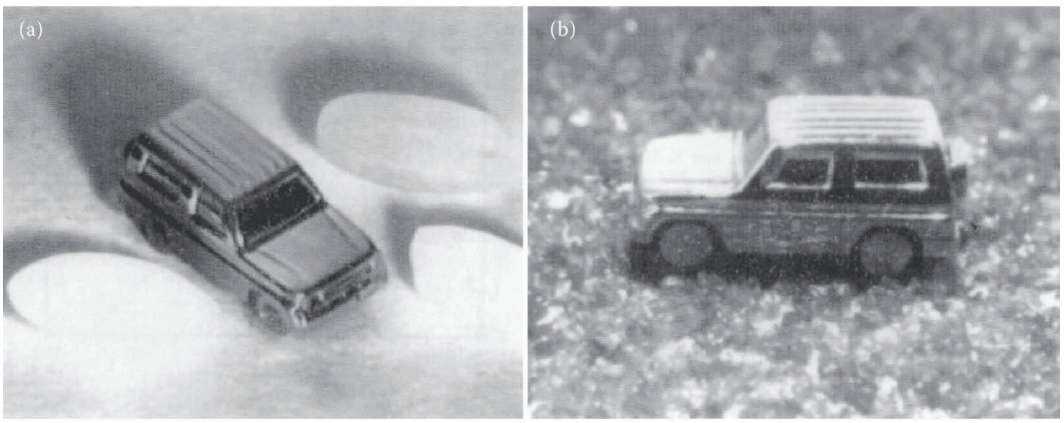

FIGURE 6.11 Micro-Car and rice grains (a) and Micro-Car on sandpaper (grain size = 200 mm) (b). The car is 7 mm long, 2.3 mm wide, and 3 mm high. (From Bier, W., G. Linder, D. Seidel, and K. Schubert. 1991. *KfK Nachrichten* 165;[16] and Teshigahara, A., et al. 1995. *J Microelectromech Syst* 4:76. With permission.[17])

car shell was Au coated to protect it from oxidation. The stainless chassis and wheels were also made by NC machining, and the core shaft and coil of the motor were made by NC machining and EDM. Wet etching of aluminum-coated glass was used for the registration plate and the emblem. A 250-µm bearing hole was drilled in the chassis for the zirconia wheel shaft. A stepping motor drives the car electromagnetically. The tube-shaped barium ferrite rotor, formed using grinding, was permanently magnetized with a special tool. The Micro-Car is powered via two 25-µm copper wires. Unfortunately, lubrication has drawbacks for microsystems, including high viscosity and adhesive effects. Therefore, the wear on the bearings is a limiting factor. Despite this, the car can run as fast as 100 mm/s, which is fast at this scale. The electromagnetic step motor is driven by an external magnetic field, and the car's permanent barium ferrite rotor runs at a maximum speed of 100 mm/s, developing a torque of about 10^{-6} Nm (at 3 V and 20 mA). To assemble the various microparts into a complete car, a cyanoacrylate adhesive and a mechanical micromanipulator, ordinarily used for handling biological cells, were used.[17]

FANUC's ROBOnano U_i is an ultraprecision multifunction micromachining station capable of making such high-precision parts as the mold for diffraction gratings or aspheric lenses (http://www.fanuc.co.jp/en/product/robonano/index.htm) (see the machine in heading of this chapter). This superprecision micromachining equipment consists of a diamond milling tool rotating at high speed on a superprecision positioning table with 1-nm step resolution and a rotation resolution of 0.00001°. It is a five-axis mill with all linear slides on air bearings. The machining operation is enclosed in an air shower with an environment controlled to within 0.01°C. The single-crystal diamond cutting tool is capable of generating 3D free curved surfaces. The machine is compact with a footprint of 1.27 m × 1.42 m and a height of 1.5 m and comes at a cost of $1 million. It is not available outside Japan at this time. Using this setup, FANUC succeeded in relief engraving a minute, mirror-surfaced Noh mask in copper with a "diamond end mill," which results in a surface smoother than a mirror. The roughness of the forehead (R_{max}) of the mask is 60 nm (see heading of this chapter). Thus, FANUC has realized a superprecision micromachining technique that allows mirror finishing in any direction except in a narrow groove. The machine was commercialized after 17 years of development by roughly 30 people. The ROBOnano is used to machine mirrors, filters, gratings, liquid crystal display panels, small lenses, and other small ultraprecise parts.

FIGURE 6.12 5-Axis-HP-Milling Center Gamma High Performance 303 by WISSNER GmbH, Göttingen, Germany.

A similar milling machine from Germany is the 5-Axis-HP-Milling Center Gamma High Performance 303 by WISSNER GmbH (Göttingen) shown in Figure 6.12. In Figure 6.13 a demonstration microstructure made on this machine, by the Fraunhofer Gesellschaft Institute for Production Systems (IPK) in Berlin, is shown.

A common limitation of the single-point diamond turning and grinding machines is their inherent ability to generate only rotationally symmetrical surfaces. Although these geometries cover the majority of requirements, there is an

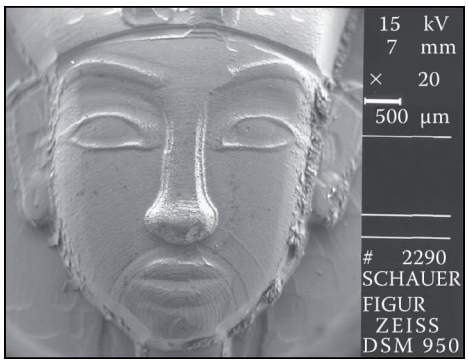

FIGURE 6.13 Demonstration on the 5-Axis-HP-Milling Center Gamma High Performance 303 by WISSNER GmbH (Göttingen, Germany) shown in Figure 6.12 by IPK (Berlin).

increasing demand for optics to incorporate more random, freeform geometries. Examples of these "freeform" geometries might be advanced laser printer optics or "conformal" windows that blend into the leading edge of an aircraft's wing. A new breed of multiaxis machines has been developed that are able to generate shapes that are no longer limited to rotational symmetry but extend to these freeform geometries. An example fabrication approach, to make, e.g., a freeform optical lens, is called computer-controlled fabrication (CCF). This may include 1) CNC grinding, 2) CNC lapping, 3) profile measuring, 4) computer-controlled corrective lapping, and 5) CNC polishing. After CNC grinding, a basic freeform surface with "peak-valley" structure is obtained. CNC lapping gets rid of the "peak-valley" and microcrack layer and decreases the surface roughness without lowering accuracy. A profile of the freeform lens is then measured with a computer-controlled coordinate measuring machine, and the machining error is obtained through a comparison between the measured data and theoretical profile data. A computer-controlled corrective lapping (CCCL) process then provides the corrective NC code by using the error data. Profile measuring and CCCL are alternated until the required accuracy is reached. Finally, the freeform lens is polished on a CNC polishing machine tool to lower the surface roughness.

Moore Nanotechnology Systems LLC, a US company, developed the Nanotech 220UPL (Figure 6.14) that is considered by many the most accurate diamond-turning machine in the world because of its groove-compensated air-bearing spindle that provides motion accuracy of less than 50 nm through its 1500-rpm speed range. Single-point diamond turning and deterministic microgrinding technologies are used for the production of plano, spherical, aspherical, conformal, and freeform optics as described above. The Nanotech 220UPL two-axis CNC single-point diamond turning lathe from Moore Nanotechnology Systems (Keene, NH) can be used to make many types of medical devices. Some applications include in vivo miniature pumps, injection-molded electroless nickel mold inserts for syringes, endoscopic lenses, or pipettes and implants.

FIGURE 6.14 Moore Nanotechnology Systems LLC, a US company, developed The Nanotech 220UPL that is considered by many the most accurate diamond-turning machine in the world because of its groove-compensated air-bearing spindle that provides motion accuracy of less than 50 nm of the whole 1500-rpm range.

Another trend in mechanical machining is toward flexible manufacturing. In response to the need for automation and the demands created by frequent design changes over a broad variety of products, the flexible manufacturing system (FMS) was developed. FMS is a combination of several technologies such as computers, CNC workstations, robots, transport bands, computer-aided design, and automatic storage. The technique was developed to produce many varieties of a certain product in smaller quantities rather than many devices of one type. CNC workstations are linked by automatic work piece transfer and handling, with flexible routing and automatic work piece loading and unloading.[18] This philosophy also underlies desktop factory design (see "Desktop Machining" below).

Ultraprecision manufacturing is the commercially preferred technique for the production of computer hard disks, mirrors for x-ray applications, photocopier drums, commercial optics such as polygon mirrors for laser-beam printers, consumer electronics such as mold inserts for the production of compact disc reader heads and camcorder viewfinders, and high-definition television (HDTV) projection lenses and VCR scanning heads.

A tutorial on mechanical drilling and milling can be found at http://www.me.mtu.edu/~microweb.

For more information on estimating manufacturing accuracies, consult http://www.isr.umd.edu/Labs/CIM/vm/ama/node19.html. Custom houses will typically report as best mechanical machining tolerances ±2 μm for cutting and ±0.4 μm for grinding (e.g., Burman tool at http://www.burman.co.uk/engineering/Machining.htm).

Abrasive Machining

Introduction

Abrasive machining is a process that removes small amounts of material from a work piece in the form of tiny chips through the contact of small, hard, sharp, nonmetallic abrasive particles. These abrasive particles may be attached to a spinning wheel (bonded), embedded in a slurry (loose), or impacted on a surface in a jet (impact). Abrasive methods in each of these categories are summarized in Figure 6.15.

Common types of abrasive machining processes using bonded abrasives include grinding, honing,* and microhoning. Lapping,† buffing, polishing, and ultrasonic machining (USM) use loose abrasive grit. Honing, microhoning, and lapping are usually termed *finishing operations* (also tertiary manufacturing methods). In USM, also called *ultrasonic impact grinding*, high-frequency vibrations delivered to a tool embedded in an abrasive slurry create accurate cavities of virtually any shape. Water jet, abrasive water jet (AWJ), and abrasive jet machining (AJM) are examples of abrasive impact machining.

The abrasive grit or cutter needs to be harder than the material to be cut (see Table 6.2). Natural abrasives include emery, corundum, quartz, garnet, and diamond. However, natural abrasives contain unknown amounts of impurities and possess

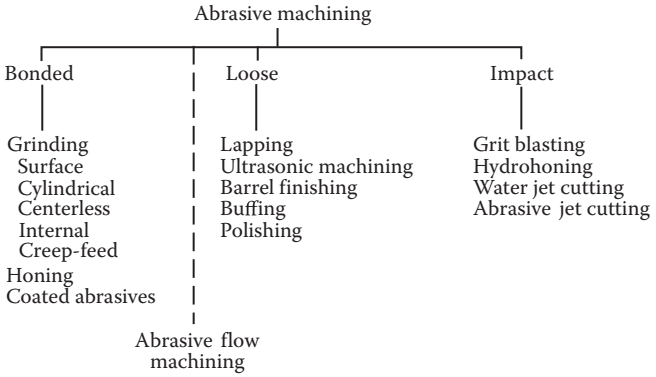

FIGURE 6.15 Categories of abrasive machining according to the matrix of the abrasive grit.

nonuniform properties, and as a result, aluminum oxide and silicon carbide abrasives are made synthetically. Conventional synthetic abrasives include aluminum oxide (Al_2O_3) and silicon carbide (SiC); superabrasives include cubic boron nitride (CBN) and diamond.

1. Aluminum oxide (Al_2O_3) known as Alundum or Aloxide. Various substances may be added to enhance hardness, toughness, and so on. Plain Al_2O_3 is white and used to grind steel, ferrous, and high-strength alloys.
2. Silicon carbide (SiC) known in trade as Carborundum and Crystalon. Harder than Al_2O_3 but not as tough. Used to grind aluminum, brass, stainless steel, cast irons, and certain brittle ceramics.
3. Boron nitride in the forms of single-crystal CBN and microcrystalline cubic boron nitride (MCBN) under trade names such as Borazon or Borpax. Used for hard materials such as hardened tool steels and aerospace alloys.
4. Diamond, a pure form of carbon, both natural and artificial. Used on hard materials such as ceramics, cemented carbides, and glass.

The temperature increase during abrasive machining can be very high (3000°F). Chips carry away heat, but a larger fraction of heat is conducted into the work piece. The effect of the temperature increase is more pronounced than in metal cutting, and the excessive temperature increase caused by grinding can temper or soften hardened metals. Abrasive machining is used when a very fine surface finish

* In honing, a simultaneous rotating and reciprocating motion between an abrasive stone and the work piece causes the removal of a small amount of material. The resulting work piece surface is one of high precision and uniform finish.

† The process of wearing down the surface of a softer material by rubbing it under pressure against the surface of a harder material that has been formed in the shape opposite to that desired on the softer material. Loose, wet abrasive generally is used between the two parts, but sometimes the abrasive is embedded in the lap in a rigid form (see diamond cutting tool).

Table 6.2 Knoop Hardness for Various Materials

Common glass	350–500	Titanium nitride	2000
Flint, quartz	800–1100	Titanium carbide	1800–3200
Zirconium oxide	1000	Silicon carbide	2100–3000
Hardened steels	700–1300	Boron carbide	2800
Tungsten carbide	1800–2400	Cubic boron nitride	4000–5000
Aluminum oxide	2000–3000	Diamond	7000–8000

and good dimensional accuracy are required and/or when the work piece materials are too hard or too brittle to work by other methods. The method is typically much slower than single-point mechanical machining (see above).

Grinding

Here, as a first example of an abrasive process and as an introduction to electrolytic in-process dressing (ELID) (see next section), we survey grinding. In grinding, the chip-removal process uses an abrasive grain or grit as the cutting tool that is bonded to a very fast spinning grinding wheel (see Figure 6.16). The grinding wheel is usually disk shaped and is precisely balanced for high rotational speeds. Grinding wheels incorporate an abrasive from the list in Table 6.2. The properties of a grinding wheel that determine how it acts are the kind and size of abrasive, how closely the grains are packed together, and amount of the bonding material.

The individual abrasive grains have an irregular geometry and are spaced randomly along the periphery of the wheel. The radial position of these cutting grains varies, and the cutting edges are extremely small. The grain size is an important parameter in determining the quality of the surface finish and the material removal rate. Small grit sizes produce better finishes, and larger grit sizes permit larger material removal rates. Also, harder materials need smaller grain sizes to cut effectively, whereas softer materials require larger grit size. The grain size of the abrasives is measured as grit size: coarse grain 8–24, medium 30–60, fine 70–180, and very fine >220. The feeds and depths of the cut in grinding are small, whereas the cutting speed is high (600 ft./min). As mentioned earlier, the temperature increase during abrasive machining can be very high (3000°F). Chips carry away heat, but a larger fraction of heat is conducted into the work piece. The effect of the temperature increase is more pronounced than in metal cutting, and the excessive temperature increase caused by grinding can temper or soften hardened metals. Burning chips are the sparks observed during grinding with no cutting fluid because the chips have heat energy to burn or melt in the atmosphere. Grinding may be classified as nonprecision or precision, according to purpose and procedure. In grinding, the chips are small but are formed by the same basic mechanism of compression and shear as in single-point machining (see above). There are three types of grain action in grinding:

1. Cutting: Grit can penetrate to the surface and performs chip removing.
2. Plowing: Grit can penetrate to the surface but cannot perform cutting. The work surface deforms.
3. Rubbing: Grits rub to the surface, and energy is consumed without cutting.

FIGURE 6.16 Common grinding wheels.

Dressing a grinding wheel is the process of resharpening the tiny cutting edges on a grinding wheel's surface. Thus, dressing a grinding wheel is shaping the grinding face of the wheel; this is often done with computer-controlled shaping features with a diamond-dressing tool kept normal to the surface at point of contact (Figure 6.17). The diamond dresses or turns the grinding wheel.

The machining energy in grinding is typically purely mechanical, but next we review a grinding

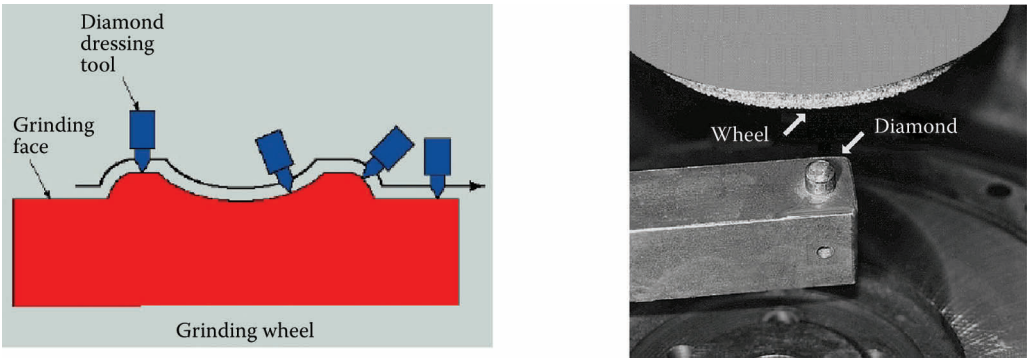

FIGURE 6.17 Shaping the grinding face of a wheel by dressing it with computer-controlled shaping features. Note that the diamond dressing tool is normal to the surface at point of contact.

process where electrochemistry plays a major role. In ELID, the material removal process (any material in this case) is purely mechanical, but an electrochemical dissolution process of the metal matrix dresses the abrasive wheel, with superabrasives embedded in a metal matrix, continuously.

Nanofinishing of Surfaces with Electrolytic In-Process Dressing

A nanosurface finish of a wide variety of brittle materials is becoming a more important demand in IC fabrication, MEMS, and NEMS. For example, a nanosurface finish is a necessity for printing nanowiring circuits using lithography techniques. The surface finish of Si wafers polished using chemomechanical polishing is found still less than ideal (see Chapter 1). To obtain a nanofinish, chip removal from the surface that is being grinded should be minimized. A *nanosurface* is only possible when the chip size of the material being removed reaches atomic level. Finishing with superabrasive grits [like diamond or cubic boron nitride (CBN)] is the method of choice to achieve these types of surfaces, but superabrasive grits need very good bonding strength to the matrix that holds them for better efficiency. Recent developments of ductile mode machining show that plastically deformed chip removal minimizes the subsurface damage of the work piece and that when chip deformation takes place in the ductile regime, a defect-free nanosurface is possible—completely eliminating the polishing process! Metal-bonded superabrasive grinding wheels in principle offer the solution here: they have the required higher bonding strength of the metal to the superabrasive grit and the required high mechanical stability. The major problems encountered using such superabrasive metal bonded wheels are that during grinding they get loaded and glazed. To avoid these difficulties, the wheel must be dressed periodically (see Figure 6.18), which

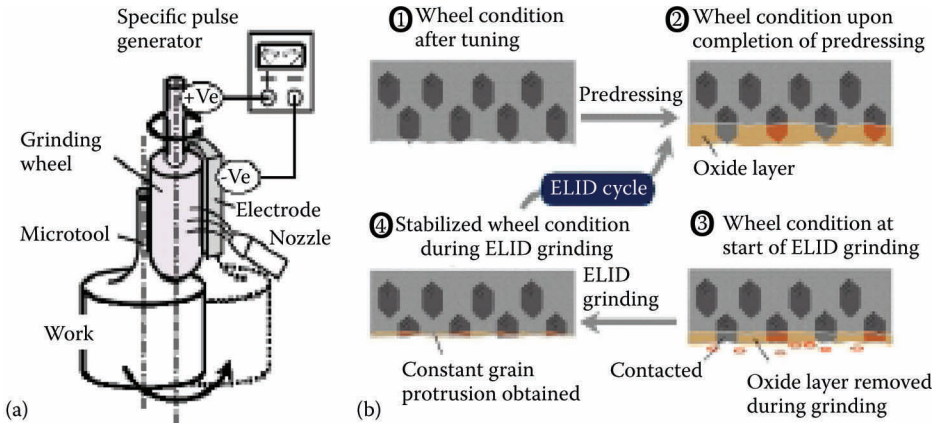

FIGURE 6.18 The ELID setup (a) and the mechanism of ELID grinding (b). (Ohmori, H., and T. Nakagawa. 1990. *Annals CIRP* 39:329.[19])

makes the grinding process very tedious. It is here that electrolytic in-process dressing (ELID) provides an elegant solution that eliminates both the wheel loading and glazing problems.

ELID is a mechanical grinding operation where the abrasive grit, embedded in a metal matrix, is kept fresh by an electrochemical dissolution process of the metal matrix. The method applies to metal and nonmetal substrates.

The concept of ELID was developed by Ohmori, chief scientist at RIKEN.[19] The system uses a metal bond grinding wheel (tool), a power supply, a grinding fluid (electrolyte), and a counter electrode as sketched in Figure 6.18a. It is important to notice that the work piece is not in the electrical circuit; thus, the grinding action here is purely mechanical, and the electrochemical assist is only there to keep the abrasive grit fresh. The metal bond wheel is made the positive electrode, whereas a negative electrode is positioned about 0.1–0.3 mm below the wheel face. The grinding fluid is supplied between the two. The grinding wheel (tool) used is the metal bond wheel in which bonding material is composed mainly of cast iron and cobalt and is sintered with the abrasive grit. The wheel is dressed using electrolysis during grinding, which helps to maintain larger grain protrusions and grit density. A DC pulse voltage is supplied between the two electrodes to electrolytically remove only the metal bond of the wheel, allowing efficient and automatic dressing of the wheel. This dressing is continued even during the grinding work to prevent reduced wheel sharpness from wear, thereby realizing highly efficient mirror-surface grinding. The mechanism of the ELID grinding method is sketched in Figure 6.18b. First the wheel bond is electrolyzed, which causes the abrasives to protrude appropriately (1). This process at the same time produces a nonconductive oxidized iron, which accumulates to form a coating on the wheel surface, automatically reducing the electrolysis current. Initial or predressing is completed at this point (2). When the grinding work is started in this state, the nonconductive oxide layer on the wheel surface comes in contact with the surface of the work piece and is removed by friction. As this takes places, the abrasives start to grind the work piece, and subsequently start to gradually wear (3). This reduces the insulation of the wheel surface, allowing the electrolytic current to flow again. As a result, the whole process starts again with the electrolysis of the wheel bond where the nonconductive oxide coating between the worn-out abrasives has become thin (4), allowing the abrasives to protrude again. This is called the ELID cycle. The ELID cycle varies according to the type of metal bond of the wheel used, electrolytic conditions, work piece, and grinding conditions. A surface finish of 2 nm may be achieved using ELID (20–50 N force for grinding).

ELID grinding is highly suitable for achieving nanosurface finishes on metals and nonmetals alike. Different types of ELID process are amenable for machining and finishing of all types of microshapes, and a nanosurface finish can be achieved using ductile mode machining on hard and brittle materials. ELID grinding can produce ductile surfaces without any subsurface damage, which eliminates the lapping and polishing processes. Thus, surface finish can be improved with higher accuracy and tolerance because the component is produced using only one process. The method is applied to process material such as silicon, glass, ceramics, extremely hard steel materials, and composite materials. Conventional applications include semiconductor substrates; electronic/optical components, such as lenses, magnetic heads, hard-disk substrates, and optical connectors; and the production of metal molds.

The major remaining difficulties with this technique are the lack of feedback devices to control the in-process dressing, optimization of machining conditions, and modeling of ductile mode grinding.

For up-to-date information on ELID, visit the web site of NEXSYS (http://www.nexsys.co.jp/index_e.htm) see Figure 6.19 for a NEXSYS desktop ELID machine. NEXSYS is an authorized RIKEN venture company established in June 1998 to provide services committed to spreading new fabrication technologies, mainly ELID mirror-surface grinding method developed at the Materials Fabrication Laboratory of RIKEN (The Institute of Physical and Chemical Research).

Ultrasonic Machining

Diamond tool machining is not only limited in the number of feature shapes and sizes that are possible it is also time consuming. Electrical discharge

FIGURE 6.19 Desktop ELID machine (500 mm × 500 mm × 560 mm) from NEXSYS (http://www.nexsys.co.jp/index_e.htm). ELID grinding is currently the best method to avoid high wheel loading and to generate mirror finish surfaces.

machining [(EDM), see Chapter 5)] is only suitable for use on conductive materials and because, just like laser beam machining [(LBM), see Chapter 5)], it is a thermal process, a heat-affected zone (HAZ) often has a negative impact on the end use of parts, especially in the case of high-reliability applications. In contrast, ultrasonic machining (USM) is a non-thermal, non-chemical and non-electrical machining process that leaves the chemical composition, material microstructure and physical properties of the work piece unchanged. This mechanical process can be used to generate a wide range of intricate features in both conductive and non-metallic materials with hardnesses of greater than 40 HRC (Rockwell Hardness measured in the C scale). The USM process can be used to fabricate precision micro-features, round and odd-shaped holes, blind cavities, and OD/ID features. Multiple features can be drilled in parallel, often reducing the total machining time significantly. Ultrasonic waves are sound waves of frequency higher than 20,000 Hz and can be generated using mechanical, electromagnetic, and thermal energy sources. They can be produced in gases (including air), liquids, and solids. One of the first applications for ultrasound was SONAR (an acronym for sound navigation ranging). It was used on a large scale by the US Navy during World War II to detect enemy submarines. Today's ultrasonic applications include medical imaging (scanning the unborn fetus), testing for cracks in airplane construction, and machining.

In ultrasonic machining (USM), also called *ultrasonic grinding*, high-frequency vibrations delivered to a tool tip, embedded in an abrasive slurry, by a booster or sonotrode, create accurate cavities of virtually any shape; that is, "negatives" of the tool. Almost any hard and brittle material, including aluminum oxides, silicon, silicon carbide, silicon nitride, glass, quartz, sapphire, ferrite, fiberoptics, and so on, can be ultrasonically machined. The tool does not exert any pressure on the work piece (drilling without drills) and is often made from a softer material than the work piece, e.g., from brass, cold-rolled steel, or stainless steel, and wears only slightly.[20] Tool material should be tough and ductile (low carbon steels and stainless steels give good performance). Tools are usually about 25 mm long, with a size equal to the "hole size" minus twice the size of abrasives. The mass of tool should be as small as possible so that it does not absorb the ultrasonic energy. The tool, typically vibrating at a low amplitude of 0.025 mm at a frequency of 20–100 kHz, is gradually fed into the work piece to form a cavity corresponding to the tool shape. The vibration transmits a high velocity to fine abrasive grains between the tool and the surface of the work piece. In the process, material is removed by microchipping or erosion with the abrasive particles. The grains are in a water slurry that also serves to remove debris from the cutting area. The high-frequency power supply for the magnetostrictive or piezoelectric transducer stack that drives the tool is typically rated between 0.1 and 40 kW. Piezoelectric transducers use the inverse piezoelectric effect using natural or synthetic single crystals (such as quartz) or ceramics (such as barium titanate), which have strong piezoelectric behavior. Ceramics have the advantage over crystals in that they are easier to shape by casting, pressing, and extruding.

Because this method is nonthermal, nonelectrical, and nonchemical, it produces virtually stress-free shapes even in hard and brittle work pieces. Ultrasonic drilling is most effective for hard and brittle materials; soft materials absorb too much sound energy and make the process less efficient. In Figure 6.20, important components of a typical USM setup are shown.[21] In the case of hard materials, microchipping is possible because of the high stress produced by particles striking the surface.

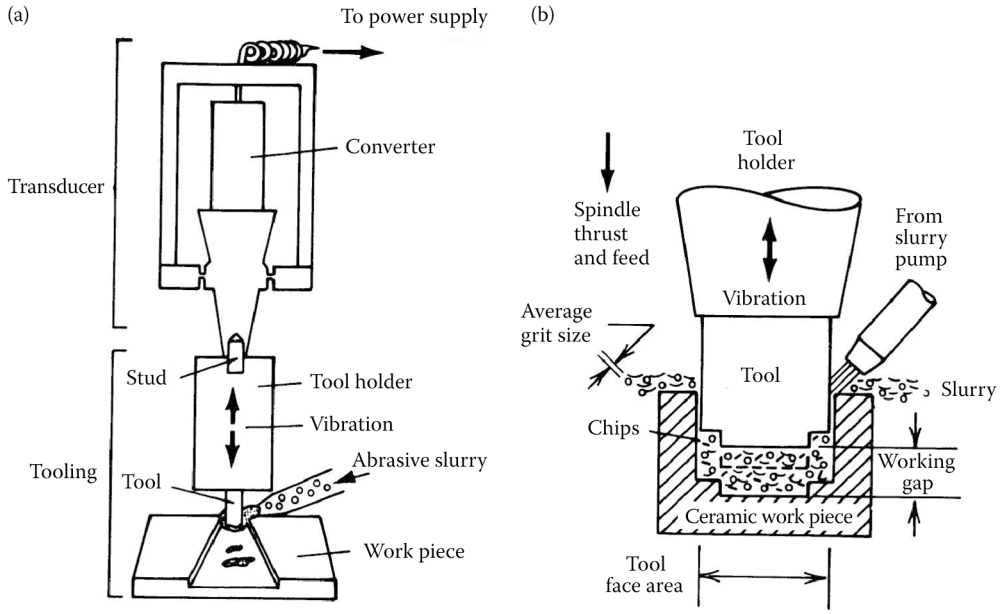

FIGURE 6.20 Schematic showing key components of a typical ultrasonic machining installation. (a) Transducer assembly coupled to tooling assembly. (b) Close-up view of tooling assembly used to machine ceramics. (From Moreland, M.A. 1992. *Engineered materials handbook*. Ed. S.J. Schneider. Metals Park, OH: ASM International. With permission.[21])

In Figure 6.21, SEM photomicrographs are shown of 640-µm holes drilled in alumina by two different techniques: USM (Figure 6.21a) and laser-beam machining (Figure 6.21b). The edges of the hole are much better defined with the ultrasonic technique. In Figure 6.22a, multiple channels and holes drilled all in parallel in a polycrystalline silicon slab are shown,[21] and in Figure 6.22b, a coin grooved with USM is displayed.

The key to USM, besides the tool itself, is the abrasive: a slurry of water or oil and small abrasive particles (large = 0.5 mm average particle diameter or small = 0.008 mm average particle diameter) of boron carbide, silicon carbide, or aluminum oxide. Boron carbide is the hardest abrasive and lasts the longest. The abrasives are suspended in water or oil at a concentration of 20–50 wt% and recirculated constantly to the work piece to supply fresh abrasive at the cutting site and remove abraded particles. The particle size and the amplitude of the vibrations used are typically made about the same. During one strike, the tool is moved down from its uppermost position with a starting speed of zero; then it speeds up to finally reach a maximum speed at the mean tool position. The tool slows down and eventually reaches zero again. When the grit size is close

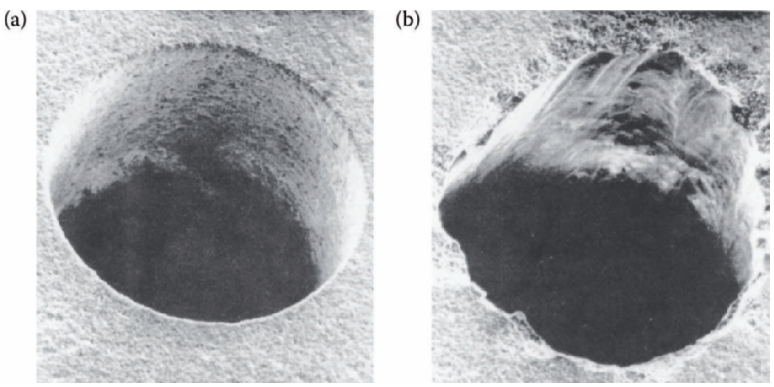

FIGURE 6.21 Scanning electron microscopy photomicrographs of 640-mm holes drilled into alumina with two different techniques. (a) Ultrasonic machining. (b) Laser-beam machining. FIGURE 6.22 (a) Channels and holes ultrasonically machined in a polycrystalline silicon wafer. (From Moreland, M.A. 1992. *Engineered materials handbook*. Ed. S.J. Schneider. Metals Park, OH: ASM International. With permission.[21]) (b) Coin with grooving carried out with USM.

to the mean position, the tool hits the grit with its full speed. The smaller the grit size, the lesser the momentum it receives from the tool. Therefore, there is an effective speed zone for the tool, and correspondingly there is an effective size range for the grits. The size of the abrasive particles determines the roughness or surface finish and the speed of the cut. Material removal rates are low, usually less than 50 mm^3/min. The mechanical properties and fracture behavior of the work piece materials also play a large role in both roughness and cutting speed. For a given grit size of the abrasive, the resulting surface roughness depends on the ratio of the hardness (H) to the modulus of elasticity (E). As this ratio increases, the surface roughness increases. For example, under identical ultrasonic cutting conditions, carbide with an H/E ratio of 1.26 has a resulting surface roughness of 0.5 µm, and glass with an H/E of 8.1 ends up with a surface finish of 1.55 µm.[21]

Higher H/E ratios also lead to higher removal rates: 4 mm^3/min for carbide and 11 mm^3/min for glass. Thus, a low fracture toughness will result in a higher material removal rate and an increase in work piece roughness values. For a given material, a larger particle size results in a rougher surface. With a very fine particle size of 0.008 mm and a low H/E ratio (e.g., alumina with H/E 2.36), a 0.5-µm surface roughness can be achieved.[22] Holes as small as 0.076 mm have been drilled, but in production applications 0.25 mm is more the norm. The upper limit on cavity size is approximately 75 mm. With a 250-µm-diameter hole, the aspect ratio is about 2.5; with increasing hole size, the aspect ratio increases. It is safe to assume that a ±10-µm tolerance can be achieved with the finest abrasive powders.

Rotary ultrasonic machining (RUM) enhances material removal rates, finish capabilities, and overall drilling efficiency. A 1/4-in. hole can be drilled 5-in. deep into glass in about 2 minutes with a rotating ultrasonic tool. To make such high-aspect-ratio holes and deep cavities, it is often required that the work piece be removed periodically to ensure uninterrupted abrasive slurry flow to the cutting zone. Conventional USM is not capable of drilling microholes much smaller than 100 µm for lack of corresponding microtools. Using microelectrode discharge machining wire cutting (µ-EDM-WC; see Chapter 5) to make microtools (similar to the pipe structures shown in Figures 5.4 and 5.5), Sun et al. made holes as small as 15 µm in diameter.[23] Surface roughness was typically about 0.2 µm, and ultrasonic drilling speed ranged from 2.0–6.0 µm/min.

Summarizing, with USM, operating costs are reasonably low and required operator skill level is modest (operator must wear eye goggles to protect against abrasive particles and microchips). The method is slow (usually less than 50 mm^3/min), but under ideal conditions, penetration rates of 5 mm/min can be obtained. The required power is usually between 0.1 and 40 kW. Normal hole

TABLE 6.3 Advantages and Disadvantages of Ultrasonic Machining

Advantages	Disadvantages
Machining of any material regardless of conductivity	Low material removal rate
Precision machining of brittle hard materials	Tool wears fast
Does not produce electric, thermal, or chemical defects at the surface	Machining area and depth are restricted
Can drill circular or noncircular holes in very hard materials	
Less stress because of its nonthermal nature	

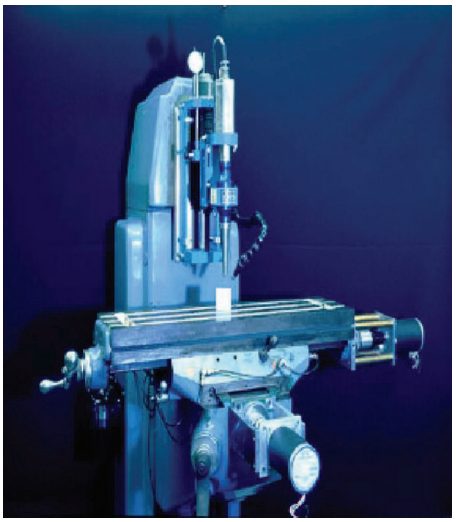

FIGURE 6.23 900-W Sonic Mill ultrasonic mill.

tolerances are 0.007 mm, and a surface finish of 0.02–0.7 µm can be achieved. Computer-controlled standard USM equipment is available with a position resolution on all axes of 0.25 µm (see Figure 6.23).

Machines cost up to $20,000, and production rates of about 2500 parts per machine per day are typical. If the machined part is a complex element (e.g., a fluidic element) of a size >1 cm^2 and the best material to be used is an inert, hard ceramic, this machining method might well be the most appropriate. A typical ultrasonic service provider is Bullen Ultrasonics (Eaton, OH; http://www.bullen-ultrasonics.com).

Advantages and disadvantages of USM are summarized in Table 6.3.

Water Jet Machining

In water jet machining, in industrial use since 1970, material is removed through mechanical impact; that is, erosion effects of a high-velocity (600–900 m/s with pressures up to 400 MPa), small-diameter (in the range of 0.07–0.5 mm) jet of water.[24] It is a nonthermal process that eliminates warping and avoids a heat-affected zone (HAZ). Water is most commonly used, but additives such as alcohols, oils, and glycerol are used when they can be dissolved in water. The exit orifice is often made of sapphire and ranges from 0.05–0.020 in. There are some advantages one can list for water jet machining:

- No heat is produced.
- Cut can be started anywhere without the need for predrilled holes.
- Burr produced is minimum.
- Environmentally safe and friendly manufacturing.

The technique is mainly used to cut soft, nonmetallic materials such as Plexiglas®, cardboard, fabrics, foam rubber, wood, food, and so on. With a water jet nozzle of 0.13 mm and a pressure of 379 MPa, a 3-mm-thick, Plexiglas plate can be cut at speeds of 0.9 m/min. Tolerances are a function of the material type and thickness, and they are usually within ± 0.1–0.2 mm.[25] Edges in water jet machining have a sandblasted appearance. Harder materials exhibit a better edge finish. Finishes range from 63 rms* to very coarse depending on the material. In Figure 6.24, we show a schematic illustration of water jet machining and examples of various nonmetallic parts cut by a water jet machine. When dealing with the choice of using laser machining (a thermal technique covered in Chapter 5) or water jet machining, one may use the following decision tree:

* Rms refers to the root mean square which is an average of peaks and valleys of a materials' surface profile (see Equation 6.5). It is given in micrometers or microinches. Rms is also called R_q.

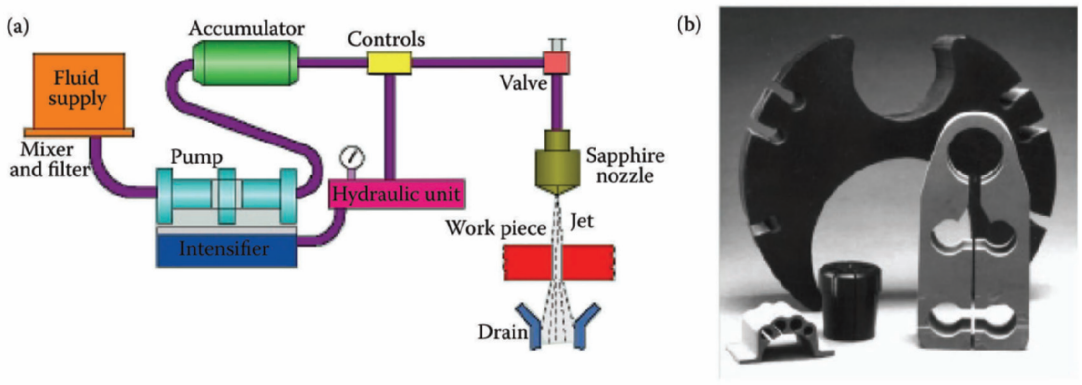

FIGURE 6.24 (a) Schematic illustration of water jet machining. (b) Examples of various nonmetallic parts cut by a water jet machine. (Courtesy of Possis Corporation.)

1. Is the material reflective or heat conductive? Yes →

LASER WATERJET

In Table 6.4 we compare advantages and disadvantages of water jet and laser machining. In water jet-guided laser machining (Chapter 5, Figure 5.23) the two techniques are combined. A thin jet of high-pressure water (between 40 and 100 μm) and water at a pressure between 20 and 500 bars is forced through a nozzle (made of diamond or sapphire). The water jet is not abrasive in this case; the material is solely ablated thermally by the laser. The high speed of the water, up to 300 m/s at 500 bars, ensures fast removal

TABLE 6.4 Advantages and Disadvantages of Water Jet and Laser Machining

Waterjet		Laser	
Advantages	**Disadvantages**	**Advantages**	**Disadvantages**
Water jet diameter 0.001–0.014 in.		Spot size as small as 0.0015 in.	
Higher material thicknesses can be cut	Equipment cost	Narrow cut (0.020 in.)	Equipment cost
No heat-affected zone	Pump maintenance (every 1000 h)	Low maintenance	Requires material that absorbs laser light; material limitations (e.g., laser reflective materials such as Cu and Al)
Does not produce electric, thermal, or chemical defects at the surface	Noise (80 db or more)	More compact nesting	Heat-affected zone (HAZ)
No part distortion	Need for filters	Faster cutting rates	
Not dependent on material property; affected only by resistance to abrasion	Slow cutting rates	Holes as small as 0.003–0.015 in.	
	User education in high-pressure plumbing	Tolerance of ±0.0003 in. through thin material	
	Finishes will range from 63 rms to very coarse	Edge finish 125 rms	
	Water must be highly purified		

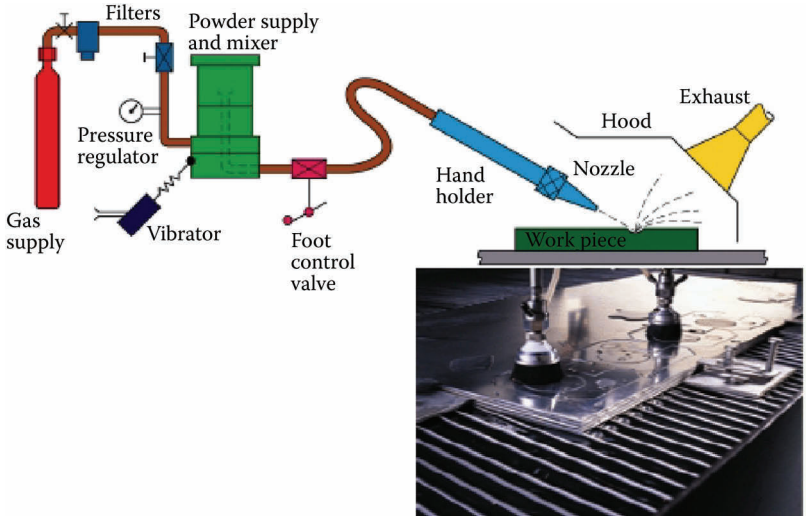

FIGURE 6.25 Abrasive water jet (AWJ) machining setup.

of debris. Water jet-guided laser etching prevents the problem of heat damage (microcracks, structural changes) inherent in any laser ablation process. The result is a heat damage-free material ablation.

Abrasive Water Jet Machining

By adding abrasives to the water jet, a much wider range of materials, including many more metals and ceramics, can be machined. Abrasive water jet (AWJ) has been in industrial use since 1982. The cutting action is a grinding process where the forces and motions are provided by water rather than a solid grinding wheel. The method is principally used for edge finishing, deburring, and polishing and has been increasingly used for treating hard-to-machine and multilayered materials and as an alternative tool for milling, turning, drilling, and polishing. In some applications AWJ is starting to replace electrical discharge machining (EDM).

An abrasive jet uses water that is pressurized up to 400 MPa and then forced through a small sapphire orifice at 1000–2500 ft./s, or up to about 2.5 times the speed of sound. Some abrasive is then pulled into this high-speed stream of water and mixed with the water in a ceramic mixer as shown in Figure 6.25. This jet of water and abrasive is then directed at the material to be machined. The jet drags the abrasive through the material in a curved path, and the resulting centrifugal forces on the particles press them against the work piece. AWJs can machine a wide range of thicknesses and materials, including metals, plastics, glass, and ceramics. Materials cut by the abrasive jet have a smooth, satin-like finish, similar to a fine sandblasted finish. Abrasive jets abrade material at room temperature. As a result, there are no heat-affected zone (HAZ) or structural changes in the work piece. Abrasive jets can also machine hardened metals and materials with low melting points. Abrasive jets typically use garnet as an abrasive. Garnet is a reddish natural crystal, with a Mohs hardness* of 6.5–7.5. No noxious gases or liquids are used in AWJ, nor are there any oils used in the machining process, so this is again a "green" machining approach. A wide range of conventional processes can be performed with this single tool such as drilling, sawing, broaching, profile milling, and so on. No heavy burrs are produced during the AWJ process. Parts can often be used directly without further deburring.

Common applications of AWJ machining include:

- Fast and precise cutting of fabrics
- Vinyl, foam coverings of car dashboard panels
- Plastic and composite body panels used in the interior of cars
- Cutting glass and ceramic tiles

Principles of Abrasive Water Jet Machining provides good further study.[26] For a tutorial on AWJ and

* Mohs hardness is defined by how well a substance will resist scratching by another substance. The scale consists of 10 minerals ranging from 1 for the softest (talc) to 10 for the hardest (diamond).

AJM on the Internet, visit http://www.waterjets.org/about_abrasivejets.html. Common water jet terminology is explained at http://www.omax.com/glossary.php. For a typical equipment supplier, visit Omax at http://www.omax.com.

Abrasive Jet Machining—Powder Blasting

Sandblasting in a pressurized air stream is used to remove paint, clean cathedrals, and decorate glass. On a finer level, powder blasting, using small particles (usually Al_2O_3 powder, particle size <100 μm) is used for device demarking in the electronics industry and in surface preparation before plating. On this level, sandblasting is called *abrasive gas jet machining* (AJM) or *microabrasive blasting*. In this type of machining, the work piece material (hard, brittle materials such as glass, silicon, tungsten, and ceramics) is removed by the mechanical impact of a high-velocity ($v_{particle}$ = 80–300 m/s) stream of abrasive-laden inert gas or air. The impact causes crack generation on the target surface.[27,28] Using masks, the method is also put to use in rapid prototyping[29] and etching of shallow intricate holes in electronic components such as resistor paths in insulators and patterns in semiconductors. The process is fast and directional, and removal rates of up to 25 μm/min have been achieved. Another application is the creation of thousands of holes at once at low cost, high speed, and high accuracy for flat panel displays.[14,28]

Recent efforts are in fine-tuning the technique for mesoscale MEMS applications. The required equipment, as schematically illustrated in Figure 6.26, is relatively inexpensive.

The setup consists of the powder blaster that regulates the flow of abrasive powder accelerated to the nozzle. An air dryer is connected to the powder reservoir to avoid moisture-induced particle agglomeration. To obtain an homogeneous scan of the work piece surface, the sample is placed on an *x,y*-translation stage. A dust collector recovers the used alumina powder. The applied pressure can typically be regulated between 1 and 5 bars.

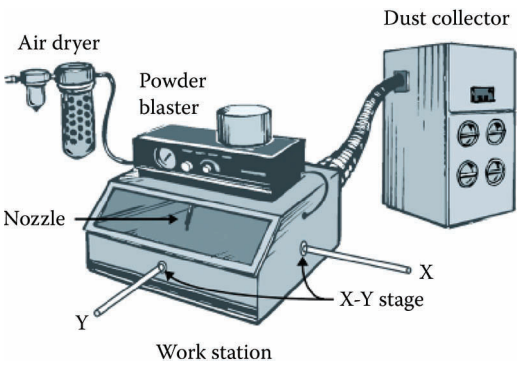

FIGURE 6.26 Schematic of powder blasting machine. (From Yamahata, C. 2005. EPF de Lausanne.[30])

A schematic diagram showing the principle of powder blasting microerosion process is presented in Figure 6.27. The different elements shown are elucidated next. A nozzle (e.g., from tungsten) provides the focusing and acceleration function for the abrasive stream generated by the blaster. A protective mask with an erosion rate much smaller than that of the substrate is also shown. In combination with suitable masks, for example, an electroplated photolithographically patterned Cu layer, minimum feature sizes of less than 50 μm, an aspect ratio of 2.5, and a depth of >1 mm in glass have been demonstrated. Polymer negative resist foils (e.g., ORDYL BF 400, specially developed for powder blasting) can also be used as mask, but in that case feature sizes are limited to 75 μm and an aspect ratio of 1.5 (http://www.el.utwente.nl/tdm/mmd/education/ d-opdrachten/powderblasting.html). Wensink et al. made a comparison study of various mask materials in powder blasting, and the same group is striving to decrease the minimum feature size to less than 10 μm (http://www.el.utwente.nl/tdm/mmd/education/d-opdrachten/powderblasting.html). The substrate in this type of machining may be glass, silicon, tungsten, or a ceramic. Finally, there is the abrasive powder.

Depending on the application aimed for, different types of abrasive powders with various shapes and hardness can be used. The most common powders are:

- Silicon carbide (SiC), because of its hardness, is the most efficient medium used for microabrasive blasting. It has a hardness of more than 9 on the Mohs scale, just below diamond.
- Crushed glass is a mild abrasive medium (Mohs hardness = 5–6), which is used when only a slight degree of abrasion is desired.
- The spherical shape of glass beads keeps them from cutting into the surface of the part. It is

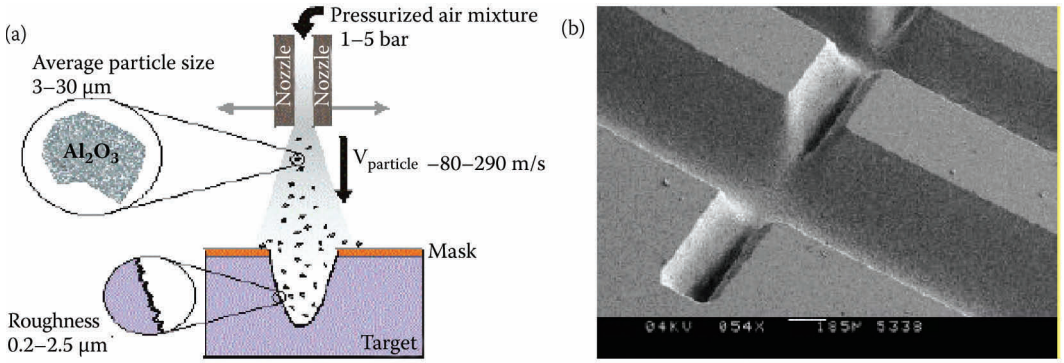

FIGURE 6.27 (a) Schematic diagram demonstrating the principle of the powder blasting microerosion process. (b) 400-μm deep-blasted glass structure. (From Yamahata, C. 2005. EPF de Lausanne[30] and http://www.anteryon.com.)

typically used to perform light deburring or to apply a satin-like finish on a work piece.
- Aluminum oxide is the most commonly used cutting abrasive because of the sharp shape of the particles and good hardness (Mohs hardness = 9).

The rate of material removal in powder blasting is commonly evaluated from the erosion rate E_{rate}, which is defined as:

$$E_{rate} = \frac{\text{weight of removed material}}{\text{weight of impacting particles}} \qquad (6.1)$$

Slikkerveer[31] studied the mechanics of powder blasting in detail. In his analysis, he introduced the erosion efficiency, E_{eff}, as:

$$E_{eff} = \frac{\text{weight of removed material}}{E_k} \qquad (6.2)$$

where E_k is the kinetic energy of the incoming particles. Combining Equations 6.1 and 6.2, one obtains:

$$E_{rate} = \frac{1}{2} E_{eff} v_{particle}^2 \qquad (6.3)$$

Notice that the erosion efficiency is a function of the kinetic energy only, whereas the erosion rate also depends on the particle velocity. E_{eff} was found to be a more useful parameter for comparison of powder blasting processes because the erosion caused by an individual particle impact directly depends on the kinetic energy of the particle. Slikkerveer et al.[32] in particular studied the erosion of brittle materials by hard angular particles impact and proposed a model that was derived from the indentation fracture theory. From their model, they concluded that the main material characteristics influencing the erosion efficiency are:

- Density (ρ) of the particles, which figures in the evaluation of the kinetic energy E_k
- Young's modulus of elasticity (E) of the substrate
- Fracture toughness (K) of the substrate, which is a measure of the ability of a material to resist the growth of an existing crack or flaw
- Indentation hardness (H) of the substrate, which characterizes a material's local resistance to a permanent deformation (e.g., scratching, abrasion, or cutting)

Powder blasting has been shown to be an appropriate micromachining technique for hard, brittle materials. It is a fast, inexpensive, and accurate directional etch technique for brittle materials such as glass, silicon, and ceramics. The time to etch

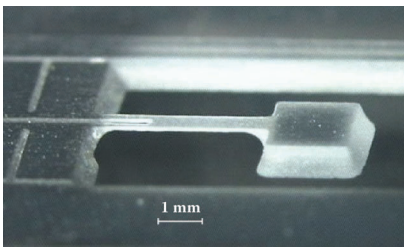

FIGURE 6.28 Powder-blasted accelerometer in glass. A first exposure of the metalized glass substrate to the eroding powder beam defines the freestanding structure and electrical contact geometry. A second exposure from the back is used to thin the cantilever beam. (Belloy, E., A. Sayah, and M. A. M. Gijs. 2000. *Sensors Actuators A* 86:231.[36] Courtesy of Dr. M. Gijs, EPFL.)

through a 500-mm-thick Pyrex wafer with one nozzle is approximately 20 minutes. The erosion process is caused by the impact of accelerated particles on brittle materials, a process that creates cracks. Powder blasting is mostly used with a powder beam at normal incidence angle to the substrate ($\theta = 90°$). Belloy et al.[33] described how, by exploiting oblique powder blasting ($\theta = 80°–40°$) and underetching phenomena of the mask on a glass substrate, a new family of 3D structures can be realized. Using this technique, a glass cantilever accelerometer beam with inertial mass was structured (Figure 6.28). Using the same method, Solignac et al.[34] fabricated capillaries for electrokinetic experiments in soda lime microscope glass slides, and Bornand et al.[35] fabricated magnetic cores from ferrite wafers for millimeter-size transformers for low power applications.

Surface Finish

The desired work piece surface determines the type of finishing operation. To rate the final surface finish of a work piece, one uses one of two criteria: the R_a or the R_q (formerly rms) value. Both are generally given in micrometers or microinches. R_a is known as the arithmetic mean value: with reference to Figure 6.29,

FIGURE 6.29 Surface roughness and center line.

it takes the average of the absolute values of the deviations for the centerline of the surface:

$$R_a = \left(\frac{|a| + |b| + |c| + \cdots}{n} \right) \tag{6.4}$$

The R_a in an older convention is also called the arithmetic average. The R_q value, which was formerly called the rms, calculates the root mean square of the values of the deviations from the centerline:

$$R_q = \sqrt{\frac{a^2 + b^2 + c^2 + \cdots}{n}} \tag{6.5}$$

Other measurements of surface roughness exist, but these two are the most common. In particular, rms or R_q is the most prevalent. In general, R_q values are 1.1–1.4 times the R_a values, but, of course, it depends on the exact surface topology.

In Figure 6.30 we represent a chart of the typical R_a readings associated with different machining

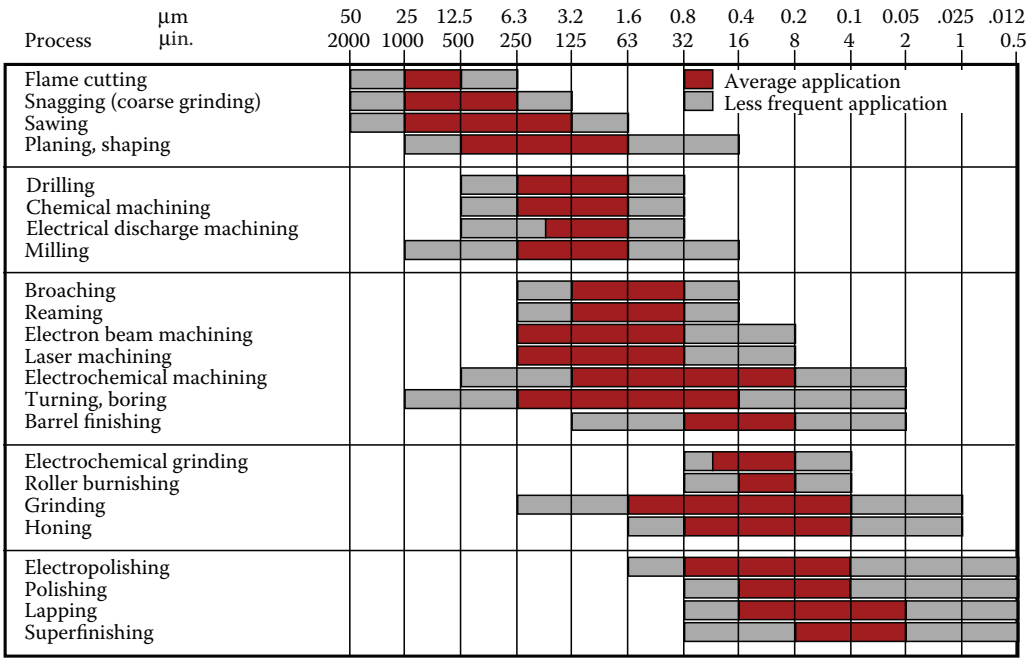

FIGURE 6.30 Typical arithmetic average roughness, R_a, for various machining methods. (Kalpakjian, S. 1984. *Manufacturing processes for engineering materials.* Reading, MA: Addison-Wesley.[37])

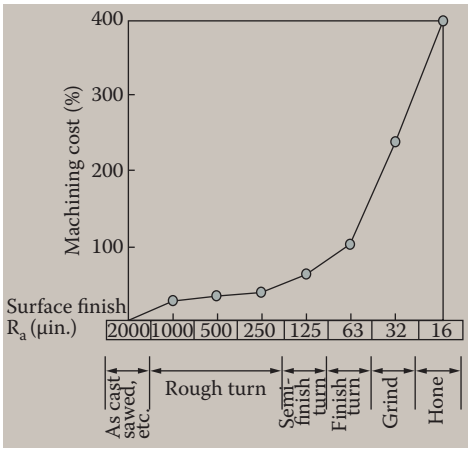

FIGURE 6.31 Increase in the cost of machining and finishing a part as a function of the surface finish required.

processes. Notice the bottom few processes—lapping and superfinishing—that are typical abrasive machining processes. Electropolishing comes close in surface finish to these abrasive methods but is generally not as good a finish as the abrasives. Also notice the very small numbers with which we are dealing. Remember a human hair is about 80 μm. In some cases we are machining to the hundredth of a micrometer! The ELID process, surveyed above, is even better. In Figure 6.31 we illustrate the increase in the cost of a machining process as a function of the surface finish required.

Focused Ion Beam Machining and Fast Atom Beam Machining

Focused Ion Beam Machining Some authors classify focused ion beam (FIB) milling as a thermomechanical technique. It is more widely accepted now as a pure mechanical machining technique in which the drill bit is replaced with a stream of energetic ions—call it ion blasting. A liquid metal ion source (e.g., gallium) is used rather than the wide argon ion beam in dry etching (see Chapter 3), and the ion beam is focused down to a submicrometer diameter. The liquid metal source uses a capillary feed (or needle) system and an acceleration voltage of 5–50 keV. Beam spots smaller than 50 nm are possible. FIB has been used for maskless implantation, metal patterning, and IC repair (see Figure 6.32).

More recently, it has been shown that FIB also constitutes a production technique of micrometer-sized objects in an arbitrary material without the requirements of anisotropy or lithography. Vasile et al., for example, described a 360° rotation mounting device used analogously to a lathe with a 20-keV Ga ion beam as the cutting tool for in-vacuum micromachining.[38,39] The ion beam they used is 0.3 μm in diameter, and they crafted tungsten needles, hooks, tuning forks, and specialized scanning probe tips. Some of these tungsten microstructures are shown in Figure 6.33. The first microstructure (Figure 6.33a and b) is a parasol-shaped scanning probe, which can be used to probe underneath resist lips and other concave features. The disc structure sits on a 1.5-μm square shank and is 4 μm in diameter and about 0.7 μm thick. The shank segment just before the disc is deliberately thinned to 0.4 μm at the thinnest point. The microshovel shown in Figure 6.33c is another illustration of the truly 3D aspect of this new manufacturing technique. The resolution limit to the fabrication process of these various tungsten structures mainly comes from the grain structure of the material. Start-to-finish fabrication time for the objects shown was ~2 hours. It should be noted that this expensive serial technique

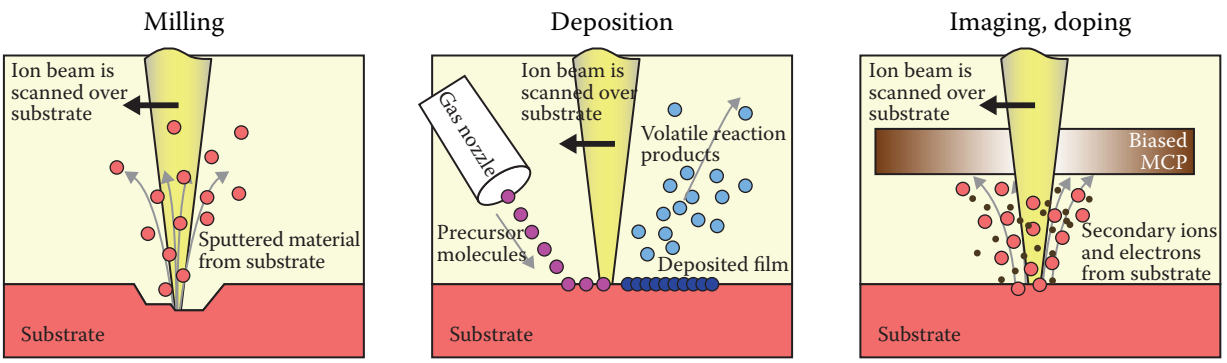

FIGURE 6.32 Uses of focused ion beam (FIB).

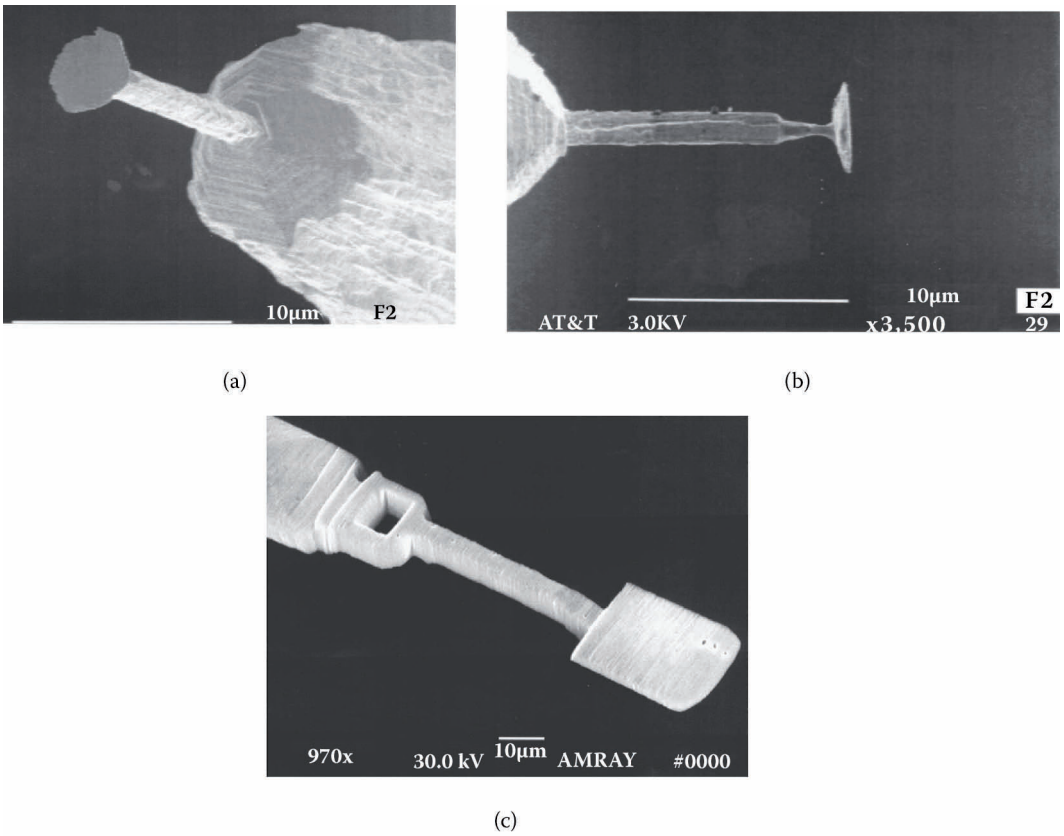

FIGURE 6.33 FIB-manufactured tungsten structures. (a) Specialized scanning tip probe parasol. (b) Side view of a parasol structure. The shank is 1.5 mm^2 and thinned down locally to 0.4 mm. The disk is 4 mm in diameter. (c) Microshovel. (From Vasile, M. J., C. Biddick, and S. A. Schwalm. 1994. *J Vac Sci Technol* B12:2388. With permission.[39] Courtesy of Dr. M. J. Vasile, Louisiana Tech University.)

might make sense for the fabrication of an atomic force microscope tool set, but to make a microshovel as shown in Figure 6.33c is of course merely meant as a fancy demonstration of the technique.

In ion-beam sputtering, a broad surface area is bombarded with energetic ions from inert gases such as argon, and momentum transfer kicks off atoms from the target. The technique was discussed in detail in Chapter 3. In reactive ion-beam etching, also reviewed in Chapter 3, a flux of reactive particles, such as CF_4^+ and F^+, is directed at the work piece in a narrow beam. In the latter process, both momentum transfer and chemical reactions are involved in the etching process, and the process cannot be solely characterized as mechanical. In reactive ion etching, the etching is almost exclusively by chemical reaction with the reactive species formed in the plasma; the method must be regarded as a dry chemical etching technique rather than a mechanical technique. The latter techniques are almost exclusively used in semiconductor settings. It is possible with these ion-machining techniques, in combination with a mask, to etch almost any material in a very controlled fashion (dimensions <100 nm).

Fast Atom Beam Machining A variation on FIB machining is fast atom beam (FAB) machining. In FAB, ionized atoms, accelerated to about 100 km/s, are neutralized and used as the mechanical cutting tool. For example, the etching rate of GaAs with chlorine atoms at 60°C is 0.15 μm/min, and vertical walls are obtained. The work piece is mounted on a lathe as in FIB, and by rotating it with respect to a Ni mask, the different faces of the GaAs work piece are etched, and 3D structures are created. Hatamura et al.[11] produced a multifaced microstructure, a micro-gojyunoto (named after an old Japanese temple tower) of 280 × 100 × 100 μm this way. A hole etched in a polyimide sheet enabled the erection of the temple with the help of the rotational robot holding the temple. More recently the same group has extended the FAB capabilities into the nanodomain

by producing ultrafine stairs, 30 nm wide and 30 nm high. Their results show that these FAB methods are effective in producing 3D microstructures and nanostructures. Combinations of these methods will make it possible to produce functional nanostructures on 3D microstructures. As we will detail in Volume III, Chapter 4 on packaging, assembly, and self-assembly, Hatamura et al. came up with several intriguing microassembly ideas, just as in the erection of the microtemple mentioned above.

Desktop Factory

Despite all the progress in mechanical micromachining reported thus far, the fact that it often takes a two-ton machine tool to fabricate microparts where cutting forces are in the milli- to micro-Newton range is a clear indication that a complete machine tool redesign is required for the fabrication of micro- and nanomachines.[40] Even with the advancement in the precision and tolerances achieved in mechanical machining, ultraprecision machining is still mostly carried out on large equipment. This equipment consumes significant amounts of floor space and energy. Figure 6.34 illustrates the volumetric utilization [V = volume of machine tool (M)/volume of work piece (W)] of conventional and mesoscale machine tools.[41] The ideal equipment should be of the same scale as the final product to constitute an optimized manufacturing system (V = 1).

The size of the equipment producing precision parts has been reduced, but the optimal size has not yet been attained. Along this line, in Japan, the concept for desktop flexible manufacturing systems, or more simply "desktop factory" (DTF), for building micromachines was proposed in the early 1990s.[42] This effort was supported by Japan's MITI (Agency of Industrial Science and Technology). In Korea, the government started a new DTF national effort at the end of 2004, and similar projects are now underway in the EEC.[12] The proposed manufacturing units would be tabletop size and include universal chuck modules to which work pieces would be continuously clamped through most of the manufacturing process. By 1999 the world's first prototype of a DTF (50 cm × 70 cm) combining miniature machine tools and manipulators was developed at AIST in Japan as shown in Figure 6.4. The factory combined a lathe, milling machine, press machine, a transfer arm, and a two-fingered hand. A next portable factory made at AIST, requiring a single 100-V AC outlet only, was packaged in a suitcase (625 mm long, 490 mm wide, and 380 mm high with a weight of about 34 kg). DTFs like these have the potential of becoming the factory of the future: totally self-contained, robotic, desktop-size machine tools that only require materials, power, and water as outside inputs. A first commercial desktop manufacturing unit by Sankyo Seiki is shown as the inset in the header of this chapter. Sankyo Seiki's management believes that DTFs might help manufacturing survive in Japan.[12]

As an example of a thermal micromachine tool, consider the Panasonic hand-held μ-EDM discussed in Chapter 5 (Figure 5.3). Another DTF reviewed in Chapter 5, combining thermal and mechanical machining, is the high-precision four-axes CNC machine developed by Liao et al. at the National Taiwan University. Parts in the size range

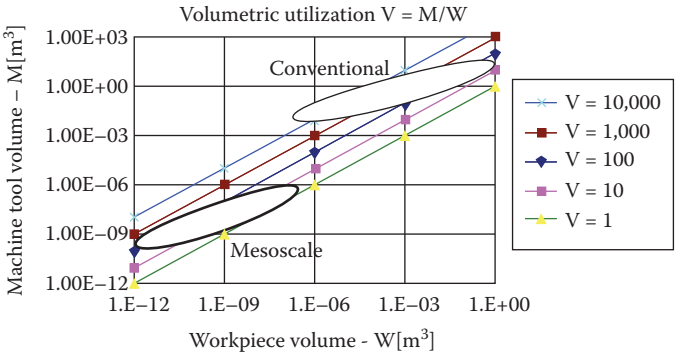

FIGURE 6.34 Volumetric utilization (V = volume of machine tool/volume work piece) of conventional and mesoscale machines. (Vogler, M.P., et al. 2002. *Transactions of NAMRI/SME* 30:653.[41])

of 0.1–2 mm can be produced on this machine tool, and all manufacturing processes are completed on the same machine without moving the work piece. This multifunction high-precision machine (accuracy of 1 μm) is capable of performing four different functions: milling, μ-EDM, μ-EDM-WC, and on-line measuring of the flatness, circularity, concentricity, dimensions, and geometric tolerances of the work piece (Figure 5.8).

In one scenario, DTFs become very automated and require very few human operators, so that exporting these machines—and thus transferring manufacturing from rich to poor countries—does not make sense anymore because no labor costs are saved. In the capitalistic/nationalistic approach, these micromanufacturing stations are owned by big centralized national entities. The other scenario, promoted by, for example, MIT's Neil Gershenfeld, sees desktop manufacturing becoming as popular as desktop publishing and the manufacturing equipment would be owned by as many people as possible.[43] In the latter, more socially responsible approach, manufacturing becomes much less centralized, and many more people get involved. In either case, the impact on society would be dramatic. The dilemma is similar to that of solar energy versus oil; solar energy is widely spread out and difficult to own/control whereas the Bush family and cohorts try to own oil that, because it is more centralized, is easier to control.

Besides high-accuracy cutting, detailed above, there is also significant progress to report in die punching. The miniature die press from Aoki and Takahashi was one of the first examples of progress in the direction of microdie punching machine tools.[44] Aoki et al. pushed the art of die forming with a press for 3D, metallic medical microcomponents to new limits.[44] Medical forceps, for insertion into an endoscope used to remove diseased tissue, have been fabricated as an example of the new capabilities. The forceps have a diameter of 0.6–1 mm and a length of 10 mm, with assembly holes measuring 0.3 mm, and 0.2-mm long teeth in the cutting tool. The final manufacturing time, including assembly, is about 3 min/piece. Some of the other successes in making DTFs are detailed in Table 6.5.

Precision Mechanical Machining versus IC-Based Micromachining

In comparing IC-based micro- and nanomachining with precision mechanically machined structures, Slocum makes some important observations.[4] He notes that, although IC-derived micro- and nanomachines are impressive for their small size, their relative accuracy is two orders of magnitude worse than is typically achieved in mechanical precision machining, which, moreover, makes for much more complex designs (see also Figure 6.3). For more than 100 years, precise mechanical machined devices have been designed and built with mechanical removal techniques achieving part-per-million (ppm) relative tolerances, and recently ultraprecision mechanical machining has entered the realm of 0.1 ppm relative tolerances. Typical IC-derived micro- and nanomachines, on the other hand, Slocum points out, are comparable with the macromachines of the early 1700s with respect to complexity and relative tolerance. Although the surface roughness of IC-derived micro- and nanomachines appears high compared with the specular finishes of precision-machined bearing surfaces, in reality, the absolute roughness is about the same. Another key issue Slocum brings up is that of metrology systems; verification of the fabricated geometry and tolerances is much more difficult for IC-derived micromachines because measurement of a displacement of 1 part in 10,000 will typically get one down to the nanometer level.

Higher-accuracy machining is needed to provide computer memory disks and optical mirrors and lenses with accuracies to a fraction of the wavelength of light. The micro- and nanofabrication techniques that are currently used in IC-derived micro- and nanomanufacturing have serious limitations in terms of the materials that can be used and the creation of complicated shapes with the required surface quality.

A better understanding of the limits of ultraprecision mechanical machining and nontraditional IC-based machining methods would help the mechanical engineer make the best choice in machining tools. At the same time, as IC-based micro- and nanomachine complexity increases, it seems appropriate

Table 6.5 Desktop Factories

Developed by	Equipment Category	Dimension of the Equipment	Features of the Equipment
Kitahara et al.[45]	Microlathe	32 mm length	*x-y* driving unit driven by laminated piezoactuators, main shaft device driven by a micromotor
Lu and Yoneyama[46]	Microlathe	200 mm length	Cutting mechanism directly observed by optical microscope
Nakao and Hatamura[47]	Nanomanufacturing factory	1.6 m × 0.9 m × 1.6 m	Fast atom beam (FAB) etching technology, concentrated motion manipulator, multidirectional SEM and an image-driven operating system
Vogler et al.[41]	Mesoscale machine tool (mMT) systems	25 mm × 25 mm × 25 mm	Air turbine spindle, piezoelectric friction drive, voice coil drives
McKeown[48]	Three-axis ultraprecision aspheric generator		High-stiffness servo drives and hydrostatic bearings, servo resolution of 1.25 nm in the *x*- and z-axes
Hatamura et al.[11]	Integrated manufacturing system for 3D microstructures	1.6 m × 0.9 m × 1.6 m	Fast atom beam etching, 3D assembly using a concentric manipulator, multiview scanning electron microscope (SEM)
Ruiz-Huerta[49]	CNC micromachining tool	130 mm × 160 mm × 85 mm	PC-based control
Mishima et al.[50]	Microfactory	Floor area: 50 × 70 cm	A microlathe, a micropress machine, a micromilling machine, a microtransfer arm, and a micro two-fingered hand
NIST (National Institute for Science and Technology)	Molecular measuring machine (M3)		Images and measures to nanometer accuracy the positions of features located anywhere within the area of 50 mm × 50 mm and up to 100 μm high
Takeuchi et al.[51]	5-axis control ultraprecision machining center	20-mm stroke for vertical movement, 1-mm minimum feature size	Air-borne linear guide and air slide for the translational axes

for the designers of these types of micro- and nanostructures, who are typically electrical engineers, to study ultraprecision machine design.

Questions

Questions by Dr. Madou assisted by Mr. Chuan Zhang, UC Irvine

6.1: What are some commonly recognized categories of mechanical removal processes?

6.2: What is the meaning of relative and absolute tolerance? Is it sufficient to use only absolute tolerances in describing the precision of a micromachining process?

6.3: What are the merits of single crystal diamond cutting tools?

6.4: Illustrate the importance of material properties in determining machining accuracy.

6.5: List some important trends and their consequences in the development of automated mechanical machining equipment (consider only single-point mechanical removal) for the manufacturing of the future.

6.6: What are the requirements for a material to be used as an abrasive grit? List some conventional abrasives.

6.7: How does the grit size affect the quality of surface finish and the material removal rates? How should the grit size be chosen when dealing with different materials?

6.8: Why must the grinding wheel be dressed periodically during the grinding process? How does electrolytic in-process dressing (ELID) solve this problem?

6.9: Why are soft materials unsuitable to be machined with ultrasonic drilling? How do hardness and modulus of elasticity impact the removal rates?

6.10: What are the advantages and disadvantages of water jet machining? If we have a piece of copper plate 1 in. thick and the heat-affected zone (HAZ) is of great concern, should we choose laser machining, water jet machining, or abrasive water jet machining? Why?

6.11: How can a wider range of materials be machined by adding abrasives to a water jet? List some applications of abrasive water jet machining.

6.12: Show how the erosion efficiency depends on the kinetic energy in powder blasting. What other factors influence the erosion efficiency?

6.13: What are the major applications of focused ion beam (FIB)? How do we operate FIB in different modes for different applications?

6.14: What are the merits of ultrasonic machining? How does a rotary setup enhance its performance?

6.15: Explain the working principle of ultrasonic machining. Why does it produce stress-free shapes?

6.16: What are the differences and similarities between focused ion beam (FIB) machining and fast atom beam (FAB) machining?

6.17: Why are micromanufacturing researchers developing desk top factories (DTFs)? Why should the ideal equipment be of the same size scale as the final product?

6.18: What are the merits and drawbacks of precision mechanical machining compared with IC-based micromachining? List two examples that are better machined with precision mechanical machining and two with IC-based micromachining.

6.19: What are the advantages of electrodischarge wire cutting (EDWC) compared with sinker EDM?

6.20: Fill in the blanks:

Precision machining is defined at a relative tolerance of or less of a feature/part size and covers both and processes.

6.21: Give a history of mankind's manufacturing methods, including major events, rough dates, and examples.

6.22: What are the underlying reasons that both Taniguchi and Moore curves have started showing signs of a slowdown in progress of manufacturing accuracy and of transistor density over time, respectively?

Introduction to Part III

Chapter 7 Physical and Chemical Vapor Deposition, Thin Film Properties, and Surface Micromachining
Chapter 8 Chemical-, Photochemical-, and Electrochemical-Based Forming
Chapter 9 Thermal Energy-Based Forming
Chapter 10 Micromolding Techniques—LIGA

Introduction to Part III

In Part III we cover additive (forming) processes, where materials are added, usually in a selective manner, to a work piece or a device under construction. In manufacturing "forming" creates an original shape from a molten mass, a solution, the gaseous state, plasma, or solid particles, and during such processes cohesion is created among individual particles. Forming techniques are often accompanied or followed by thermal processing to obtain desired material properties and substrate adhesion. Subtractive manufacturing techniques, covered in Part II, are categorized according to the energy used at the work piece as *mechanical*, *chemical*, or *thermal*. This classification—straightforward in the case of subtractive processes—breaks down quickly when applied to additive processes. Take physical vapor deposition (PVD), covered in Chapter 7, a method classified as a mechanical additive technique because material is deposited onto the work piece by direct line-of-sight impingement deposition. However, in additive techniques the depositing material itself might be generated through the application of thermal energy (e.g., thermal evaporation) or mechanical energy (e.g., sputter deposition) to a source material. In such case, the rule is to categorize the technique with the name of the process that brings the depositing material to the substrate, not for the process that generates the depositing material. For example, laser ablation deposition, also called *laser sputter deposition* (Chapter 7), uses thermal energy to ablate the material to be deposited but must be categorized as a mechanical method because the depositing material reaches the surface in a line-of-sight manner (mechanical). Most complicated to categorize are forming methods where chemical and thermal effects are intertwined in the deposition process on the substrate itself. Along this line, laser-assisted chemical vapor deposition (LCVD) (Chapter 9) is called a *thermal technique* because the heat of the laser beam induces the local material deposition, but because it involves a chemical reaction at the surface it could also have been termed a *chemical additive process*. (Remember that subtractive laser machining is a purely thermal technique; see Chapter 5.) In such cases one could refer to the technique as *thermochemical*, as in the case of the thermal oxidation of Si in a stream of humidified oxygen at 900°C, but in practice one classifies such methods as either *chemical* or *thermal*, depending on the primacy of the chemical reaction or the heat application, with the lower-temperature processes typically classified as *chemical* (e.g., sol-gel, screen printing of organics, and ink-jetting) and the higher-temperature processes as *thermal* (e.g., LCVD, screen printing of inorganics, and spray pyrolysis).

Although deposition methods in MEMS and NEMS, especially in the thin-film arena, are generally the same as in integrated circuits (ICs), additive processes in miniaturization science span a much wider and diverse range from inorganic to organic materials. Besides the typical microelectronic elements (Si, Al, Au, Ti, W, Cu, Cr, O, N, and Ni-Fe alloys), miniaturization science involves deposition of several nontypical elements such as Zr, Ta, Ir, C, Pt, Pd, Ag, Zn, In, Nb, and Sn. Moreover, a plethora of exotic compounds ranging from enzymes to shape memory alloys and from hydrogels to piezoelectrics is used in miniaturization science. In comparison, the number of materials and compounds involved in IC fabrication is very limited. In miniaturization science, particularly in chemical sensors and biomedical devices, modular, thick-film deposition technologies are more prevalent than in the IC industry.

In Table III.1 we list IC and MEMS/NEMS materials, typical deposition techniques, and an example

Table III.1 IC and MEMS/NEMS Materials, Deposition Method, and Typical Application

Material	Deposition Technique	Typical Application
Organic thin films		
Hydrogel	Silk screen	Internal electrolyte in chem. sensors
Photoresist (0.1–2 μm)	Spin-on	Masking, planarization
Thick photoresist (10–1000 μm)	Casting	Mold for metal plating
DNA	Ink-jetting	DNA array for molecular diagnostics
Polyimide	Spin-on	Electrical isolation, planarization, microstructures
Metal oxides		
Aluminum oxide	CVD, sputtering, anodization	Electrical isolation
Indium oxide	Sputtering	Semiconductor
Tantalum oxide	CVD, sputtering, anodization	Electrical isolation
Tin oxide (SnO_2)	Sputtering	Semiconductor in gas sensors
Zinc oxide	Sputtering	Electrical isolation, piezoelectric
ZrO_2	Thermal spray deposition from plasmas or flames	Coatings for aircraft engine parts and ZrO_2 sensors
Compound semiconductors		
Cadmium sulphide (II–VI compound)	Spray pyrolysis (CVD)	Solar cell
Gallium arsenide (III–V compound)	Metalorganic CVD (MOCVD)	Optoelectronic devices
Gallium-aluminum arsenide	Molecular beam epitaxy (MBE)	A semiconductor alloy used as the light confinement layer in both single- and double-heterostructure diode lasers
Noncrystalline silicon compounds		
α-Si-H	CVD, sputtering, plasma CVD	Semiconductors
Polysilicon	CVD, sputtering, plasma CVD	Conductor, microstructures
Silicides	CVD, sputtering, plasma CVD, alloying of metal and silicon	Conductors
Metals (thin films) with ρ in μΩ cm in parentheses		
Silver (Ag) (1.58)	Evaporation, sputtering	Electrochemistry electrode
Aluminum (Al) (2.7)	Evaporation, sputtering, plasma CVD	Electrical interconnects, limited to operations <300°C
Chromium (Cr) (12.9)	Evaporation, sputtering, electroplating	Electrical conduction, adhesion layer (10–100 nm)
Gold (Au) (2.4)	Evaporation, sputtering, electroplating	Electrical interconnects for higher temperatures than Al, optical reflection in the IR
Iridium (Ir) (5.1)	Sputtering	Electrochemistry electrode, biopotential measurements
Molybdenum	Sputtering	Electrical conduction
Platinum (Pt) (10.6)	Sputtering	Electrochemistry electrode, biopotential measurements
Palladium (Pd) (10.8)	Sputtering	Electrical conduction, adhesion layer, electrochemistry electrode, solder wetting layer
Tungsten (W) (5.5)	Sputtering	Electrical interconnects at higher temperatures
Titanium (Ti) (42)	Sputtering	Adhesion layer
Copper (Cu) (1.7)	Sputtering	Low resistivity interconnects
Alloys with ρ in μΩ cm in parentheses		
Al-Si-Cu	Evaporation, sputtering	Electrical conduction
Nichrome (NiCr) (200–500)	Evaporation, sputtering	Thin film laser-trimmed resistor
Permalloy™ (Ni_xFe_y)	Sputtering	Magnetoresistor, thermistor
TiNi (80)	Sputtering	Shape memory alloy

(*Continued*)

Table III.1 IC and MEMS/NEMS Materials, Deposition Method, and Typical Application (*Continued*)

Material	Deposition Technique	Typical Application
Chemically/physically modified silicon		
n/p-type silicon	Implantation, diffusion, incorporation in the melt	Conduction modulation, etch stop
Porous silicon	Anodization	Electrical isolation, light-emitting structures, porous junctions
Silicon dioxide	Thermal oxidation, sputtering, anodization, implantation, CVD	Electrical and thermal isolation, masking, encapsulation
Silicon nitride	Plasma-enhanced CVD (PECVD)	Electrical and thermal isolation, masking, encapsulation

application for the deposit. As in the case of subtractive processes (Part II), only the underlying physical and chemical principles of the various additive processes dealt with in Part III are explored.

Physical vapor deposition (PVD) processes and chemical vapor deposition (CVD) are topics of Chapter 7. In the same chapter we survey thin-film properties and detail surface micromachining, an important application of thin-film deposition techniques. In surface micromachining, features are built up, layer by layer, on the surface of a substrate (e.g., a single-crystal silicon wafer). Dry etching defines the surface features in the x,y-plane, and wet etching releases them from the plane by undercutting. In surface micromachining, shapes in the x,y-plane are unrestricted by the crystallography of the substrate.

In Chapter 8 we deal with additive chemical, photochemical, and electrochemical processes.* In chemical forming, chemical reactions create features by forming new compounds. The energy at work in these additive processes is chemical. Some of the best-known examples, with the chemical reaction dominant over the heat application, are sol-gel, reaction injection molding (RIM), colloidal processes, and self-assembled monolayers (SAMs). With the growth of the bio-MEMS field, techniques for depositing organic materials for chemical and biological sensors, often arranged in some type of an array configuration, are gaining importance. The chemical-forming methods covered in Chapter 8 are geared toward bio-MEMS applications. In photochemical forming, photoenergy solidifies a material into a 3D shape, as illustrated in rapid prototyping and microphotoforming (stereolithography). In the case of electrochemical forming, the energy at work is electrochemical. Electrochemical and electroless metal deposition are gaining renewed interest because of their emerging importance in making mold inserts for replication methodologies in both MEMS and NEMS (see also Chapter 10).

Chapter 9 covers thermal forming techniques where thermal energy provided by a heat source "transforms" a material as in crystallization, sintering, alloying, annealing, decomposition, and pyrolizing. Chemical and thermal forming techniques are often intertwined because reactions are induced by combining different chemicals and are aided by heat and catalysts. Along this line, screen printing is treated as a thermal process when dealing with inorganic material deposition (high temperature) and as a chemical process when depositing organics (low temperature). Similarly, the high-temperature ceramic application of tape casting (also called *doctor blading* or *knife coating* when dealing with paper, polymers, and paints) is treated as a thermal process where it is called *green tape technology*.

Replication methods based on plastic molding and LIGA—a sophisticated type of replication technique combining x-ray lithography with electroplating and plastic molding—are discussed in Chapter 10. Plastic molding techniques include RIM, thermoplastic injection molding (IM), and compression molding or hot embossing. Of the three, only RIM is a chemical-forming technique; the other two are thermal methods. Plastic

* Under subtractive chemical processes (Part II), we grouped purely chemical processes and electrochemical and photochemical machining together; in Part III we treat additive chemical, electrochemical, and photochemical as clearly distinct processes.

molding technology often is the least expensive manufacturing technique available. One only has to look around the home or office to recognize the pervasive nature of highly intricate, very low-cost plastic parts surrounding us. This method has the capability of making truly 3D parts with a wide range of feature sizes. Master molds can be made with both nonlithography- (e.g., CNC-machined master mold) and lithography-based (e.g., LIGA mold) techniques.

Introduction

Chapter 7 introduces physical vapor deposition (PVD) and chemical vapor deposition (CVD). PVD constitutes a group of direct line-of-sight impingement deposition techniques, and CVD represents a class of diffusive-convective mass transfer deposition techniques. Evaporation, sputtering, laser ablation deposition, ion plating, cluster deposition,

molecular beam epitaxy (MBE), and aerosol deposition (AD) represent the PVD techniques discussed. CVD techniques covered are plasma-enhanced CVD (PECVD), high-density plasma CVD (HDPCVD), atmospheric pressure CVD (APCVD), low-pressure CVD (LPCVD), very low-pressure CVD (VLPCVD), electron cyclotron resonance CVD (ECRCVD), metalorganic CVD (MOCVD), and atomic layer deposition (ALD).

Epitaxial techniques arrange atoms in single-crystal fashion on a crystalline substrate that acts as a seed crystal so that the lattice of the newly grown film duplicates that of the substrate. If the film is of the same material as the substrate, the process is called *homoepitaxy*, *epitaxy*, or simply *epi*. Epi deposition represents one of the cornerstone techniques for building micromachines, and a separate section reviews progress in epitaxial methods. Epitaxial techniques are usually chemical (CVD) in nature but may also be physical (e.g., MBE is a PVD technique).

The mechanical properties of thin CVD and PVD films are discussed next, and their applications in surface micromachining are detailed. We review thin film material properties in general, focusing on significant differences with bulk properties of the same material. Because of the complexity of the many parameters influencing thin film properties, we present the deposition of polysilicon as a case study. This is followed by a review of the main surface micromachining processes. Bulk micromachining means that three-dimensional (3D) features are etched into the bulk of crystalline and noncrystalline materials (see Chapter 4). In contrast, surface micromachined features are built up, layer by layer, on the surface of a substrate (e.g., a single crystal silicon wafer). Dry etching defines the surface features in the *x*,*y*-plane, and wet etching releases them from the plane by undercutting. In surface micromachining, shapes in the *x*,*y*-plane are unrestricted by the crystallography of the substrate. For illustration, in Figure 7.1 we compare typical bulk micromachining etching (both dry and wet) with polysilicon surface micromachining. Not reflected in this figure is the fact that the surface micromachined devices typically end up a bit smaller than their bulk micromachined counterparts.

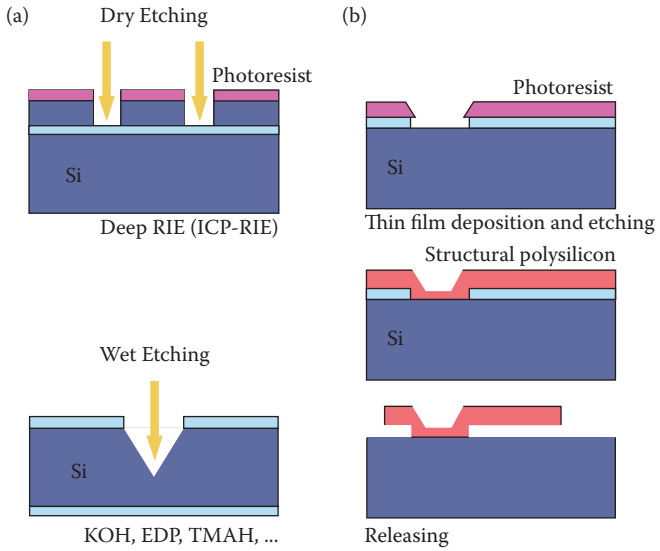

FIGURE 7.1 Typical bulk micromachining (dry and wet) (a) versus polysilicon surface micromachining process steps (b). (Figure by Dr. Han Xu.) Acronyms such as RIE, ICP-RIE, EDP and TMAH are explained in this chapter.

Physical Vapor Deposition

Introduction

Many different kinds of thin films in integrated circuits (ICs) and micro- and nanomachines are deposited by evaporation and sputtering, both of which are examples of physical vapor deposition (PVD). The technique represents a very versatile coating technology applicable to an almost unlimited combination of coating substances and substrate materials. PVD reactors may use solid, liquid, or vapor as raw source material in a variety of configurations and are used to apply a wide variety of metals, alloys, ceramics, and other inorganic compounds, and even certain polymers. However, in practice, the technique is mostly used to deposit metals. Possible substrates include semiconductors, metals, glass, and plastics. At the low pressures used in a PVD reactor, the vaporized material encounters few intermolecular collisions while traveling to the substrate. Consequently, modeling of deposition rates is a relatively straightforward exercise in geometry.

Most PVD processes consist of the following elementary steps: 1) the synthesis of the coating vapor from the source material, 2) transport of the vapor to the substrate, and 3) condensation of vapors onto the surface of the substrate. These steps are generally

Table 7.1 Principal Types of PVD Techniques

PVD Process	Features and Coating Materials
Thermal evaporation	Features: Equipment is relatively low cost and simple; deposition of compounds is difficult; coating adhesion not as good as for other PVD processes Typical coating materials: Ag, Al, Au, Cr, Cu, Mo, W
Sputtering	Features: Better throwing power and coating adhesion than vacuum evaporation; can coat compounds; slower deposition rates and more difficult process control than vacuum evaporation Typical coating materials: Al_2O_2, Au, Cr, Mo, SiO_2, Si_3N_4, TiC, TiN
Ion plating and cluster deposition	Features: Best coverage and coating adhesion of PVD processes; most complex process control; higher deposition rates than sputtering Typical coating materials: Ag, Au, Cr, Mo, Si_3N_4, TiC, TiN
Laser sputter deposition or laser ablation deposition	Features: Best for complex compound deposition Typical coating materials: high-temperature superconductor $YBa_2Cu_3O_{7-x}$ and biocompatible calcium hydroxylapatite, or $Ca_{10}(PO_4)_6(OH)_2$
Aerosol deposition	Features: Lowest temperature deposition Typical coating materials: ceramic coatings on all types of substrates

carried out in a vacuum chamber; therefore, evacuation of the chamber precedes the PVD processes. The substrates are held upside down to minimize particulate contamination. The PVD techniques may be grouped into five principal types: 1) thermal evaporation, 2) sputtering, 3) ion plating and cluster deposition, 4) laser sputter deposition or laser ablation deposition, and 5) aerosol deposition as listed in Table 7.1. Ion plating and cluster deposition are based on a combination of evaporation and plasma ionization and offer some of the advantages inherent to both techniques. In aerosol deposition, solid particles are impacted at high speed on a substrate. This promising new process, we will learn, deviates significantly from all other PVD processes.

PVD is applied in the fabrication of electronic devices, microelectromechanical systems (MEMS), and nanoelectromechanical systems (NEMS), principally for depositing metal to form electrical connections. However, applications also include thin decorative coatings on plastic and metal parts such as trophies, toys, pens and pencils, watchcases, and interior trims in automobiles. The coatings in this case are thin films of aluminum (around 150 nm) coated with clear lacquer to give a high-gloss silver or chrome appearance. Another use of PVD is to apply antireflection coatings of magnesium fluoride (MgF_2) onto optical lenses. Ion plating is widely used to coat titanium nitride (TiN) onto cutting tools and plastic injection molds for wear resistance, and pulsed laser deposition (PLD) is particularly useful when dealing with complex compounds, as in the case of the deposition of high-temperature superconductor films (HTSC), for example, $YBa_2Cu_3O_{7-x}$. Another example application of PLD is the deposition of the biocompatible calcium-phosphate-based ceramic, calcium hydroxylapatite, or $Ca_{10}(PO_4)_6(OH)_2$. Aerosol impact deposition excels at making ceramic films at low temperature on all types of substrates.

Thermal Evaporation

Certain materials (mostly pure metals) can be deposited onto a substrate by transforming them first from the solid source to the vapor state in a vacuum and then letting them condense on the substrate surface. Thermal evaporation represents one of the oldest thin film deposition techniques. Evaporation is based on the boiling off (or sublimating) of a heated material onto a substrate in a vacuum. From thermodynamic considerations, the number of molecules leaving a unit area of evaporant per second, i.e., flux F, is given by:

$$F = N_0 e^{\frac{\phi_e}{KT}} \tag{7.1}$$

where N_0 is a slowly varying function of temperature (T) and Φ_e is the activation energy (in eV) required to evaporate one molecule of the material. The activation energy for evaporation is related to the enthalpy of formation of the evaporant, H, as $H = \Phi_e \times e \times N$ (Avogadro's number) J/mol.

Table 7.2 suggests the need for a good vacuum during evaporation; even at a pressure of 10^{-5} Torr,

Table 7.2 Kinetic Data for Air as a Function of Pressure

Pressure (Torr)	Mean Free Path (cm)	Number Impingement Rate (s^{-1}. cm^{-2})	Monolayer Impingement Rate (s^{-1})
10^{1}	0.5	3.8×10^{18}	4400
10^{-4}	51	3.8×10^{16}	44
10^{-5}	510	3.8×10^{15}	4.4
10^{-7}	5.1×10^{4}	3.8×10^{13}	4.4×10^{-2}
10^{-9}	5.1×10^{6}	3.8×10^{11}	4.4×10^{-4}

Source: Brodie, I., and J. J. Muray. 1982. *The physics of microfabrication.* New York: Plenum Press. With permission.[1]

4.4 contaminating monolayers per second will impinge on the substrate.[1] For reference purposes, the number of atoms per unit area corresponding to a monolayer for a metal is about 10^{15} atoms/cm^2. Moreover, to avoid reactions at the source (e.g., oxide impurities being formed), the oxygen partial pressure needs to be less than 10^{-8} Torr.

In a laboratory setting, metals are often evaporated by passing a high current through a highly refractory metal. A refractory metal (for example, W or Mo) is formed into a suitable container [e.g., a tungsten crucible (boat) or filament] to hold the source material. Current is applied to heat the container, which then heats the material in contact with it. One problem with this heating method is possible alloying between the holder and its contents so that the deposited film becomes contaminated with the metal of the container. This method is called *resistive heating* (Figure 7.2a). Resistive evaporation is simple but easily spreads contaminants present in the filament, and the small size of the filament limits the thickness of the deposited film. Because heating is accomplished in a vacuum, the temperature required for vaporization is significantly below the corresponding temperature required at atmospheric pressure. Also, the absence of air in the chamber prevents oxidation of the source material at the heating temperatures.

In industrial applications, resistive heating has been surpassed by electron beam (e-beam) and radiofrequency (RF) induction evaporation. In the e-beam mode of operation, a high-intensity e-beam gun (3–20 keV) is focused on the target material that is placed in a recess in a water-cooled copper hearth. As shown in Figure 7.2b, the e-beam is magnetically directed onto the evaporant, which melts locally. In this manner, the metal forms its own crucible, and the contact with the hearth is too cool for chemical reactions, resulting in fewer source-contamination problems than in the case of resistive heating. E-beam evaporation not only results in higher quality films, but it also provides a higher deposition rate

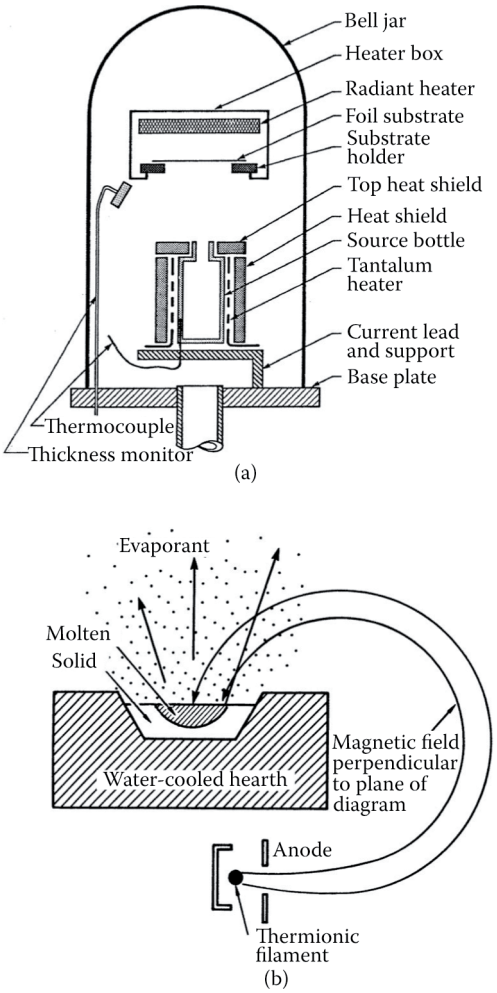

FIGURE 7.2 Thin film deposition by evaporation. (a) Typical evaporation setup. (b) Diagram of a magnetized deflection electron-beam evaporation system. (From Brodie, I., and J. J. Muray. 1982. *The physics of microfabrication.* New York: Plenum Press. With permission.[1])

(50–500 nm/min). Two disadvantages of e-beam evaporation are that the process might induce x-ray damage and possibly even some ion damage to the substrate (at voltages >10 kV, the incident e-beam causes x-ray emission) and that the deposition equipment is more complex. X-ray damage may be avoided by using a focused, high-power laser beam instead of an e-beam. However, this technique is expensive and has not yet penetrated commercial applications.

In RF induction heating, a water-cooled RF coupling coil surrounds a crucible with the material to be evaporated. Because about two-thirds of the RF energy is absorbed within one skin depth of the surface, the frequency of the RF supply must decrease as the size of the evaporant charge increases. With a charge of a few grams of evaporant, frequencies of several hundred kilohertz are sufficient.

In Table 7.3, we compare the different heat sources available for thermal evaporation.

The substances used most frequently for thin-film formation by evaporation are elements or simple compounds whose vapor pressures range from 1–10^{-2} Torr in the temperature interval from 600–1200°C. Refractory metals such as platinum, molybdenum, tantalum, and tungsten do not easily heat to the temperatures required to reach that vapor pressure range. To obtain a deposition rate high enough for practical applications, the vapor pressure at the source must be above the background pressure and reach at least 10^{-2} Torr. An evaporation source operating at a vapor pressure of 10^{-1} Torr, for example, can deliver rates of about 1000 atomic layers per second. The rate of atoms or molecules lost from the source as a result of evaporation, flux *F*, in molecules/unit area/unit time (Equation 7.1), can also be expressed in the following relationship derived from kinetic considerations on how the vapor pressure of the evaporant relates to the evaporation rate:

$$F = \frac{P_v(T)}{(2\pi MKT)^{\frac{1}{2}}} = 3.513\ 10^{22}\ \frac{P_v(T)}{(MT)^{\frac{1}{2}}} \qquad (7.2)$$

where M = molecular weight of the evaporant
T = source temperature in Kelvins
$P_V(T)$ = vapor pressure of the evaporant in Torr

Metal deposition rates of 0.5 µm/min are typical when operating in the 10-mTorr range. Whatever the vaporization technique, evaporated atoms leave the source and follow straight-line paths until they collide with other gas molecules or strike the substrate to be coated. If a high vacuum is established, most atoms/molecules will deposit on the substrate without suffering intervening collisions with other gas molecules. The fraction of particles scattered by collisions (N/N_0) with atoms of residual gas is proportional to:

$$\frac{N}{N_0} \propto 1 - e^{\frac{d}{\lambda}} \qquad (7.3)$$

where d = distance between source and substrate (see Figure 7.3a)
λ = mean free path of the particles

At 10^{-5} Torr, the mean free path in air hovers about 5 m, and at about 0.5 m at 10^{-4} Torr (see Table 7.2). The source-to-wafer distance must be smaller than the mean free path of the residual gas. Typically, this distance is 25–70 cm. With $\lambda > d$, Equation 7.3 approaches 1, i.e., no particles are scattered ($N = N_0$).

On contact with the relatively cool substrate surface, the energy of the impinging atoms is suddenly reduced to the point where they cannot remain in the vapor state; they condense and become attached to the solid surface, forming a deposited thin film. Reaching the substrate, atoms, depending on their energy, still may diffuse laterally over the surface according to:

$$D = D_0 e^{-\frac{E_D}{kT}} \qquad (7.4)$$

Table 7.3 Comparison of Heat Sources for Evaporation

Heat Sources	Advantages	Disadvantages
Resistance	No radiation	Contamination
Electron beam	Low contamination	Radiation
RF	No radiation	Contamination
Laser	No radiation, low contamination	Expensive

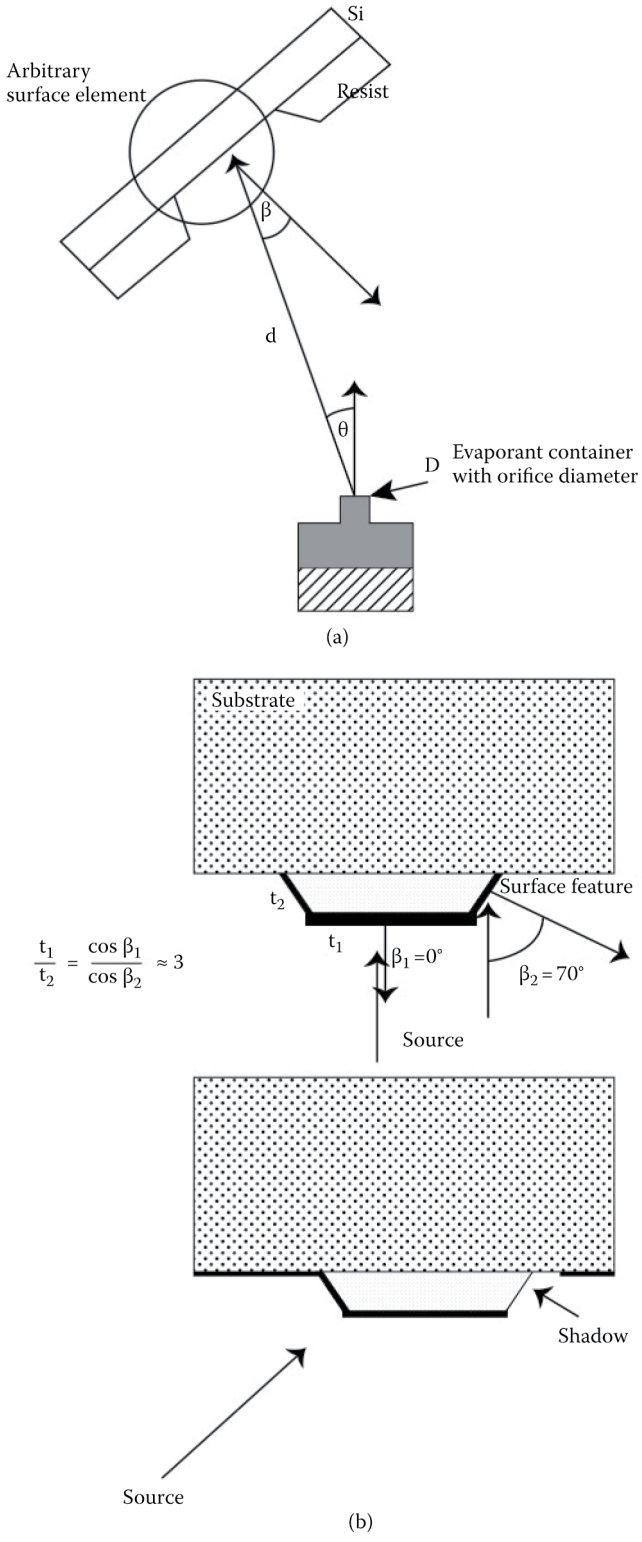

FIGURE 7.3 Geometric considerations in evaporation. (a) Geometric considerations of arrival rate A at an arbitrary surface element in an evaporation experiment. (b) Nonuniform thickness of deposits over varying topography with θ = 0° (top) and θ ≠ 0°C (bottom).

where E_D is the activation energy for diffusion (~2–3 eV) and kT is the energy of the diffusing species. For atoms, after arrival on the surface, to find the best energetic site one must either use energetic atoms or heat the substrate. In a low energy deposition system, such as molecular beam epitaxy (MBE) (see Ion Cluster Beam Deposition—Nanoparticle Deposition section), arriving atoms (~0.1 eV) may form islands unless one picks the right substrate or the substrate is heated to high temperatures. On the other hand, in a high energy deposition system, such as in sputtering (~1 eV), one gets smoother films at lower substrate temperatures, but intermixing may occur.

In a configuration where the evaporant is held in a container with a small hole (i.e., in an *effusion* or *Knudsen cell* as shown in Figures 7.2a and 7.3a) rather than in an open containment structure, the flow through the exit orifice of the evaporant source can range from free molecular to viscous. If the Knudsen number (*Kn*, ratio of the mean free path, λ, to the orifice diameter, *D*) is greater than 1:

$$\mathrm{Kn} = \frac{\lambda}{\mathrm{D}} > 1 \tag{7.5}$$

an atom or molecule passes the orifice in a single, straight track and the flow is free molecular. If, on the other hand, the Knudsen number is <0.01, the flow is viscous, that is, the atom or molecule, before emerging from the orifice, bounces several times into the orifice's sidewalls. A transition region exists between the two.

By kinetic molecular theory the mean free path relates to the total pressure as:

$$\lambda = \left(\frac{\pi \mathrm{RT}}{2\mathrm{M}}\right)^{\frac{1}{2}} \frac{\eta}{\mathrm{P_T}} \tag{7.6}$$

where P_T = pressure at the point of interest
R = ideal gas constant
η = gas viscosity

Low pressure, low molecular weight, and high viscosity translate into a large mean free path. A high vacuum prevents oxidation of, e.g., aluminum and also ensures a purer material deposit with very little

gas inclusions. The arrival rate, *A*, at distance *d* from a small evaporation source follows the cosine law of deposition:

$$A \sim \frac{\cos\beta \cos\theta}{d^2} \tag{7.7}$$

where β = angle between the normal to the substrate and the radial vector joining the source to the arrival point being considered

θ = angle between the normal to the evaporation source and the same radial vector (see Figure 7.3a)

The deposition, according to Equation 7.7, is not spherical; maximum deposition occurs in directions normal to the evaporation source, where $\cos\theta$ is maximum ($\theta = 0$). With the substrate positioned at a distance *d* from the aperture and directly in line with the aperture, the arrival rate, *A*, or total number of molecules per second striking a unit area of substrate, is:

$$A = 3.513\ 10^{22}\ \frac{P_v(T)}{d^2(MT)^{\frac{1}{2}}} \tag{7.8}$$

(See also Equation 7.2 for the evaporation rate *F*.) The straight line or directional deposition of evaporant leads to difficulties in obtaining a continuous coating over topographical steps on a wafer, a problem known as *shadowing*. This is of particular concern in micromachining, where high-aspect-ratio features are common. Figure 7.3b illustrates a typical case. Because the thickness of the deposited film, *t*, is proportional to the $\cos\beta$, the ratio of the film thickness shown in Figure 7.3b, at $\theta = 0°$, is given as:

$$\frac{t_1}{t_2} = \frac{\cos\beta_1}{\cos\beta_2} \tag{7.9}$$

In case of a steep wall, $\beta_2 \sim 70°$ and $\beta_1 \sim 0°$, the ratio of t_1/t_2 is approximately 3. The thinner section, t_2, is susceptible to cracking at the extreme ends of the interval. Two methods can help overcome this problem. The first requires heating of the substrate during deposition to 300–400°C to increase the surface mobility of the metal atoms. The second relies on rotating the wafers in planetary wafer holders so that the angle β varies during deposition (see Figure 7.4).[2] Shadowing prevents the formation of a conformal coat over a step. Mounting the substrates on rotating planetaries aids in making the coat more conformal. A conformal coat is uniform in thickness independent of the underlying topography (see Figure 7.5).

Evaporation is fast (e.g., 0.5 µm/min for Al) and comparatively simple; it registers a low-energy impact on the substrate (~0.1 eV); that is, no surface damage results except when using e-beam evaporation. Under proper experimental conditions, evaporation can provide films of extreme purity and known structure. In cases where the purity of the deposited film is of prime importance, evaporation is the preferred technique. For example, for electrochemical sensors, where the electrocatalytic activity of the top monolayers of the sensing electrode determines proper operation, material purity

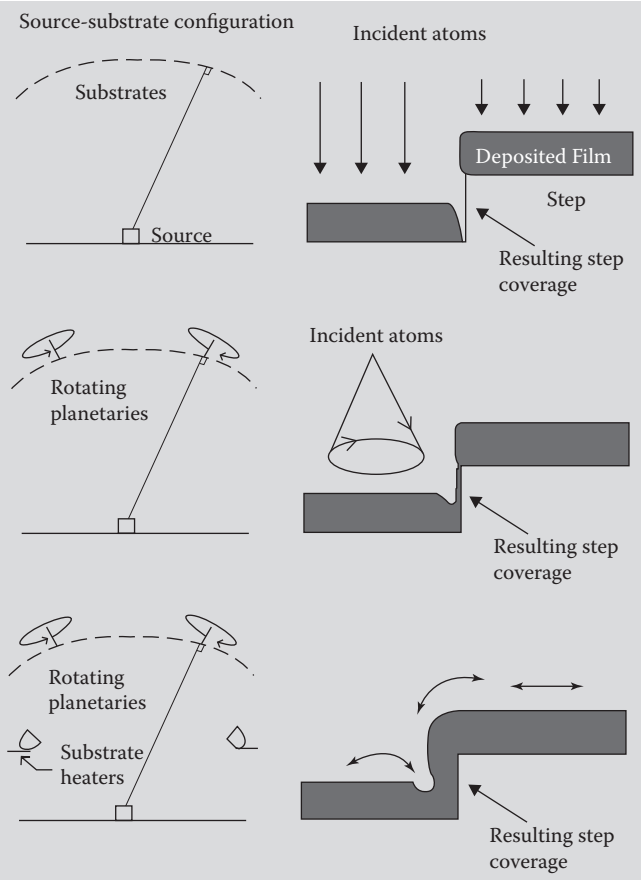

FIGURE 7.4 Shadowing effect may be overcome by using rotating planetaries and heating of the substrate.

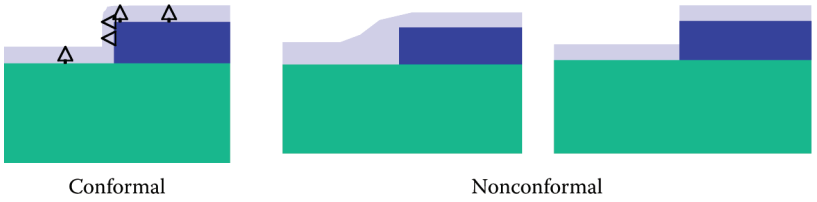

FIGURE 7.5 Illustration of conformal and nonconformal step coverage.

is a priority consideration. In chemical sensors, the surface purity of films is more important than the bulk resistivity (a criterion often used to evaluate IC films). As we just learned, evaporators emit material from a point source (e.g., a small tungsten filament), resulting in shadowing and sometimes causing problems with deposition, especially on high-aspect structures. Difficulties also arise for large areas where highly homogeneous films are required, unless special setups are chosen. A different problem to overcome arises from the source materials decomposing at high evaporation temperatures. Although this risk does not exist when evaporating pure elements, it becomes a problem in the evaporation of compounds and substance mixtures. The e-beam heating systems have an advantage here because only a small part of the metal source evaporates. The initial evaporant stream is richer in the higher-vapor-pressure component; however, the melt depletes that constituent locally, and eventually an equilibrium rate is established. The best way to deposit complex metal alloys is then to e-beam evaporate the metallic elements from different sources because modern quartz-crystal deposition rate monitors enable excellent control in alloy composition. To form oxides of the deposited metals, evaporation is performed in a low-pressure oxygen atmosphere. This process is known as *reactive evaporation*. The oxygen supply comes from a jet directed at the substrate during deposition. To obtain the correct stoichiometry, the deposition needs to take place on a heated substrate.

Evaporated thin films are usually under tensile stress, and the higher the material's melting point, the higher the stress. Tungsten and nickel, for example, can have stress in excess of 500 MPa, which may lead to curling or peeling.[3] Increasing the temperature of the substrate tends to lower the internal stresses in the thin film.

Theoretical film thickness profiles for deposition into an arbitrary-shaped cavity or trench can be calculated using a computer program named SAMPLE, which gives the thin film profile for particular input parameters (http://www.eecs.berkeley.edu/~neureuth).[4,5] In Figure 7.6a we show a SAMPLE result for the line-of-sight deposition in the case of reentrant side-wall angles. The program correctly predicts a discontinuity in the thin film lines in Figure 7.6b. In Figure 7.6c it is shown how, for the case of wafers rotating on a planetary system, step coverage is significantly improved. However, the solution is not perfect because a keyhole effect might result if too much material is deposited (Figure 7.6d).

Sputtering

During sputtering, the target (a disc of the material to be deposited), at a high negative potential, is bombarded with positive argon ions (other inert gases such as Xe can be used as well) created in a plasma (also glow discharge). The target material is sputtered away mainly as neutral atoms by momentum transfer, and ejected surface atoms are deposited (condensed) onto the substrate placed on the anode. The substrate must be placed close to the cathode and is usually heated to improve bonding of the coating atoms. A typical arrangement is shown in Figure 7.7.

Sputtering is preferred over evaporation in many applications because of a wider choice of materials to work with, better step coverage, and better adhesion to the substrate. Whereas vacuum evaporation is generally limited to metals, sputtering can be applied to nearly any material, both metallic and nonmetallic elements, alloys, ceramics, and polymers. Films of chemical compounds can also be deposited by using reactive gases that form oxides, carbides, or nitrides with the sputtered metal. Films of alloys and compounds can be sputtered without changing their chemical compositions. Sputtering

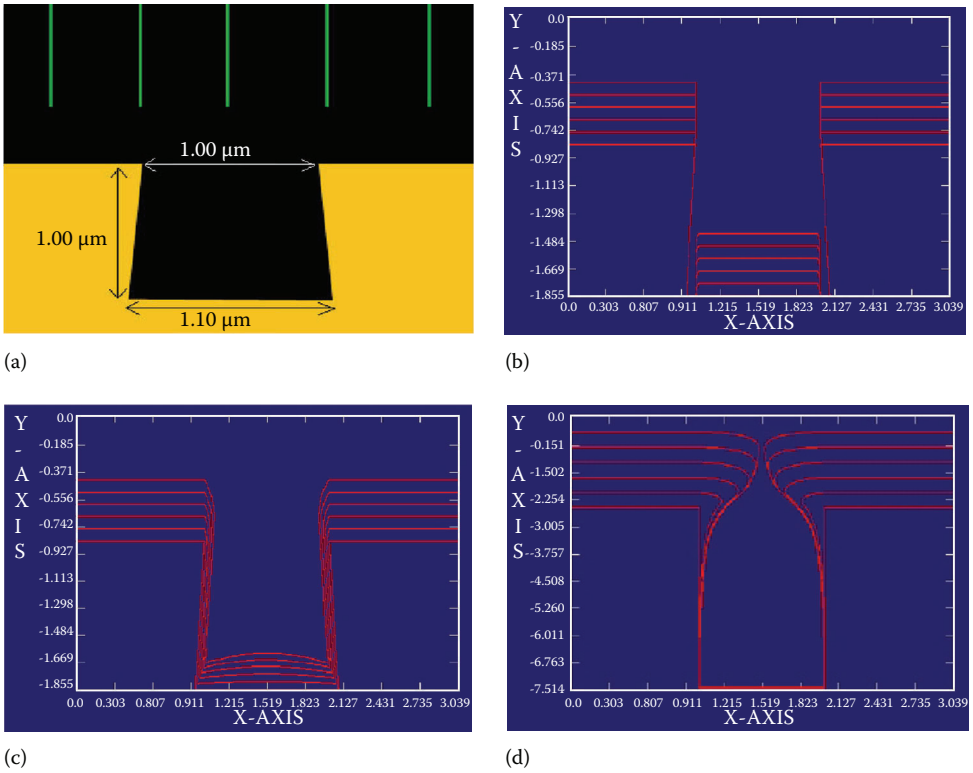

FIGURE 7.6 The SAMPLE computer program gives the thin film profile for particular input parameters (http://www.eecs.berkeley.edu/~neureuth). (a) dimensions of feature to be coated. (b) predicted line-of-sight deposition profile in the case of re-entrant side-wall angles. Notice the discontinuity in the thin film lines. (c) for wafers rotating on a planetary system, step coverage is improved. (d) the solution is not perfect, however, because a keyhole effect might result.

is used in laboratories and production settings, whereas evaporation mainly remains a laboratory technique. Other reasons to choose sputtering over evaporation can be concluded from a comparison of the two techniques in Table 7.4.

Because most aspects pertaining to the physics and chemistries of DC and RF plasmas were discussed in Chapter 3, we will only amplify these topics here as they apply to material deposition. During ion bombardment, the source is not purposely

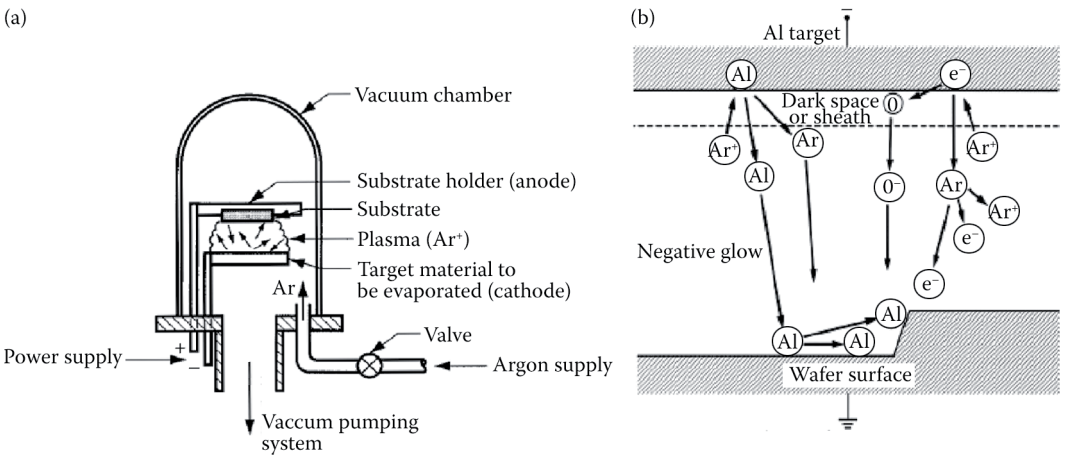

FIGURE 7.7 (a) One possible setup for sputtering, a form of physical vapor deposition. (b) Gas ions are accelerated by a high voltage, producing a glow discharge or plasma. A source (the *cathode*, also called the *target*) is bombarded in high vacuum by gas ions. Atoms from the target (Al in this case) are ejected by momentum transfer and move across the vacuum chamber. Atoms are deposited on the substrate to be coated and form a thin film.

Table 7.4 Comparison of Evaporation and Sputtering Technology

	Evaporation	Sputtering
Rate	Thousand atomic layers per second (e.g., 0.5 μm/min for Al)	One atomic layer per second
Choice of materials	Limited	Almost unlimited
Purity	Better (no gas inclusions, very high vacuum)	Possibility of incorporating impurities (low-medium vacuum range)
Substrate heating	Very low	Unless magnetron is used substrate heating can be substantial
Surface damage	Very low, with e-beam x-ray damage is possible	Ionic bombardment damage
In situ cleaning	Not an option	Easily done with a sputter etch
Alloy compositions, stoichiometry	Little or no control	Alloy composition can be tightly controlled
X-ray damage	Only with e-beam evaporation	Radiation and particle damage is possible
Changes in source material	Easy	Expensive
Decomposition of material	High	Low
Scaling up	Difficult	Good
Uniformity	Difficult	Easy over large areas
Capital equipment	Low cost	More expensive
Vacuum path	High: few collisions, line-of-sight deposition, little gas in film	Low: many collisions, less line-of-sight, gas inclusions
Number of depositions	Only one deposition per charge	Many depositions can be carried out per target
Thickness control	Not easy to control	Several controls possible
Adhesion	Often poor	Excellent
Shadowing effect	Large	Small
Film properties (e.g., grain size and step coverage)	Difficult to control, larger grain size, fewer grain orientations	Control by bias, pressure, substrate heat, smaller grain size, many grain orientations

heated to high temperature, and the vapor pressure of the source is not a consideration as it is in vacuum-evaporation. The amount of material, W, sputtered from the cathode is inversely proportional to the total gas pressure, P_T, and the anode-cathode distance, d[1]:

$$W = \frac{kVi}{P_T d} \tag{7.10}$$

where V = working voltage
i = discharge current
k = proportionality constant

Other energetic particles, such as secondary electrons, secondary ions and photons, and x-rays are created at the target and can be incorporated in the growing film and/or influence its properties through heating, radiation, or chemical reactions. Deposition rate is roughly proportional to sputter yield, S, for a given plasma energy. The sputter yield S, we saw in Chapter 3, stands for the average number of atoms removed per incident ion (S = number ejected/number incident) and is a function of the bombarding species (for example, with a heavier sputtering gas, S increases), the ion energy of the bombarding species, the target material, the incident angle of the bombarding species, and its electronic charge. Target atoms come off with a nonuniform distribution as shown in Figure 3.16, where we plot the sputter yield S as a function of θ, the angle at which ions are directed at the surface (0° is perpendicular and 90° is glancing). Sputtering is seen here to be most efficient at about 20–30° off glancing. In sputtering at energies <50 keV, the incoming ions are modeled as hard spheres colliding with the substrate, with 95% of the incident energy going into the substrate (that is why in sputter deposition cooling of the target is required!) and only 5% of the incident energy carried off by substrate/target atoms. Some yield figures for commonly used metals are tabulated in Table 7.5.[6] Sputtering yield is

Table 7.5 Sputter Yields of Several Commonly Used Metals with 500 eV of Argon

Element	Symbol	Sputter Yield S
Aluminum	Al	1.05
Chrome	Cr	1.18
Gold	Au	2.4
Nickel	Ni	1.33
Platinum	Pt	1.4
Titanium	Ti	0.51

low, usually from less than 1% up to 4% depending on the materials and ion energy level. Because of the low sputtering yield, sputter deposition rates are low (slow process). Another drawback is that because the ions bombarding the surface are embedded in a gas, traces of that gas can usually be found in the coated films; the entrapped gases sometimes adversely affect mechanical properties.

A typical sputter yield as a function of ion energy was shown in Figure 3.15.[1] In the low-energy region, the yield increases rapidly from a threshold energy. The sputter threshold, usually in the range of 10–130 eV, is essentially independent of the bombarding ion species used and equals about four times the activation energy for evaporation. This threshold voltage decreases with increasing atomic number within each group of the periodic table. Above a few hundred volts, a changeover region takes hold. Its value depends on the ion species and the target used, but after its occurrence the sputter yield increases more slowly. Ion energies in the range of 0.5–3 kV are typically used for sputter deposition because nuclear collisions are predominant in this range. In this region, the sputter yields typically range from 0.1–20 atoms per ion, and the yield of most metals is about 1 (see Table 7.5). An ion can only penetrate up to a certain depth into the target and still effect a recoil collision that can reach the surface with sufficient energy to eject atoms (e.g., 1 nm/kV penetration for argon ions in copper). Consequently, at ion bombardment energies in the range of 10 keV to 1 MeV, the sputter yield reaches a maximum and then gradually decreases in value as a result of deep ion implantation. Average ejection energies of ions from the target range between 10 and 100 eV. At those energies, the incident ion can penetrate a substrate one to two atomic layers into the surface on which it lands. As a result, the adhesion of sputtered films is superior to films deposited by other methods.[7] Although sputtering is basically a low-temperature process, considerable amounts of energy are dissipated at the target surface. To liberate one atom requires 100–1000 times the activation energy needed for evaporation, limiting useful sputtering rates to about one atomic layer per second (1000 times less than evaporation from a source operating at 10^{-1} Torr). The target needs water cooling because most of the energy, estimated at about 95%, dissipates into it, and excessive heating might result. Only 1% of the remaining energy goes into sputtering, and the rest is dissipated by secondary electrons that bombard and heat the substrate.

Figure 7.7 exemplifies a typical sputtering setup. Sputtering systems often have a load-lock connected to the sputtering chamber used for loading and unloading the substrates. With the use of a load-lock system, the sputtering station can be kept under continuous high vacuum; the target and chamber can be kept free of contamination from gaseous atmospheric components. Instead of pumping the large sputtering chamber, only the small load-lock chamber is pumped, resulting in a significant shorter cycle time.

To prevent sputtering of the structural elements of the cathode assembly, a shield of metal at anode potential is placed around all the surfaces to be protected at a distance less than that of the dark space at the cathode in Figure 7.8.[7] No discharge will

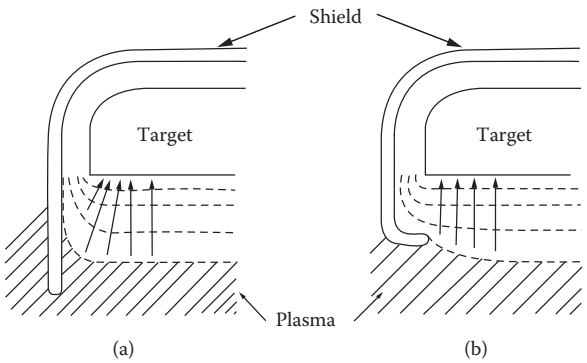

FIGURE 7.8 Sputtering: use of cathode shield. (a) Reducing rim effect by extending cathode shield. (b) Reducing rim effect by wrapping shield around the cathode. (From Maissel, L. I., and R. Glang, eds. 1970. *Handbook of thin film technology.* New York: McGraw-Hill.[7])

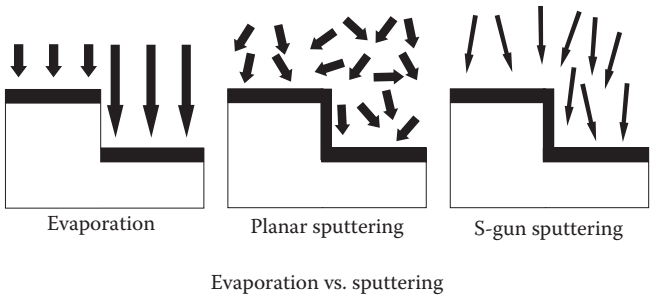

FIGURE 7.9 Sputtering leads to better step coverage than evaporation. (By Dr. Han Xu.)

take place between two surfaces that have a separation less than the Crookes cathode dark space (see Chapter 3).

Crucial to the formation of sustained DC plasma, as discussed in Chapter 3, is the production of ionizing collisions between secondary electrons released from the cathode and the gas in the sputtering chamber. In effect, this requires a relatively high working pressure of greater than 1×10^{-2} Torr. However, if the pressure is too high, significant numbers of the sputtered atoms cannot pass through the sputtering gas and are reflected back to the cathode by collisions. At 10^{-1} Torr, the mean free path of the sputtered metal atoms is about 1 mm, which is near the practical limit. Because of the multiple collisions of the metal atoms in the path between the cathode and anode, the metal atoms arrive at the anode at random incident angles. This leads to a better step coverage compared with evaporation (Figure 7.9). Furthermore, because the sputtering target is very broad compared with an evaporation point source, evidence of shadowing decreases drastically. Sputtering at low gas pressure leads to improved film adhesion because the sputtered atoms have a higher energy. Reduced pressure also reduces contamination of the film by trapped gas molecules, resulting in films of higher density and purity. The higher material density causes a slower chemical etch of the deposited film.

For conductors, a DC sputtering setup can be used. Insulating materials require an RF power supply. The two types of setups are schematically shown in Figure 7.10. Before sputter deposition, the substrate may be sputter etched by connecting it to the negative pole of the power supply. Sputter cleaning further promotes adhesion of subsequent metallizations. In situ cleaning can also be done efficiently with an ion gun.

As in dry etching, the plasma can be confined and densified by using electron cyclotron resonance (ECR) in a planar or cylindrical magnetron or an S-gun using a conical magnetron, which produces higher deposition rates than evaporation produced by electron beam (e-beam) or RF induction. Higher ion densities permit higher sputter rates at lower gas pressures (down to 0.5 mTorr). In a planar magnetron sputtering apparatus, the crossed electric and magnetic fields (magnets of 200 Gauss are put behind the target) contain the electrons and force them into long, helical paths, thus increasing the probability of an ionizing collision with an argon atom (see Figure 7.11). Furthermore, secondary electrons emitted by the cathode as a result of ion bombardment are bent by the crossed fields and are collected by ground shields. This eliminates the secondary electron bombardment of the substrates, which is one of the main sources of unplanned substrate heating. The deposition rate reaches hundreds of angstrom per minute. For some materials such as aluminum, the deposition rate can be as high as 1 μm/min. Magnetron sputter enhancement can be

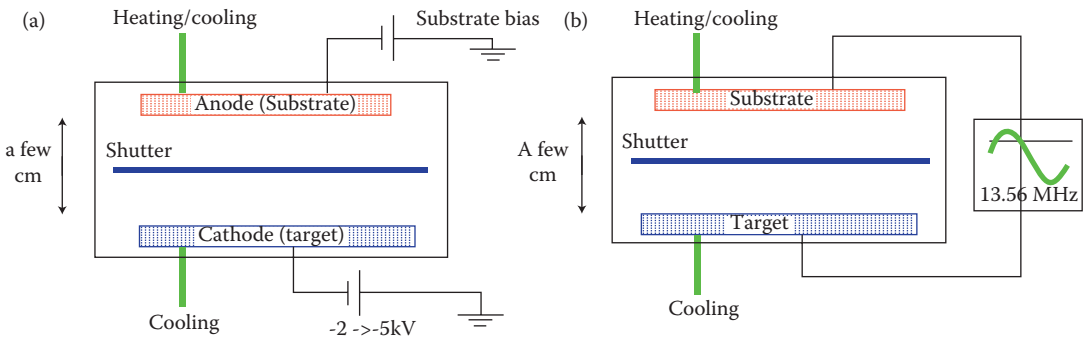

FIGURE 7.10 The DC (a) and RF (b) sputter deposition setups.

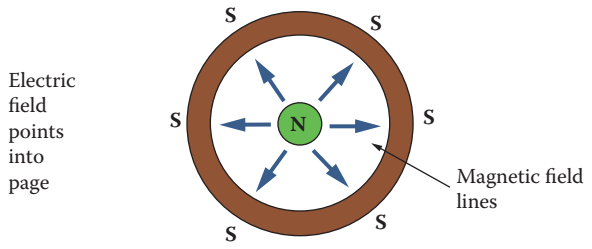

FIGURE 7.11 Magnets behind the target in a magnetron trap electrons near the cathode, causing more ionization near the cathode (10×) with fewer electrons reaching the substrate (less heating).

used in high-frequency sputtering systems, as well as in DC sputtering systems.

The substrate is also often heated to promote film adhesion and reduce film stress. Stress levels vary from compressive at low pressures (0.1–1 Pa) to tensile at high pressures (1–10 Pa). The transition regime between compressive and tensile is often sharp (more than a few tenths of Pa), making the crossover, an ideal point for zero-stress deposition, difficult to control.[3] In general, it is preferable to have ions strike the substrate while growing a film. The plasma ions add energy to the film and keep the surface atoms mobile enough to fill virtually every void. The influence of plasma on a depositing film is considered in more detail in the section on plasma-enhanced chemical vapor deposition (PECVD) further below.

Sputtering often is carried out in the presence of a reactive gas, ensuring control or modification of the properties of the deposited film in so-called *reactive sputtering*. A sensor material produced this way is IrO_X, a low-impedance pH-sensing material arrived at by sputtering from a pure Ir target with argon ions in the presence of oxygen.[8] The exact mechanism for compound formation in reactive sputtering still eludes researchers. It is conjectured that at low pressures the reaction takes place at the substrate as the film is being deposited. At high pressure, the reaction is believed to occur at the cathode with the compound transported to the substrate.

Composite films can also be made by cosputtering or by sputtering from a single composite target. Because the various elements in a target have different sputtering rates and sticking probabilities, the composition of the target might differ somewhat from that on the substrate. However, the decomposition is less significant than in evaporation because no thermal equilibrium is established at the target, and atoms are ejected by momentum transfer. High substrate temperatures are needed to obtain the right composition and to promote adhesion.

TABLE 7.6 Unique Characteristics of Sputter Deposition

Characteristics
Uniform thickness over large area
Simple thickness control (because it is so slow!)
The alloy composition maintains stoichiometry with the original target composition
Deposition rates do not differ a great deal from one material to another
Sputtering cleaning before initiating film deposition is possible; the surface is not again exposed to ambient after such cleaning
The lifetime of a sputtering target may be as long as hundreds of runs and is seldom less than 20

In Table 7.6 we list some of the salient characteristics of sputter deposition.

Nowadays, sputtering equipment applies films to compact discs, computer disks, large area active-matrix liquid crystal displays, and magneto-optic disks.[9] Bearing gears, saw blades, and so on also can be coated with a number of hard, wear-resistant coatings such as TiN, TiC, TiAlN, NbN, CrN, TiNbN, or CrAlN.[10] Commercial in-line sputtering equipment is available, enabling, in a series of evacuated chambers and load locks, depositions of insulators such as SiO_2, Si_3N_4, and Ta_2O_5, metals, and semiconductors such as indium tin oxide (ITO) on substrate with sizes of 830 × 1500 mm. Some example materials deposited by sputter deposition are listed in Table 7.7.

In one particular setup, one can perform continuous sputter deposition (Figure 7.12) on rolls

TABLE 7.7 Example Materials Deposited by Sputtering

Type of Material: Examples
Metals: Al, Cu, Zn, Au, Ni, Cr, W, Mo, Ti
Alloys: Ag-Cu, Pb-Sn, Al-Zn, Ni-Cr
Nonmetals: graphite, MoS_2, WS_2, PTFE
Refractory oxides: Al_2O_3, Cr_2O_3, Al_2O_3-Cr_2O_3, SiO_2, ZrO_2-Y_2O_3
Refractory carbides: TiC, ZrC, HfC, NbC
Refractory nitrides: TiN, Ti_2N, ZrN, HfN, TiN-ZrN, TiN-AlN-ZrN
Refractory borides: TiB_2, ZrB_2, HfB_2, CrB_2, MoB_2
Refractory silicides: $MoSi_2$, WSi_2, Cr_3Si_2

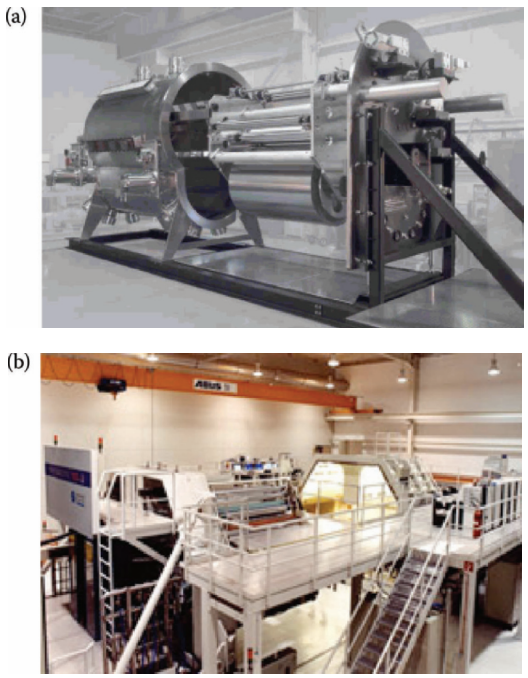

FIGURE 7.12 Continuous deposition. (a) Mill Lane offers systems for continuous vacuum web coating (http://www.mill-lane.com). (b) Innovative Sputtering Technology (I.S.T.), Belgium. Southwall Technologies (http://www.southwall.com) uses two-story high sputtering machines to manufacture transparent sputtered films on 2 m wide × 5,000 m long rolls of polyethylene terephthalate (PET) substrate that is 25 μm or 50 μm thick. One roll allows fabrication of up to 10,000 square meters of film.

of substrate, including foils and fabrics. In a high-vacuum chamber, the rolled substrate is unwound and passes over the cathode cylinder where thin layers of target material are deposited. The substrate is continuously rewound on the other side of the deposition site. The sputter target is a long cylinder, and reactive and nonreactive processes are available.[11] Roll-to-roll (R2R) manufacturing is currently used to print, for example, newspapers and labels. One envisions that many other products could be manufactured the same way. For example, organic light-emitting diodes (OLEDs) could be manufactured by patterning all layers with continuous deposition processes (web vs. batch). This would be potentially low cost and be scalable to large areas (see also Volume III, Chapter 1). Innovations like these might help revive the potential of micromachined chemical sensors for which Si batch processes are often too expensive. When manufacturing microfabricated chemical sensors, one often competes with continuous fabrication processes (e.g., continuous printing of glucose sensor paper strips), and classical Si micromachining cannot beat the cost advantages these offer. A process as described here, complemented by continuous lithography, might enable chemical microsensor fabrication at an acceptable cost (see Volume III, Chapter 1). A good reference on continuous, roll-to-roll thin film coating is *Vacuum deposition onto webs, films, and foils* by Charles A. Bishop (William Andrew Publishing, 2007).

The most negative aspects of sputtering are its complexity compared with an evaporation process, the excessive substrate heating resulting from secondary electron bombardment, and, finally, the slow deposition rate. In a regular sputtering process, the rate is one atomic layer per second versus thousand atomic layers per second available from a typical evaporation source at a vapor pressure of 10^{-1} Torr. Controls in a sputtering setup include argon pressure, flow rate, substrate temperature, sputter power, bias voltage, and electrode distance.

Example 7.1: Sputtered Polysilicon

The quest for low-temperature polysilicon deposition processes is driven in part by the need for compatibility with prefabricated aluminum-metallized complementary metal oxide semiconductor (CMOS) circuitry. This makes the 350°C sputter deposition of polysilicon especially interesting.

Honer et al.[12] introduced sputtered polysilicon to the MEMS community. Sputtered silicon can be used to fabricate polysilicon microstructures (the key mechanical structural element in surface micromachining; see section on Doped Polysilicon) atop standard, aluminum-metallized CMOS at temperatures less than 350°C. A drawback for sputtered boron doped Si films is that to increase their conductivity (to 25 Ω/□) they need to be clad in symmetric, 50-nm-thick layers of titanium-tungsten. Films with stress values less than 100 MPa are routinely obtained.

An important benefit of this low-temperature polysilicon process is that it is not only compatible with conventional oxide sacrificial layers (sacrificial layers, we shall see below, are another key ingredient in surface micromachining) but also with certain organic sacrificial layers (e.g., polyimide). Organic layers can be removed in a dry

oxygen plasma etch, thus avoiding the stiction and selectivity problems associated with wet etch releases and at the same time alleviating the concerns over chemical attack on structural elements by HF.

Ion Plating

In ion plating, evaporation of a material is combined with ionization of the atom flux by an electron filament or plasma. The principle of ion-plating in argon plasma is illustrated in Figure 7.13.[13] The substrate is set up to be the cathode in the upper part of the chamber, and the source material is placed below it. A vacuum is then established in the chamber. Argon gas is admitted, and an electric field is applied to ionize the gas (forming Ar^+) and establish plasma. This results in ion bombardment (sputtering) of the substrate so that its surface is atomic clean (interpret this as "very clean"). Next, the source material (Ti in the example case) is heated sufficiently to generate coating vapors. The heating methods used here are the same as those used in vacuum evaporation: resistance heating, e-beam bombardment, and so on. The Ti vapor passes through the plasma and coats the substrate. Sputtering is continued during deposition; thus, the ion bombardment of the substrate consists not only of the original argon ions but also of source material ions (Ti) that have been energized while being subjected to the same energy field as the argon. The effect of these processing conditions is to produce films of uniform thickness and excellent adherence to the substrate. Ion plating is applicable to parts with irregular geometries because of the high degree of scattering of the depositing material in the plasma. An example of interest here is TiN coating of high-speed cutting tools (for example, drill bits). As shown in Figure 7.13, the addition of a gas (nitrogen in this case) to the reactor enables one to make new compounds (such as TiN) on the substrate surface, with the gas reacting with the ionized atoms from the evaporation source (Ti). Because of the high kinetic energy of the impacting ions, a very well-adhering, dense TiN film with extraordinarily low friction coefficient and high hardness coefficient (Vickers hardness of 50,000) forms. Because of the thermal nature of the process, very high deposition rates can be achieved. In addition to coating uniformity and good adherence, other advantages of the process include high deposition rates, high film densities, and the capability to coat the inside walls of holes and other hollow shapes.

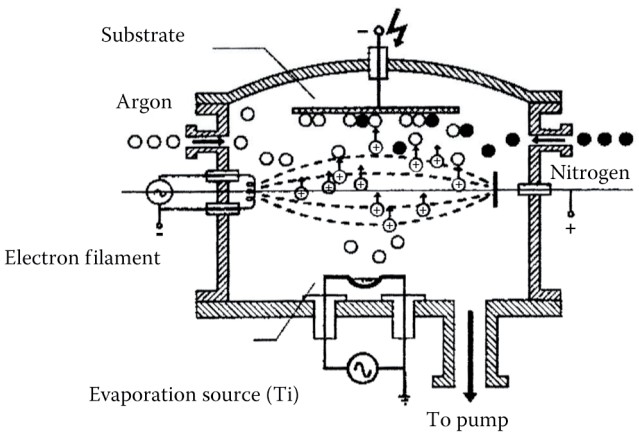

FIGURE 7.13 Principle of ion plating. (From Menz, W., and P. Bley. 1993. *Mikrosystemtechnik fur Ingenieure.* Weinheim, Germany: VCH Publishers.[13])

The NTH-1000 from Nanotec Corp. (http://nanotec-jp.com/www_nanotec/english/nth1000.html) uses a tandem hollow cathode discharge technique to deposit high-quality TiN, CrN, TiCN, and TiCrN thin films on cutting tools, machine parts, and molds.

Ion Cluster Beam Deposition—Nanoparticle Deposition

Clusters are aggregations of atoms or molecules, intermediate in size between individual atoms and aggregates that are large enough to be called *bulk matter.* Atom clusters are also called *nanoparticles* because their size is on the order of nanometers or tens of nanometers. The ultrasmall size of building blocks leads to dramatically different properties, and it is anticipated that such atomically engineered materials can be tailored to perform as no previous material could. T. Takagi, from Kyoto University, first proposed the idea of ionized cluster beam (ICB) thin film deposition in 1972. Conditions for formation of ion cluster beams, suitable for thin film deposition, were only established following an additional 20 years of effort. When applying cluster beam technology, ionized atom clusters (e.g., 100–1000 atoms) are deposited on a substrate in a high vacuum (10^{-5}–10^{-7} mbar). Those atom clusters typically

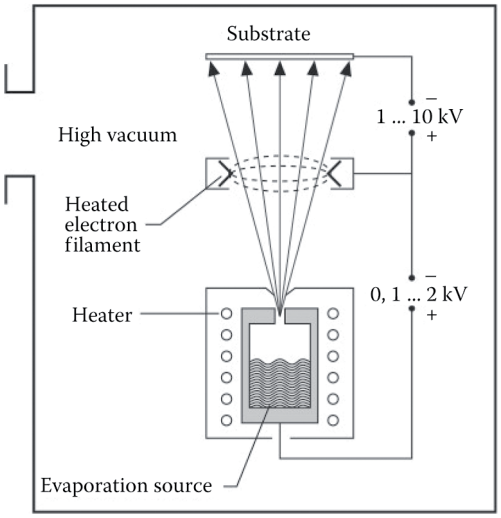

FIGURE 7.14 Setup for ion-cluster beam deposition. (From Menz, W., and P. Bley. 1993. *Mikrosystemtechnik fur Ingenieure.* Weinheim, Germany: VCH Publishers.[13])

carry one elementary charge per cluster and therefore achieve the same energy in an electrical field as would a single ion.

A special evaporation cell must be used to generate these atom clusters. As shown in Figure 7.14,[13] the heating of the evaporant in an evaporation cell with a small opening causes an adiabatic expansion of more than 100–10^{-5} or 10^{-7} mbar on exiting that cell. The expansion causes a sudden cooling, inducing the formation of atom clusters. These clusters are then partially ionized by an electron bombardment from a heated filament. Low-energy neutral clusters (0.1 eV) and somewhat higher energy ionized clusters (a few eV) arrive at the surface where they flatten and form a film (Figure 7.15)[13] of excellent adhesion and purity, with a relatively low number of defects. Cluster beam epitaxy is possible at temperatures as low as 250°C, and no charge buildup occurs when depositing on an insulator. Ion cluster beam technology qualifies as a gas-phase nanoparticle synthesis method. In gas-phase synthesis of nanoparticles supersaturation is achieved by vaporizing material into a background gas. Condensation to form particles is induced by cooling, e.g., by mixing with a cool gas or expansion through a nozzle. In ion cluster beam technology the cooling occurs when the vapor exits the evaporation cell. Other types of gas-phase nanoparticle fabrication techniques are discussed in Chapter 9 on thermal energy-based forming techniques.

The cluster beam technology is also applied to shallow ion implantation, high-yield sputtering, smoothing, surface cleaning, and low-temperature thin film formation. Cluster ion beam processing is now expanding into new industrial fields presently limited by the available atomic and molecular ion beam processes. With the wide variety of selective layers needed in chemical sensors and the frequent need for low-temperature deposition of thick, well-adhering layers, ion plating, laser sputter deposition (see below), and cluster beam technology seem destined to play a more crucial role in chemical sensor development in the future. Also, building devices from atomic constituents (bottom-up approach), with proximal probes for example, is too time consuming when performed one atom at the time. To speed up the process, massive parallelism is required; for example, by using an army of coordinated proximal probes. Cluster beam technology better enables nanomachining because the size of the building blocks lends itself to being built faster.

Epion (http://www.epion.com) is an example of a company selling ion cluster beam equipment, and their units feature surface smoothing to less than 3 Å, surface cleaning, and high-yield sputtering.

Pulsed Laser Deposition, Laser Sputtering, or Laser Ablation Deposition

Pulsed laser deposition (PLD) uses intense laser radiation to erode a target and deposit the eroded material onto a substrate. A high-energy focused laser beam avoids the x-ray damage to the substrate encountered with e-beam evaporation. A high-energy UV excimer laser pulse (10 ns) coming from, for example, a KrF laser at 248 nm with a pulse energy in the focus of 2 J/cm^2, is directed onto the material to be deposited, as sketched in Figure 7.16. As shown here, the laser ablates material from the target, forming a high-temperature vapor plume incident on the sample. The target may be just about anything, and one can operate at atmospheric pressures or in a very high vacuum.

The PLD process can be split into the following basic steps:

1. The energy of the very short wavelength radiation is absorbed in the upper surface of the target, i.e., absorption of the laser pulse in the material (for a metal, the absorption depth is ~10 nm, depending on λ).
2. Energy relaxation to the lattice through electron-phonon interaction (~1 ps).
3. Heat diffusion (microseconds), melting (tens of nanoseconds), and evaporation of a small amount of material.
4. Plasma creation.
5. Absorption of light by plasma and ionization.
6. Interaction of target and ablated species with plasma.
7. Cooling and resolidification between pulses.

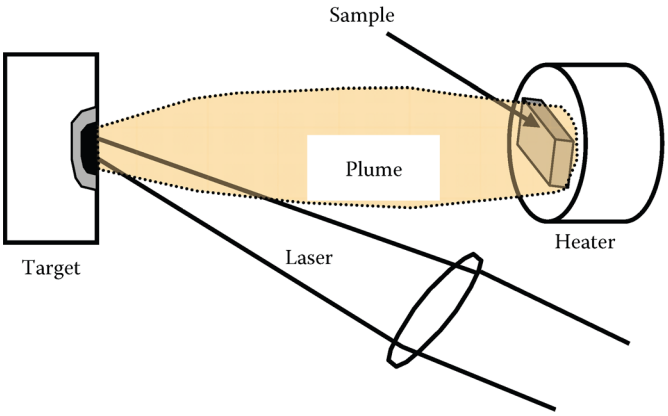

FIGURE 7.16 Schematic of pulsed laser deposition (PLD).

Laser ablation is a very nonequilibrium process. At the peak of the laser pulse, temperatures on the target can reach >10^5 K (>40 eV!) with electric fields >10^5 V/cm (accompanied by high magnetic fields) and plasma temperatures of 3000–5000 K. The ablated species come with energies in the 1–100-eV range.

Laser ablation deposition was first mentioned in Chapter 5, under thermal removing techniques, where we learned that laser subtractive machining leaves an undesirable heat-affected zone (HAZ) on a surface that is being machined. The size of the HAZ is a function of the laser pulse duration and the thermal conductivity and specific heat of the work piece. The HAZ constitutes a problem in the case of laser subtractive machining because it degrades the quality of the cut. Moreover, during the ablation process, the expulsion of material in the plasma jet redeposits material onto the surrounding region, further compromising the fidelity of the process. In the case of PLD, we take advantage of this deposition of materials from the plume onto an adjacent substrate surface.

Splashing is the bane of PLD. The laser superheats the subsurface layer before the surface reaches its evaporation point, and, as a consequence, the surface breaks apart into large (micrometer-sized) globular particles when the subsurface expands. This leads to globular deposits. Another problem with PLD is the expansion of the plume, which causes a sudden decrease in the pressure just above the surface. This shock wave pulls droplets of liquid of the surface. The thermal shock also causes irregularities in the surface to break off (exfoliation). Advantages and disadvantages of PLD are summarized in Table 7.8.

As we saw in Chapter 5 with ultrashort laser pulses (<1 ps), so much energy is deposited in the material at such a fast rate that the material is forced directly into a plasma state; the material goes from a solid to a gas phase without first going through a melt phase. The reason behind this is that pulse width is now shorter than the electron lattice-relaxation time; thus, the heat diffusion and melting are significantly reduced. This plasma then expands away from the material as a highly energetic gas, taking almost all the heat away with it. This leads

TABLE 7.8 Advantages and Disadvantages of Pulsed Laser Deposition (PLD)

Advantages	Disadvantages
Flexible, easy to implement	Uneven coverage
Growth in any environment	High defect or particulate concentration
Exact transfer of complicated materials (YBCO)	Not well suited for large-scale film growth
Variable growth rate	Mechanisms and dependence on parameters not well understood
Epitaxy at low temperature	Uneven coverage
Resonant interactions possible (i.e., plasmons in metals, absorption peaks in dielectrics and semiconductors)	Splashing as a result of subsurface boiling, shock wave recoil, exfoliation
Atoms arrive in bunches, allowing for much more controlled deposition	
Greater control of growth (e.g., by varying laser parameters)	

Source: Based on *Pulsed laser deposition of thin films.* New York: John Wiley and Sons, 1994.[230]
The table does not take into account pulsed laser deposition with ultrafast pulses improving the technique a lot, for example, smoother films result.

not only to cleaner cutting but also smoother film deposition (fewer particulates, less splashing) and the potential for ultrahigh quality films, circuit writing, isotope enrichment, new materials, and nanoparticle production.

The ablated material, partially ionized in the laser-induced plasma, is deposited onto a substrate almost without decomposition. This technique is particularly useful when dealing with complex compounds, as in the case of the deposition of high-temperature superconductor films (HTSCs), for example, $YBa_2Cu_3O_{7-x}$. PLD faithfully replicates the atomic ratios present in the hot isostatically pressed target disc onto the thin film coating. Achieving complex stoichiometries presents more difficulties with any other deposition technology. Approximately 10,000 pulses (pulse length of 20 ns and a repetition rate of 15 pulses/s) are needed to achieve a film thickness of 0.1 µm on the substrate. Normally, the laser-deposited films are amorphous. The energy necessary to crystallize the film comes from heating the substrate 700–900°C and from the energy transferred from the intense laser beam to the substrate via atomic clusters.

Figure 7.17a shows a schematic setup of a laser deposition system.[14] Here, a pulsed excimer laser is used to deposit superconductor materials such as those based on YbaCuO.[14] Figure 7.17b shows an improved laser deposition setup where substrate heating can be replaced in part or completely by

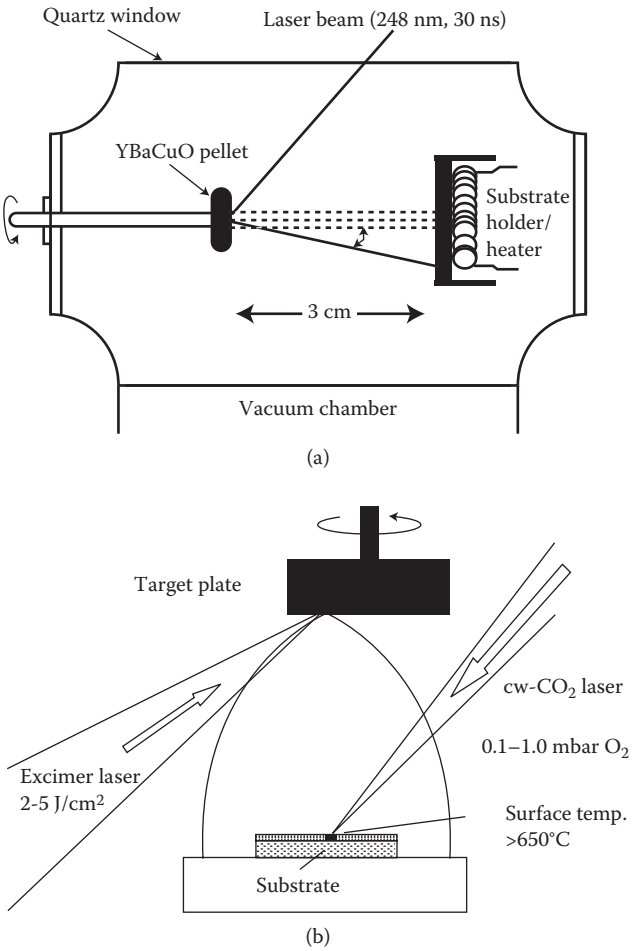

FIGURE 7.17 Laser deposition system. (a) Traditional laser ablation system. (From Dutta, B., X. D. Wu, A. Inam, and T. Venkatesan. 1989. Pulsed laser deposition: a viable process for superconducting thin films? *Solid State Technol* February:106–10. With permission.[14]) (b) Laser ablation with additional laser for surface heating.

additional laser radiation, in this case, a continuous wave-CO_2 (cw-CO_2) infrared laser. With this setup, using two crossed laser beams, it is possible to deposit and induce the correct crystalline structure in the growing HTSC film while it is being deposited.[15] Superconductive Components Inc. manufactures superconducting and nonsuperconducting ceramic targets for use in sputtering and laser ablation systems (http://www.superconductivecomp.com/targets2.html).

A sensor-related application of PLD is the protection of components in contact with body fluids using the biocompatible calcium-phosphate-based ceramic calcium hydroxylapatite, or $Ca_{10}(PO_4)_6(OH)_2$. This material exemplifies the most stable calcium phosphate in contact with body fluids. Deposition methods of this material include sputtering, plasma spraying, electrophoretic deposition, and combinations of these techniques. In all cases, a postdeposition treatment is needed to crystallize the partially or wholly amorphous and/or dehydrated films. With the laser pulse technique, in water-vapor-enriched inert gas environments, deposition of the right hydroxyl apatite was observed at temperatures between 400 and 700°C. Adhesion of this material to Si and Ti-6Al-4V was found to be excellent.[16] Laser sputtering also could help prepare complex and stoichiometry-sensitive coatings such as electrochromic devices.

Pulsed laser ablation, like ion cluster beam deposition, can also be used as a nanoparticle gas-phase synthesis method. In this approach the solid precursor is heated by absorption of laser energy. Typically an infrared laser (CO_2) is used, and laser energy may be directly absorbed by precursors or by an inert photosensitizer (SF_6). The use of a pulsed laser shortens the reaction time and allows for the preparation of the smallest particles. In 1995, at Rice University it was reported that synthesis of carbon nanotubes could be accomplished by laser ablation.[17] A pulsed or continuous laser is used to vaporize a graphite target placed in an oven at 1200°C (Figure 7.18). The oven is filled with argon gas to keep the pressure at 500 Torr. A very hot vapor plume forms, which then expands and cools rapidly. Contact with a cooled copper substrate causes the carbon atoms to be deposited in the form of nanotubes.

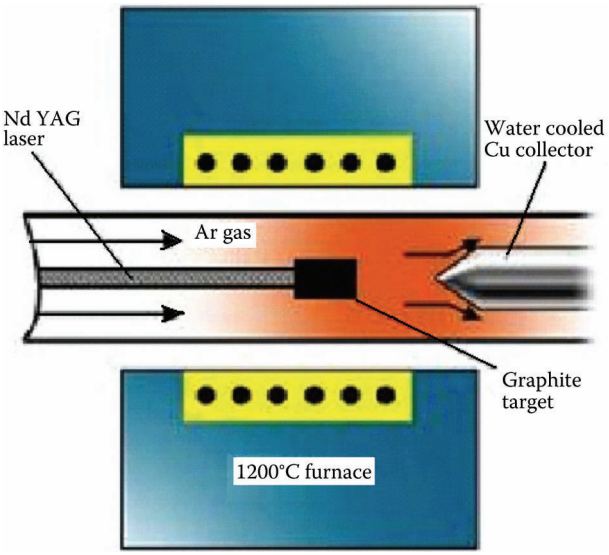

FIGURE 7.18 Laser ablation system for carbon nanotube production.

Laser vaporization produces a higher yield of single-walled nanotubes (SWNTs) with better properties and with a narrower size distribution than nanotubes produced by arc discharge. Laser ablation also produces nanotubes that are more pure (up to 90% purity) than those produced by arc discharge.

Pulsed laser deposition (PLD) with ultrafast pulses (<1 ps) is opening up all types of new research and application opportunities as evidenced by the Defense Advanced Research Projects Agency's (DARPA's) mesoscopic integrated conformal electronics (MICE) program. The goal of that program is to create electronic circuits and materials on any surface, e.g., to print electrical circuits on the frames of eyeglasses or interwoven with clothing (see Figure 7.19). MICE efforts have demonstrated the ability to print metal lines on curved surfaces, feature sizes as small as 5 μm, and print speeds close to 1 m/s. Other exciting developments include the demonstration of 1) printed zinc-air batteries that have four times more volumetric power density than commercial batteries, 2) direct-write antennas, and 3) direct-write solar cells. A single laser does surface pretreatment, spatially selective material deposition, surface annealing, component trimming, ablative micromachining, dicing, and via drilling.

To sum up, laser ablation is a good technique for preparing thin films of any desired stoichiometry,

FIGURE 7.19 Direct writing in air with pulsed laser deposition (PLD).

but, because of the small source size, it is not useful for large-scale coatings. A small source size might make it essential, especially when working with high-aspect-ratio micromachined structures, to rotate the sample at an angle with respect to the material flux so as to obtain coverage of the vertical features in the device. The possibility of using PLD for nanoparticles and carbon nanotubes and the use of PLD with ultrashort laser pulses (<1 ps) has given the technique an added impetus. For further reading on laser sputtering, refer to references 14–16,18,19.

Epion, for example, sells large-area PLD systems (http://www.pvdproducts.com/products/pld_systems.aspx).

Molecular Beam Epitaxy

Epitaxial techniques arrange atoms in single-crystal fashion on a crystalline substrate acting as a seed crystal so that the lattice of the newly grown film duplicates that of the substrate. If the film is of the same material as the substrate, the process is called *homoepitaxy*, *epitaxy*, or simply *epi*. Epi deposition represents one of the cornerstone techniques for building micromachines. Of special importance is that Si membranes of a predetermined thickness and doping level can be fashioned. The growth rate of an epilayer depends on the substrate crystal orientation. Si (111) planes have the highest density of atoms on the surface, and the film grows most easily on these planes. Important epi applications are Si on Si substrates and GaAs on GaAs substrates. If the deposit is made on a chemically different substrate, usually of closely matched lattice spacing and thermal expansion, the process is termed *heteroepitaxy*. One important heteroepitaxy application is the deposition of silicon on insulator (SOI), for example, Si on SiO_2 or Si on sapphire (Al_2O_3). Various sapphire orientations such as $<01\bar{1}2>$, $<10\bar{1}\,2>$, and $<1\,\bar{1}02>$ have been used to grow <100>-oriented silicon layers. The lattice mismatch between sapphire and silicon crystals limits the thickness of the Si to about 1 μm. Another example of heteroepitaxy is that of gallium phosphide on gallium arsenide.

Various types of epitaxy techniques exist. Chemical vapor phase and liquid epitaxy are described further below. Here, we briefly discuss PVD epitaxy, that is, molecular beam epitaxy (MBE), invented in late 1960s at Bell Laboratories by J. R. Arthur and A. Y. Cho. In MBE, the heated single-crystal sample (e.g., between 400 and 800°C) is placed in an ultrahigh vacuum (10^{-11} Torr) in the path of streams of atoms from heated cells that contain the materials of interest. These atomic streams impinge, in a line-of-sight fashion, on the surface-creating layers with a structure controlled by the crystal

structure of the surface, the thermodynamics of the constituents, and the sample temperature. This technique is the most sophisticated form of PVD. The deposition rate of MBE is very low (i.e., about 1 μm/h or 1 monolayer/s), and considerable attention is devoted to in situ material characterization to obtain high-purity epitaxial layers. Once on the substrate, the atoms or molecules move around until they find an atomic site to chemically bond to. Fast-acting shutters control the deposition. One or two atomic layers of material lie between the shutter action. This becomes important when an ultrasharp profile is called for. The low deposition rate gives the operator better control over the film thickness. Ultrasharp profiles are needed, for example, when making quantum well devices. A quantum well might be 40 Å thick. To uniquely define its energy levels it must be 40 ± 2 Å. Figure 7.20 represents a schematic of a molecular beam deposition setup.[1]

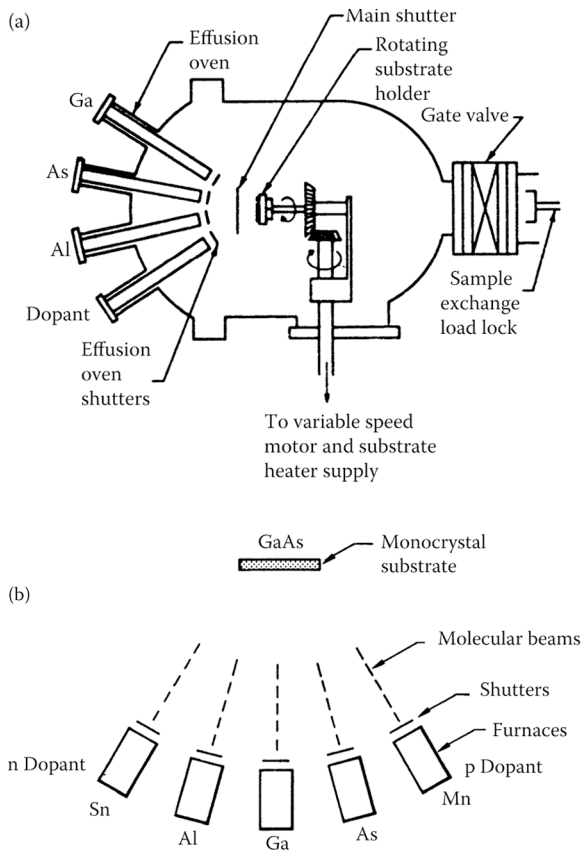

FIGURE 7.20 (a) Schematic of molecular beam epitaxy growth chamber. (b) Example is the growth of GaAlAs epi on GaAs single crystal. (From Brodie, I., and J. J. Muray. 1982. *The physics of microfabrication.* New York: Plenum Press. With permission.[1])

TABLE 7.9 Key Points in MBE

Characteristics
Ultrahigh vacuum
High purity layers with good crystal structure
No chemical byproducts created at growth surface
High uniformity (<1% deviation)
Often uses multiples sources to grow alloy films
High control of composition
Growth rates are very low (0.1–10 μm/h)
In situ monitoring and feedback
Expensive
Mature production technology

The technique has several potential advantages over CVD epitaxy (see next section): for example, the relatively low growth temperatures reduce diffusion and autodoping effects. Precise control of layer thickness and doping profile on an atomic layer level is possible. Novel structures such as quantum devices, silicon/insulator/metal sandwiches, and superlattices can be made. Today, half of the lasers that are used in CD players, as well as those in pen-sized laser pointers, are grown by MBE. Figure 7.20 shows the deposition of n- and p-type GaAlAs on a GaAs single-crystal surface.[20] With MBE, virtually any device structure can be made. The limitations to consider lie in volume manufacturing and cost. The ultrahigh vacuum requirements make operation very expensive. From the available epi techniques, MBE exemplifies one that is perhaps the most complicated.[21] In Table 7.9 we review the key points concerning MBE, and in Figure 7.21 we show a typical commercial MBE station.

FIGURE 7.21 Typical MBE system photo.

Aerosol Deposition—Impact Deposition

Aerosol deposition (AD) is a mechanical film fabrication method invented in 1997 by Dr. Jun Akedo of the National Institute of Advanced Industrial Science and Technology (AIST) in Japan.[22] In Figure 7.22 we illustrate the overall configuration for film fabrication using AD, together with electron micrographs of raw powder and a resulting AD film.

Raw powders with an average powder diameter of 600 nm are mixed and vibrated with a carrier gas to form an aerosol. By using the pressure difference between the aerosol and a vacuum chamber, the aerosol is sprayed from a nozzle and impacted onto a substrate. Using this simple process, AD films with ultrafine crystalline particles of several tens of nanometers can be formed as shown in the cross-sectional image of the AD film in Figure 7.22. The impact of solid-state particles creates a strongly adherent, high-density nanocrystalline film by gas blasting the nanosized particles onto the surface. The deposition rate is 30 times faster (10 μm/min) than traditional deposition rates and can be carried out even at room temperature. The formation mechanism is assumed to be room-temperature shock-compaction. The impacting 600-nm particles are deformed and fractured into nanocrystalline structures of 10–30-nm size. Uniform deposition rates over a 200-mm square area have been achieved. The raw powders may be manufactured by conventional processing methods for most materials.

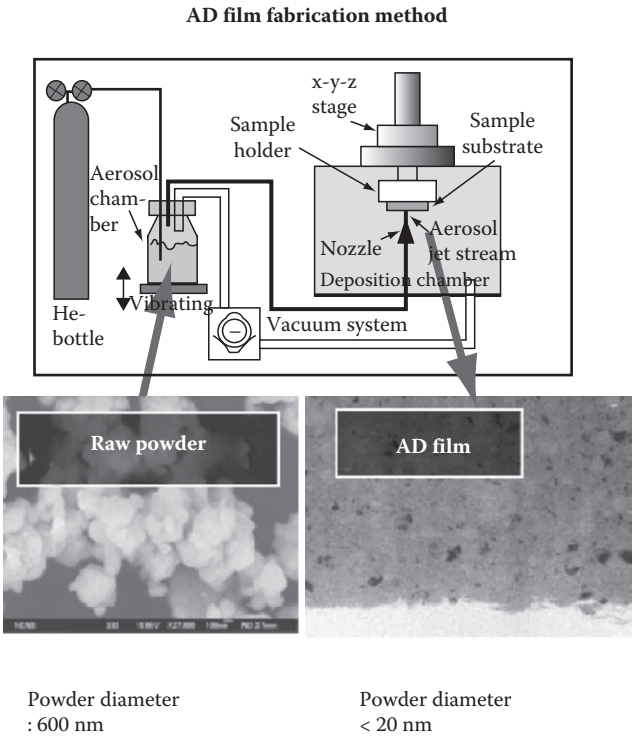

FIGURE 7.22 Schematic illustration of aerosol deposition (AD), powder, and a resulting AD film [solid solution of PNN (lead nickel niobate) and PZT (lead zirconate titanate)]. (http://www.nec.co.jp/techrep/en/journal/g07/n01/070115.html)

The two most important distinguishing characteristics of the AD process are that 1) the deposited films maintain the crystalline properties of the raw powder even at low deposition temperatures, and 2) relatively thick films can be produced fast. This stands in stark contrast to the thin film-forming methods such as sputtering, molecular beam epitaxy (MBE), and chemical vapor deposition (CVD). When these latter methods are used to deposit a material at low temperatures, for example, a piezoelectric material (typically an oxide with a perovskite crystalline structure) onto a substrate such as glass, an amorphous layer results, and all piezoelectric properties are lost. To maintain the piezoelectric function of this material, it is essential to retain the perovskite crystalline structure. To achieve this, one relies on the surface energy of the substrate and a temperature high enough for the atoms to be rearranged to form the desired perovskite oxide film. In this type of deposition process, restructuring the particles in the crystallization process occurs at the atomic level and far from equilibrium, inducing many lattice defects that result again in the degradation of the piezoelectric effect.

For many piezoelectric actuator applications, a film, several micrometers thick, is essential to output sufficient mechanical energy for a given electrical input. When a thick film of more than several micrometers is formed onto a substrate with the conventional thin film-forming technologies, various problems often occur: the speed of film forming is not fast enough, composition tends to vary, too much heat is required to crystallize the film limiting the choice of substrates, and so on. Because of these concerns, the conventional thin film-forming technologies have been used only for limited applications, such as for thin film sensors. In case thicker films are required, bulk-type piezoelectric ceramics

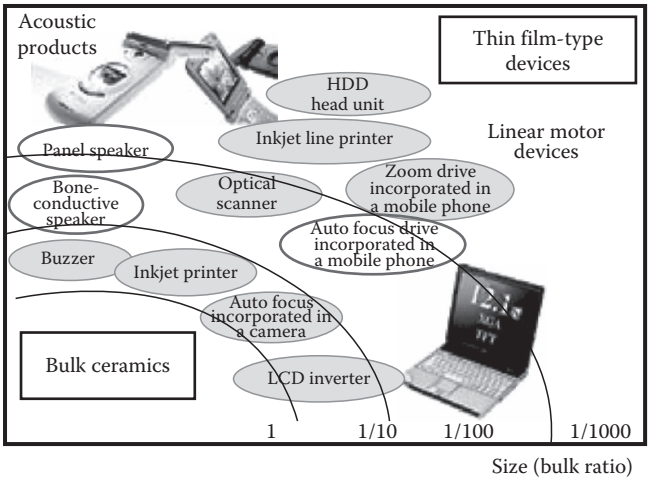

FIGURE 7.23 Use of piezoelectrics in consumer products. (http://www.nec.co.jp/techrep/en/journal/g07/n01/070115.html.)

made of sintered powders have usually been adopted (see Figure 7.23).

Screen-printing of piezoelectrics is a thick-film technique that, in principle, could cover the meso-range between bulk ceramics and thin films. In screen-printing one uses a mixture of ceramic powder and binder to make an ink. After screen-printing, the ink is fired at 1000°C or more (screen-printing of ceramics is a thermal additive technique covered in Chapter 9). This limits this technology to ceramic substrate materials.

As suggested in Figure 7.23, thick film-formed piezoelectric devices integrated onto a substrate will be essential for many piezoelectric actuators of the future, such as in sound equipment and for products that require a high-precision positioning motion. The AD method is a film fabrication method that can fulfill that need. Piezoelectric AD results in nanocrystalline films that preserve a large dielectric and piezoelectric effect and that are little influenced by the underlying layers and/or substrates. For example, by using ceramic particles that feature chemically unstable surface characteristics, AD technology has been used to form ceramic films at room temperature on resin circuit boards to which ceramic is usually difficult to adhere. The maximum dielectric constant of the newly created ceramic film was 400, i.e. 10 times the dielectric constant of ceramic combined with resin, and is approximately at the same level as that of ceramic film made with the sputtering method that uses heat treating at a high temperature of 600°C. A condenser composed of three layers was also successfully created on an FR4 printed circuit board. The capacitance of the newly created condenser was 300 nF/cm^2, a high level that is ideal for practical use (http://www.nec.co.jp/techrep/en/journal/g07/n01/070115.html).

From the above, the AD method is an excellent candidate for the fabrication of piezoelectric thick film actuators for the manufacture of micropumps, ultrasonic mixers in microelectromechanical systems (MEMS) and micrototal analysis systems (μ-TAS), micromanipulators for medical applications, ink-jet printer heads, flapper actuators for high-density hard disk drives, and other applications where large strains and high-speed response are necessary (see Figure 7.23).

An AD of a solid solution of PNN (lead, nickel, and niobate) and PZT (lead zirconate titanate) was attempted on zirconate ceramics and stainless steel substrates. Zirconate ceramics have good high-temperature resistance and stainless steel features, superior corrosion resistance, and processability that lead to low-cost manufacturing of practical piezoelectric devices. The AD film-forming process was carried out at room temperature with a deposition rate of 10 μm/min or higher over an area of 10×10 mm^2. These process conditions confirm that this process is amenable to mass production. Figure 7.24 shows a comparison of the film properties between the piezoelectric film formed by the AD and the conventional film deposition method. The piezoelectric film fabricated by AD showed a piezoelectric constant (–d31) of 158 mp/V on a stainless substrate, which is almost the same value as that of film fabricated by conventional film-forming technology. On a zirconate substrate, 360 pm/V was achieved, which is similar to that for bulk ceramics. As shown in Figure 7.24, where we plot the piezoelectric constant as a function of film thickness of the actuator, AD covers a broad range of thicknesses—between bulk ceramic material and thin film—with a better piezoelectric constant than screen printing (http://www.nec.co.jp/techrep/en/journal/g07/n01/070115.html).

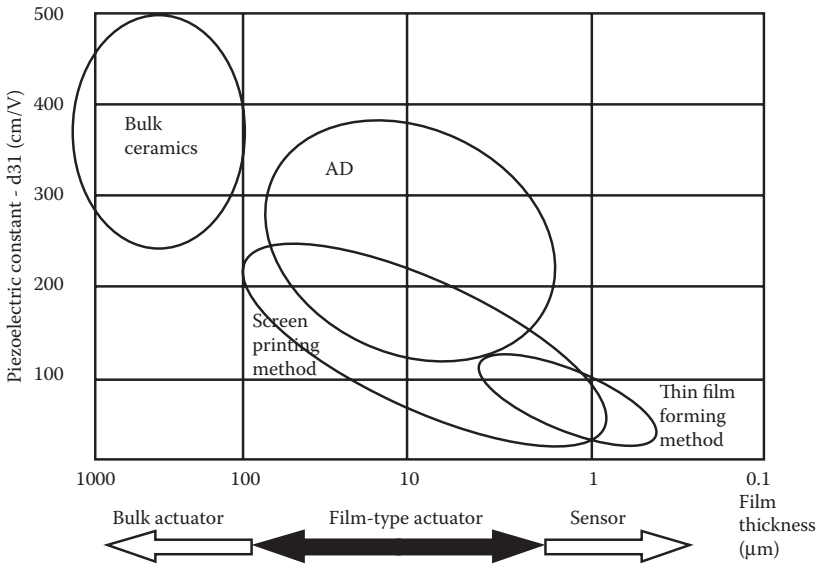

FIGURE 7.24 Plot of the piezoelectric constant (–d31) as a function of film thickness of the actuator [solid solution of PNN (lead nickel niobate) and PZT (lead zirconate titanate)] and manufacturing means. AD covers the thickness range between bulk and thin film. (Based on http://www.nec.co.jp/techrep/en/journal/g07/n01/070115.html by Dr. Han Xu.)

Chemical Vapor Deposition

Introduction

Chemical vapor deposition (CVD) is one of the principal thin film manufacturing options. In Figure 7.25 we show how thin film processes fit in the overall IC fabrication scheme. In the case of thin film of silicon dioxide, if the surface of the wafer is silicon (e.g., at the start of IC fabrication), then thermal oxidation is the appropriate process by which to form a layer of SiO_2. If the oxide layer must be grown over materials other than silicon, such as aluminum or silicon nitride, then an alternative technique must be used, such as CVD. During CVD, the constituents of a vapor phase, often diluted with an inert carrier gas, react at a hot surface (typically higher than 300°C) to deposit a solid thin film. In CVD, the diffusive-convective transport to the hot substrate surface involves many intermolecular collisions, and mass and heat transfer modeling of deposition rates is consequently much more complex than in PVD. Chemical vapor deposition of SiO_2 is accomplished by reacting a silicon compound such as silane (SiH_4) with oxygen onto a heated substrate. The reaction is carried out at around 425°C and can be summarized by:

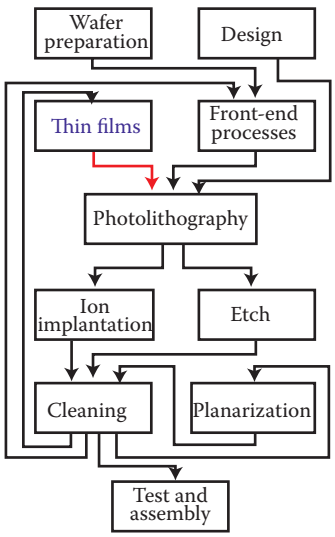

FIGURE 7.25 Thin films. CVD is a broad class of processes using controlled chemical reactions to create thin films on substrates. A variant of CVD, called *plasma-enhanced chemical vapor deposition* (PECVD), uses gas plasma to lower the temperature required to obtain a chemical reaction and achieve film deposition.

$$SiH_4 + O_2 \rightarrow SiO_2 + 2H_2 \qquad \text{Reaction 7.1}$$

The density of a CVD silicon dioxide film and its bonding to the substrate are generally poorer than that achieved by thermal oxidation. Consequently, CVD is used only when the preferred process is not feasible: when the substrate surface is not silicon or when the high temperature used in thermal oxidation cannot be tolerated.

In the CVD reaction chamber, the reactants are adsorbed on the heated substrate surface, and the adatoms undergo a series of processes resulting in film formation. When a molecule has reached the surface, the required reaction analysis is the same, regardless of deposition method. The molecular phenomena at the surface to be considered include sticking coefficient, surface adsorption, surface diffusion, surface reaction, desorption, and film or crystal growth. Gaseous byproducts are desorbed and removed from the reaction chamber. The reactions forming a solid material do not always occur on or close to the heated substrate (heterogeneous reactions) but can also occur in the gas phase (homogeneous reactions). As homogeneous reactions lead to gas-phase cluster deposition and result in poor adhesion, low density, and high defect films, heterogeneous reactions are preferred. The slowest of any of the CVD steps mentioned, the gas phase or surface process determines the rate of deposition. The sample surface chemistry, its temperature, and thermodynamics determine the compounds deposited. The most favorable end product of the physical and chemical interactions on the substrate surface is a stoichiometric-correct film. Several activation barriers need to be surmounted to arrive at this end product. Some energy source, such as thermal, photon, or ion bombardment, is required to achieve this.

The CVD method is very versatile and works over a wide range of temperatures and pressures. Amorphous, polycrystalline, epitaxial, and uniaxially oriented polycrystalline layers can be deposited with a high degree of purity, control, and economy. CVD is used extensively in the semiconductor industry and has played an important role in transistor miniaturization, for example, by introducing very thin film deposition of silicon. More recently, CVD copper and low dielectric insulators ($\varepsilon < 3$) also have become important CVD applications. CVD embodies the principal building technique in surface micromachining (see section on Doped Polysilicon). Modern interest in CVD is also focused on coating applications, such as coated carbide tools, solar cells, depositing refractory metals on jet engine turbine blades, and other applications where resistance to wear, corrosion, erosion, and thermal shock

Table 7.10 Example CVD Reactions

Process Description Reaction
1. The Mond process includes a CVD process for decomposition of nickel from nickel carbonyl [$Ni(CO)_4$], which is an intermediate compound formed in reducing nickel ore: $$Ni(CO)_4 \xrightarrow{400\,°F\,(200\,°C)} Ni + 4CO$$
2. Coating of titanium carbide (TiC) onto a substrate of cemented tungsten carbide (WC-Co) to produce a high-performance cutting tool: $$TiCl_4 \xrightarrow{1800\,°F\,(1000\,°C),\ excess\ H_2} TiC + 4HCl$$
3. Coating of titanium carbide (TiC) onto a substrate of cemented tungsten carbide (WC-Co) to produce a high-performance cutting tool: $$TiCl_4 + 0.5N_2 + 2H_2 \xrightarrow{1650\,°F\,(900\,°C)} TiN + 4HCl$$
4. Coating of aluminum oxide (Al_2O_3) onto a substrate of cemented tungsten carbide (WC-Co) to produce a high-performance cutting tool: $$2AlCl_3 + 3CO_2 + 3H_2 \xrightarrow{900\,°F\,(500\,°C)} Al_2O_3 + 3CO + 6HCl$$
5. Coating of silicon nitride (Si_3N_4) onto silicon (Si), a process in semiconductor manufacturing: $$3SiF_4 + 4NH_3 \xrightarrow{1800\,°F\,(1000\,°C)} Si_3N_4 + 12HF$$
6. Coating of silicon dioxide (SiO_2) onto silicon (Si), a process in semiconductor manufacturing: $$2SiCl_3 + 3H_2O + 0.5O_2 \xrightarrow{1600\,°F\,(900\,°C)} 2SiO_2 + 6HCl$$
7. Coating of the refractory metal tungsten (W) onto a substrate, such as a jet engine turbine blade: $$WF_6 + 3H_2 \xrightarrow{1100\,°F\,(600\,°C)} W + 6HF$$

Table 7.11 Comparison of a Typical PVD Method (Sputtering) with a CVD Method

	PVD	CVD
Example processes	Sputtering	PECVD
Advantages	Clean process Easy to control composition Easy mechanism Good adhesion Safe process High deposition rate	Good step coverage
Disadvantages	Poor step coverage	Expensive High impurity using toxic gas hardware complexity
Example of deposited films	Ti, TiN, Co, W	W, TiN (MOCVD), Ti, TiN, … SiO_2, Dielectrics

are important. Table 7.10 presents some examples of CVD reactions that result in deposition of a metal or ceramic coating onto a suitable substrate.

A few words about the difference between physical vapor deposition (PVD) and chemical vapor deposition processes follow. PVD constitutes a group of direct line-of-sight impingement deposition techniques, and CVD represents a class of diffusive-convective mass transfer deposition techniques. Whereas CVD includes a wide range of pressures and temperatures and can be applied to a great variety of coating and substrate materials, PVD is mostly limited to metal film deposition. With PVD techniques we saw that sputtering leads to a better conformal coating than evaporation, but CVD is better than sputtering in this respect. Unlike CVD, which operates at elevated temperature, PVD operates at room temperature; consequently, CVD often produces better crystalline films than PVD. Advantages typically cited for CVD include that 1) it is possible to deposit refractory materials at temperatures below their melting or sintering temperatures, 2) control of grain size is possible, 3) the process can be carried out at atmospheric pressure (it does not require vacuum equipment); and 4) there is good bonding of coating to substrate surface.

Disadvantages include that 1) the corrosive and/or toxic nature of chemicals generally necessitates a closed chamber and special pumping and disposal equipment, 2) certain reaction ingredients are relatively expensive, and 3) material utilization is low. Many gases used in CVD systems are toxic (hazardous to humans), corrosive (causes corrosion to stainless steel and other metals), flammable (burns when exposed to an ignition source and an oxygen source), and explosive and/or pyrophoric (spontaneously burn or explode in air, moisture, or when exposed to oxygen). In Table 7.11 we compare a specific PVD technique (sputtering) with a specific CVD technique, i.e., plasma-enhanced chemical vapor deposition (PECVD). With CVD, layer thicknesses range from 1 monolayer to 100 µm.

Reaction Mechanisms and CVD Reactor

Figure 7.26 illustrates the various transport and reaction processes underlying CVD schematically[23]:

- Mass transport of reactant and diluent gases (if present) in the bulk gas flow region from the reactor inlet to the deposition zone (1)
- Gas-phase reactions (homogeneous) leading to film precursors and byproducts (often unselective and undesirable) (2)
- Mass transport of film precursors and reactants to the growth surface (3)
- Adsorption of film precursors and reactants on the growth surface (4)
- Surface migration of film formers to the growth sites (5)
- Surface reactions (heterogeneous) of adatoms occurring selectively on the heated surface, and incorporation of film constituents into the growing film, that is, nucleation (island formation) (6)
- Desorption of byproducts of the surface reactions (7)
- Mass transport of byproducts in the bulk gas flow region away from the deposition zone toward the reactor exit (8)

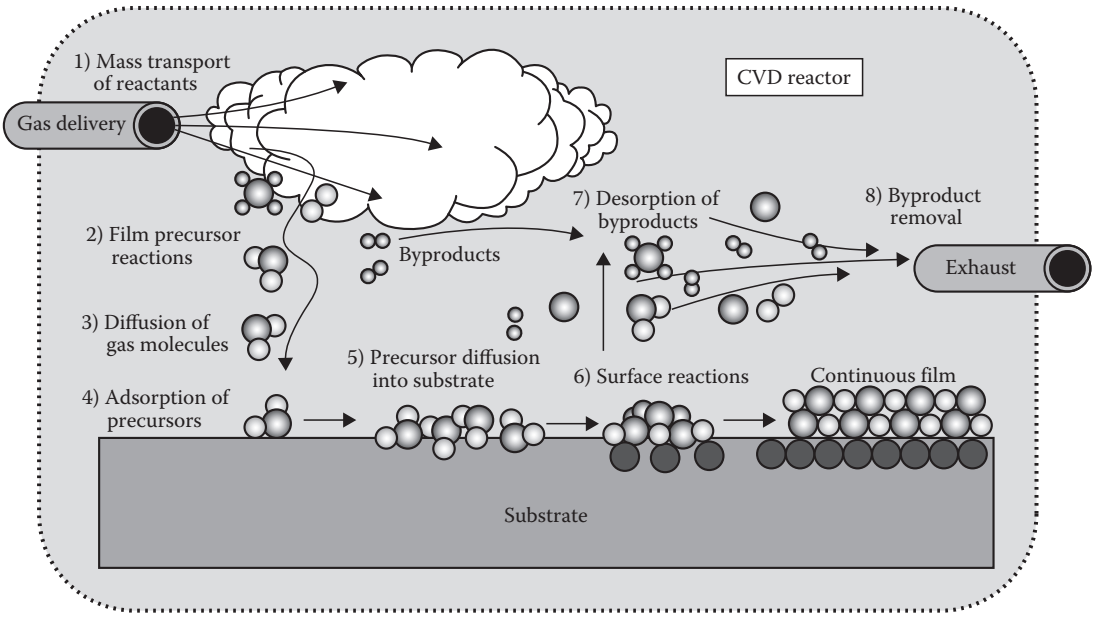

FIGURE 7.26 Schematic of transport and reaction processes underlying CVD. (Based on Jensen, K. F. 1989. *Microelectronics processing: chemical engineering aspects.* Eds. D. W. Hess, and K. F. Jensen. Washington, DC: American Chemical Society.[23])

CVD processes are carried out in a reactor as shown in Figure 7.27, which consists of 1) reactant supply system, 2) deposition chamber, and 3) recycle/disposal system. The purpose of the reactant supply system is to deliver reactants to the deposition chamber in the proper proportions. The deposition chamber contains the substrates and the chemical reactions that lead to the deposition of reaction products onto the substrate surfaces. Deposition occurs at elevated temperatures, and the substrate may be heated by induction heating, radiant heat, or other means. Deposition temperatures for different CVD reactions can range from around 250–1950°C; therefore, the chamber must be designed to meet these temperature demands. The recycle/disposal system is to render harmless the byproducts of the CVD reaction.

In the case of a thermally driven CVD reaction, a temperature gradient is imposed on the reactor; the gas-phase species (e.g., SiH_4) forms in a hot region; and the equilibrium shifts toward the desired solid (e.g., Si) in a slightly colder region. Either the gas phase or the surface processes can determine rate. Thermal energy is the sole driving force in high-temperature CVD reactors; for lower-temperature deposition, an additional energy source is needed. A radiofrequency (RF) plasma, photoradiation, or laser radiation can be used to enhance the process,

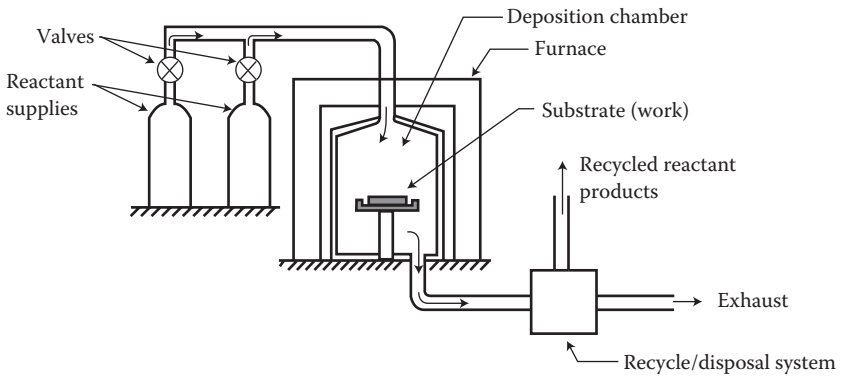

FIGURE 7.27 Schematic of a CVD reactor.

known as *plasma-enhanced chemical vapor deposition* (PECVD), photon-assisted CVD,[24] and laser-assisted CVD (LCVD),[25] respectively.

With photon- and laser-assisted CVD systems, part of the energy needed for deposition is provided by photons. This method fills the need for lower-temperature deposition processes. With a laser source, it is possible to write a pattern on a surface directly by scanning the micrometer-size light beam over the substrate in the presence of the suitable reactive gases. By adjusting the focal point of the laser continuously, it is even possible to grow 3D microstructures such as fibers and springs in a wide variety of materials such as boron, carbon, tungsten, silicon, SiC, Si_3N_4, and so on. Laser CVD is treated as a thermal additive technique in Chapter 9.[25]

In PECVD, which also encompasses high-density plasma CVD (HDPCVD), plasma activation provides the radicals that result in the deposited films, and ion bombardment of the substrate provides the energy required to arrive at the stable desired end products. Operational temperatures are lower because part of the activation energy needed for deposition now comes from the plasma.

Because CVD processes involve carrier gas flow over the substrate's surface, the issue of the "fluid/solid interface" must be dealt with in assessing the effectiveness of the CVD process. Whenever a fluid is flowing over a solid surface, a "boundary layer" is created, as shown in Figure 7.28. The boundary layer acts as a barrier to transfer of heat or transport of medium. Transport in the gas phase takes place through diffusion proportional to the diffusivity of the gas, *D*, and

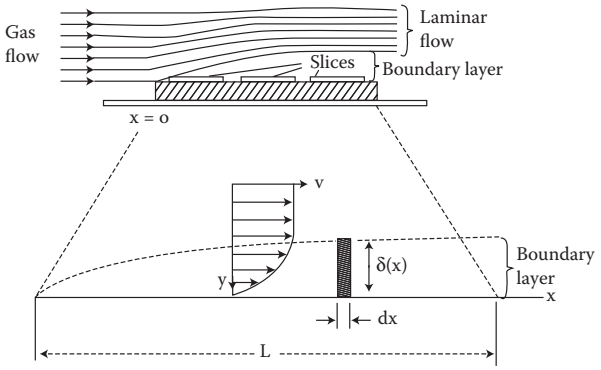

FIGURE 7.28 Development of a boundary layer in gas flowing over a flat plate. The figure shows an expanded view of the boundary layer. (Granger, R. A. 1995. *Fluid mechanics.* New York: Dover Publications.[26])

the concentration gradient across the boundary layer that separates the bulk flow (source) and substrate surface (sink). The flux of depositing material is given by Volume I, Equation 4.20 (Fick's first law):

$$J = -D\frac{\delta N(x,t)}{\delta x}$$

The boundary layer thickness, $\delta(x)$, as a function of distance along the substrate, *x* (see Figure 7.28), can be calculated from (x = 0 is the leading edge):

$$\delta(x) = \left(\frac{\eta x}{\rho V}\right)^{\frac{1}{2}} \tag{7.11}$$

where η = gas viscosity
ρ = gas density
V = gas stream velocity parallel to the substrate

The average boundary layer thickness, in the boundary layer model from Prandtl,[26] can then be calculated over the whole plate as follows:

$$\delta = \frac{1}{L}\int_0^L \delta(x)dx = \frac{2}{3}L\left(\frac{\eta}{\rho VL}\right)^{\frac{1}{2}} \tag{7.12}$$

where *L* stands for the length of the plate receiving the deposit.

The dimensionless Reynolds number, *Re*, is a most important figure in fluid dynamics characterizing the nature of a fluid flow (gas or liquid) (see Volume I, Chapter 6). It is given by:

$$Re = \frac{\rho VL}{\eta} \qquad \text{(Volume I, Equation 6.71)}$$

It equals the ratio of the magnitude of inertial effects to viscous effects in fluid motion. For low values (<2000–3000), the flow regime is called *laminar*, whereas for larger values the regime is *turbulent*. Substituting the expression for the Reynolds number in Equation 7.12, we obtain:

$$\delta = \frac{2L}{3\sqrt{Re}} \tag{7.13}$$

Control of δ and its uniformity over the substrate is an important design factor. In a horizontal CVD reactor (see Figure 7.29a) the substrate is often tilted

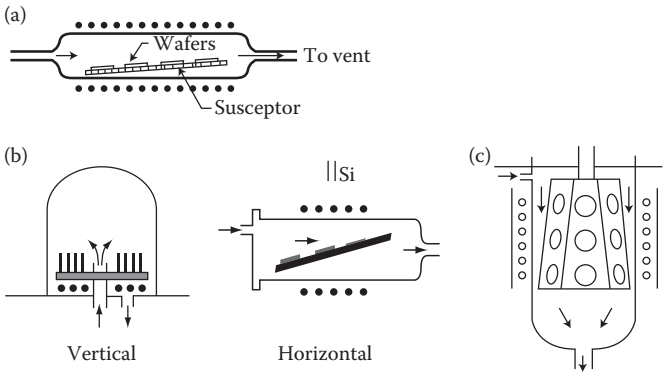

FIGURE 7.29 CVD reactor configurations: horizontal (a), vertical reactor (b), and barrel CVD reactor (c).

1–3° for Si and 5–15° for GaAs. The susceptor is tilted so that the cross-sectional area of the chamber is decreased, increasing the gas velocity along the susceptor. This compensates for both the boundary layer and depletion effects.

In a vertical reactor (see Figure 7.29b and c) one may use a baffle to deflect the gas from the center of the susceptor in addition to substrate rotation, again leading to a more uniform δ. The stability of the flow in a CVD reactor is crucial in achieving uniform deposition. The criterion for flow stability depends on whether the flow is fully developed (i.e., laminar) before it reaches the susceptor. Gas flows in containment structures (internal flows), e.g., a cylindrical tube CVD reactor, differ from external flows in that there is a boundary layer and a uniform free stream in the entry region of an internal flow that accelerates according to the rate of growth of the boundary layer as shown in Figure 7.30. The velocity is uniform at the entrance, and the boundary layer grows with distance from the entrance until the flow becomes fully developed at X_L. From the continuity equation (see Volume I, Chapter 6) it follows that the frictionless core must accelerate, whereas from applying the Bernoulli equation (see Volume I, Chapter 6) to a streamline in the free stream region, we learn that the pressure must decrease. At X_L the velocity varies over the entire channel, and there is no free stream anymore. The laminar development length X_L for the flow to become fully developed can be empirically determined as:

$$X_L = 0.056\,Re\,D \tag{7.14}$$

where D is the diameter of the tube. The thermal entrance length X_T is the length beyond which the dimensionless temperature profile is constant with x and before which it varies with x (i.e., is developing). For laminar flows in a tube, the thermal entrance length is a function of the Reynolds number and the Prandtl number, and for uniform surface temperature it is given as:

$$X_T = 0.033\,Pr\,Re\,D \tag{7.15}$$

where the Prandtl number is defined as $Pr = \nu/\lambda_d$ (see Volume I, Equation 6.61), i.e., the ratio of kinematic viscosity and thermal diffusivity. The interpretation of this number is the ratio of the thickness of the fluid velocity boundary layer to the fluid temperature boundary layer (for water Pr is 10, and for air it is 0.71). Both velocity and thermal entrance length are considerably longer when the flow is turbulent.

By substituting the value for the average boundary layer thickness from Equation 7.12 in Volume I, Equation 4.20 (i.e. Fick's first law with dx = δ), the following expression for the material flux to the substrate results:

$$J = -D\frac{\Delta N}{2L}3\sqrt{Re} \tag{7.16}$$

According to Equation 7.16, the film growth rate in the mass flow-controlled regime should depend on the square root of the gas velocity, V (because the Reynolds number is proportional to gas velocity V).

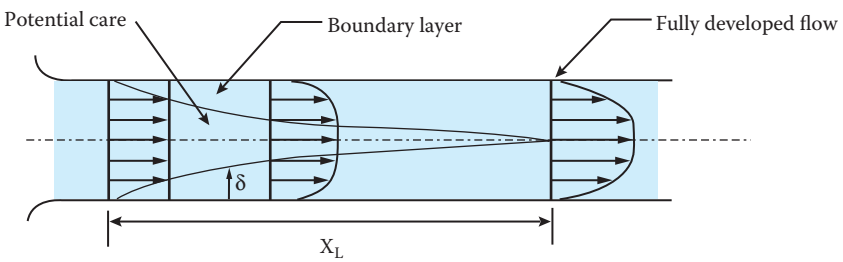

FIGURE 7.30 Flow in the entry region of a pipe for laminar flow.

Table 7.12 Mass Transport: Fundamental and Experimental Parameters

Fundamental Parameters	Experimental Parameters
Reactant concentration	Pressure
Diffusivity	Gas velocity
Boundary layer thickness	Temperature distribution
	Reactor geometry
	Gas properties (viscosity…)

Because gas-phase mass transport (see Table 7.12) is not an activated process, it is not strongly temperature-dependent. In Figure 7.31A we show a plot of silicon growth rate (in micrometers per minute) as a function of the gas flow rate (in liters per minute and proportional to the gas velocity in a fixed volume reaction chamber) with a substrate temperature of 1270°C, and the predicted square root dependence is clearly observed over a wide range of flow rates.[27]

At high flow rates, the growth rate reaches a maximum and then becomes independent of flow. In this regime, the reaction rate controls the deposition, evidenced by the exponential dependence of the growth rate on temperature observed at those flow rates (see Figure 7.31Ba).[27]

Surface reactions can be modeled by a thermally activated phenomenon proceeding at a rate, k, given by:

$$k = k_0 e^{\frac{E_a}{kT}} \tag{7.17}$$

where k_0 = frequency factor

E_a = activation energy in electronvolts

In Figure 7.31Bb, the growth rate (in micrometers per minute) of Si as a function of substrate temperature and a variety of precursor gases is illustrated in an APCVD reactor. From the slope of an Arrhenius plot, as demonstrated here, the activation energy of the rate-determining surface process can be deduced (for most surface reactions, E_a ranges from 1–4 eV).

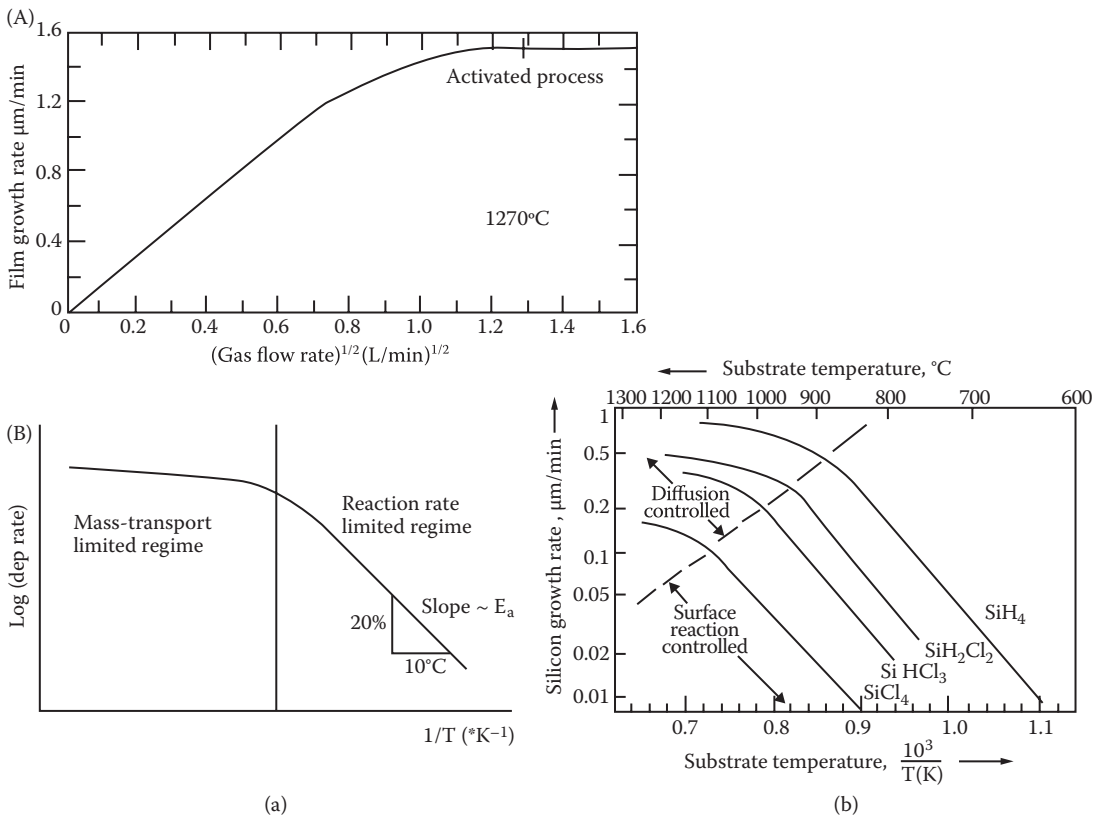

FIGURE 7.31 Growth rate dependence in a Si CVD process as a function of gas flow rate (A) and temperature (B). At high flow rates, the growth rate reaches a maximum and then becomes independent of flow. In this regime, the reaction rate controls the deposition, evidenced by the exponential dependence of the growth rate on temperature observed at those flow rates (see a). The growth rate (in micrometers per minute) of Si as a function of substrate temperature and a variety of precursor gases is illustrated in an APCVD reactor (see b). (Bb) Various precursor gases are used. (Wolf, S., and R. N. Tauber. 1987. *Silicon processing for the VLSI era.* Sunset Beach, CA: Lattice Press.[27])

We want the deposition reaction to occur at the gas/wafer boundary (heterogenous reaction). However, the higher temperatures (650–800°C for silane) used to enhance surface migration also result in gas-phase decomposition of silane, resulting in particles (homogeneous reaction). This is undesirable because particles tend to fall onto the wafers. Higher-quality (fewer defects) material is obtained at temperatures higher than 800°C. To be able to operate at higher temperatures, instead of silane, chlorosilanes that are stable up to higher temperatures are commonly used. Dichlorosilane (SiH_2Cl_2) is the most common and allows growth at ~800–1050°C. For a certain rate-limiting reaction, the temperature may increase high enough for the reaction rate to exceed the rate at which reactant species arrive at the surface. In such a case, the reaction rate cannot proceed any faster than the rate at which the reactant gases are supplied to the substrate by mass transport, no matter how high the temperature is increased (see plateau in Figure 7.31Ba and b). This situation is referred to as a mass transport-limited deposition process. Temperature is less important in this regime than it is in the reaction rate-limited (Arrhenius) one. In the latter case, the arrival rate of reactants is less important because their concentration does not limit the growth rate.

A direct practical application of these two possible rate-limiting processes is the way substrates are stacked in low-pressure CVD (LPCVD) (<10 Pa) versus atmospheric pressure to slightly reduced pressure CVD (APCVD) (±100–10 kPa) reactors. In an LPCVD reactor (e.g., at ~1 Torr), the diffusivity of the gas species is increased by a factor of 1000 over that at atmospheric pressure, resulting in a one order of magnitude increase in the transport of reactants to the substrate. The rate-limiting step becomes the surface reaction. LPCVD reactors enable wafers to be stacked vertically at very close spacings as the rate of arrivals of reactants is less important (Figure 7.32). On the other hand, APCVD, operating in the mass transport-limited regime, must be designed such that all locations on the wafer and all wafers are supplied with an equal flux of reactant species. In this case, the wafers often are placed horizontally or at a slight incline (Figure 7.29a). In APCVD, reactor walls typically are cooled in a so-called *cold wall reactor type* (where only the susceptor holding the substrates is heated) to minimize particulate and impurity problems caused by deposition on them. Horizontal tube, hot wall reactors are the most widely used LPCVD reactors. In this case, not only the wafers but also the reaction chamber walls get coated. Such systems require frequent cleaning to avoid serious particulate contamination. They find wide application because of their economy, throughput, and uniformity.

FIGURE 7.32 Vertical stacking of substrates in LPCVD reactors.

The Reynolds number in a typical LPCVD reactor is smaller than that for APCVD. Consequently, the thermal entrance length for APCVD is longer than that for LPCVD reactors (see Equation 7.15).

Step Coverage

Thin deposited films grow more readily on horizontal, exposed surfaces than within trenches or holes, resulting in poor coverage of the surface with the film. The gaps that are formed can lead to shorts, reliability problems, etching failures, and other generally undesirable phenomena. Poor step coverage results from different deposition rates in different parts of a microstructure. The profile of the thin films deposited by any CVD or PVD techniques depends on:

1. Equipment configuration
2. Deposition method (e.g., LPCVD, PECVD, PVD)
3. Reaction chemistry
4. Reactant transport mechanism

TABLE 7.13 Mean Free Path in Various Gases at 20°C

Gas	P_T (Torr) λ (m) (cm·Torr) at 20°C	
O_2	4.9×10^{-3}	Atmospheric pressure (760 Torr) ~40 nm (smaller than most chip features)
N_2	4.6×10^{-3}	
H_2	9×10^{-3}	Low vacuum (0.76 Torr) ~40 μm (larger than most chip features)
He	13.6×10^{-3}	
Ar	4.8×10^{-3}	Medium vacuum (7.6 Torr) ~4.0 mm (larger than working gap)
Ne	9.3×10^{-3}	
Xe	2.7×10^{-3}	High vacuum (7.6 μTorr) ~4.0 m (larger than chamber)
CO_2	3.0×10^{-3}	
H_2O	3.0×10^{-3}	Evaporated material travels straight to wafer (line of sight; thus, is very directional)
Cl	2.3×10^{-3}	
NH_3	3.5×10^{-3}	

Here we emphasize step coverage in CVD processes. The mean free path of a molecule, λ, based on a slightly modified Equation 7.6, is given by:

$$\lambda = \frac{kT}{2^{\frac{1}{2}} P_T \pi a^2} \tag{7.18}$$

where *a* is the molecular diameter.[28] If we assume a = 3 Å and T = 300 K, then $P_T(\text{torr})\lambda(\text{m}) = 7.810^{-5}$. Therefore, if λ = 30 cm, then a pressure of 2.6×10^{-4} Torr is required (see also Table 7.13).

Equation 7.18 is of crucial importance in understanding CVD coating of micromachined features. CVD films may electrically isolate underlying features from subsequent layers or protect them against the atmosphere, determined by the degree at which edges and pits of the underlying features can be covered uniformly. As demonstrated in Figure 7.33A, three cases can be distinguished. Ideally, a uniform, dense, and conformal coating should form (Figure 7.33Aa). This can occur in instances where the reactants, after first hitting the solid, have enough energy left for surface migration before a bond is established with the underlying substrate. Coatings in which equal film thickness exists over all substrate topography, regardless of its slope, are called *conformal* (see also Figure 7.5). In a second case, as shown in Figure 7.33Ab, the mean free path of the molecules is large enough to reach the bottom of the trench, but little energy remains for surface migration. Finally, in the third case, shown in Figure 7.33Ac, the mean free path length is too short to reach the bottom, and there is little surface migration (temperature too low). Whereas sputtering is better than evaporation, for the best conformal coating CVD is preferred. Evaporated and sputtered metal films often have trench profiles as shown in the Figure 7.33Ab, whereas CVD (especially LPCVD) deposited films are often more uniform and conformal, as demonstrated in Figure 7.33Aa.

The value of the integral of the material flux in Equation 7.16 (∫Jdθ), and thus the CVD film thickness, is directly proportional to the range of feasible angles of arrival, θ, of the depositing species (in the absence of surface migration). Different

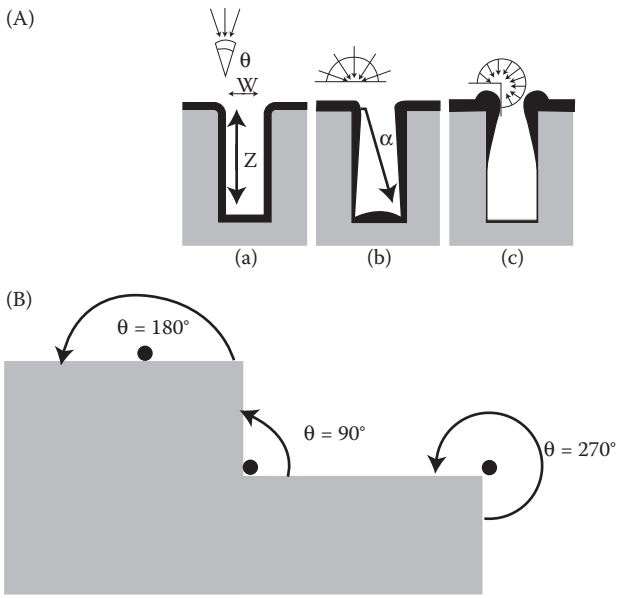

FIGURE 7.33 Step coverage cases of deposited film. (Aa) Uniform coverage resulting from rapid surface migration. (Ab) Nonconformal step coverage for long mean free path and no surface migration. Distance a is the longest path a molecule travels to reach the corner of the trench. (Ac) Nonconformal step coverage for short mean free path and no surface migration. (B) Different arrival angles in two dimensions.

arrival angles in two dimensions are illustrated in Figure 7.33B. The arrival angle at a planar surface is 180°. At the top of a vertical step, the arrival rate is nonzero over a range of 270°; the resultant film thickness is 270/180, or 1.5 times greater than that for the planar case. At the bottom corner of a trench, the arrival angle is only 90°, and the film thickness is 90/180 or one-half that of the planar case. The CVD profile in Figure 7.33Ac, where the mean free path is short compared with the trench dimensions and there is no surface migration, reflects the 180°, 90°, and 270° arrival angles. The thick cusp at the top of the step and the thin crevice at the bottom combine to give a re-entrant shape that is particularly difficult to cover with evaporated or sputtered metal. Gas depletion effects also are observed along the trench walls. Along the vertical walls, the arrival angle, θ, is determined by the width of the opening, and the distance from the top and can be calculated from:

$$\theta = \arctan\frac{w}{z} \tag{7.19}$$

where w is the width of the opening and z the distance from the bottom of the trench to the top surface (Figure 7.33Aa). This type of step coverage, as shown in Figure 7.33Ab, thins along the vertical walls and may have a crack at the bottom of the step. For uniformity of deposition, in the case of Figure 7.33Ab, where the mean free path is longer than the distance α (the longest path a molecule must travel to reach the corner of the trench), the rate of surface migration of adspecies should exceed the rate of adsorption of adspecies. The condition of $\lambda > \alpha$ can be met by working at low pressures, based on Equation 7.18:

$$\frac{kT}{2^{\frac{1}{2}} P_T \pi a^2} > \alpha \tag{7.20}$$

For a given gas, Equation 7.20 gives us the pressures and temperatures at which $\lambda > \alpha$. The most important variable influencing the requirement for large surface diffusion is the reactor temperature. The mobility of surface species is largest on metallic and semiconducting surfaces, where bonding is not very directional, and rather limited on dielectrics, where highly directional covalent bonds tend to hold a molecule in one place once it is chemisorbed. There is another factor influencing conformality, namely, the reactive stiction coefficient, S_c, which might be even more important than surface diffusion. To appreciate the importance of this parameter we need to reintroduce some simple facts about the mean free path in various deposition systems. Remember that the mean free path for APCVD is 40 nm at 760 Torr (see Table 7.13), smaller than most features on an IC or a micromachine. However, the mean free path is 10 μm in typical working conditions for LPCVD and PECVD, and for sputtering it is a few centimeters; therefore, in this case one can ignore collisions between the gas particles when they are inside a via or a trench-like structure. The only collisions are those with the surface of the wafer. The particular flow characteristics around an IC, MEMS, or NEMS feature on a substrate are given by the value of the Knudsen number (*Kn*), defined in this case as the ratio of the mean free path of the molecules (λ) to the characteristic dimension of the structure to be coated (e.g., the width D of the structure) (see also Equation 7.5). If the Knudsen number is greater than 1, the flow is free molecular. If, on the other hand, the Knudsen number is <0.01, the flow is viscous, that is, the atom or molecule bounces several times into the feature's sidewalls. A transition region exists between the two. The flow around micromachined features is typically in this transition regime ($0.1 < Kn = \lambda/w < 10$) or in the free molecular regime ($Kn > 10$).

The transport of reactants to the surface at low pressures is sketched in Figure 7.34. The three processes shown here are 1) direct deposition, 2) re-emission, and 3) surface diffusion. In most applications, it has been found that the surface diffusion (3) is less important than re-emission (2), which is controlled

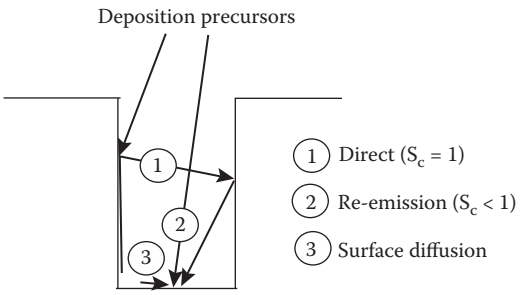

FIGURE 7.34 The transport of reactants to the surface at low pressures.

by the reactive stiction coefficient, S_c. The stiction coefficient is the ratio of incident precursor species minus re-emitted ones, i.e., all the species that remain on the surface react, over the total of incident precursor species:

$$S_c = \frac{\Gamma_{\text{incident}} - \Gamma_{\text{re-emission}}}{\Gamma_{\text{incident}}} = \frac{\Gamma_{\text{reaction}}}{\Gamma_{\text{incident}}} \qquad (7.21)$$

The reactive sticking coefficient (RSC) S_c depends on the nature of the incoming species (molecule, ion, neutral, radical, size of molecule) and on the surface conditions. A radical or other unstable precursor molecule is likely to react readily with a surface site and stick wherever it strikes ($S_c = 1$). A more stable precursor may not react readily, particularly at higher temperatures or when the surface is already saturated with adsorbents ($S_c < 1$). Particularly in dielectric deposition, it has been shown that an important mechanism for transport of the material into gaps and holes is through multiple adsorption and re-emission from the surface: that is, from precursors having a low RSC. When such "reflections" occur many times, the flux of precursor to the surface inside a hole may differ very little from the flux onto the horizontal surfaces. In other words, the likelihood of reaction is important because successive adsorption and re-emission is one of the key mechanisms determining the effect of topography of a surface on the thickness of a film deposited on that surface, and is one of the key advantages of CVD over evaporation or sputtering of thin films. Therefore, for a direct deposition (1) $S_c = 1$ and with any degree of re-emission (2) $S_c < 1$. Shadowing of the direct flux by the walls reduces the flux at the bottom corners of a via or a trench, resulting in thinner deposition. Lower reaction stiction coefficients increase the number of bounces in the trench or via and hence increase the probability of deposition precursors reaching the bottom. Thus, step coverage is better for lower S_c (see Figure 7.35).

To illustrate the effect of a lower S_c, imagine that we have a couple of metal lines (e.g., aluminum) on a substrate that are being used as wires, and that we need to cover them up with an insulating dielectric so that a subsequent layer of metal can be deposited without being shunted out. When leaving voids

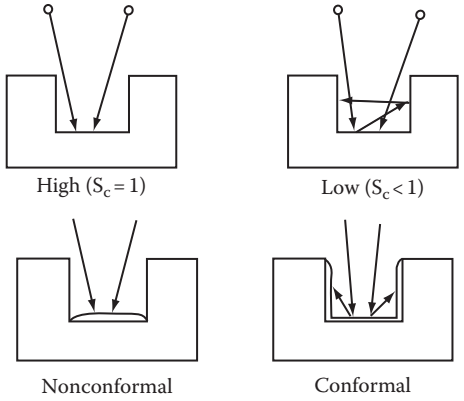

FIGURE 7.35 A low S_c can produce more conformal coverage because of redeposition (usually more important than surface diffusion)

in a fill they trap chemicals that may lead to cracks (dielectric) or large contact resistance and sheet resistance (metallization). In Figure 7.36 we show how a decreasing S_c fills the gap between the two metal lines better with the dielectric material and that at a value of $S_c = 0.007$ the gap is filled completely. The simulation model used here is SPEEDIE,

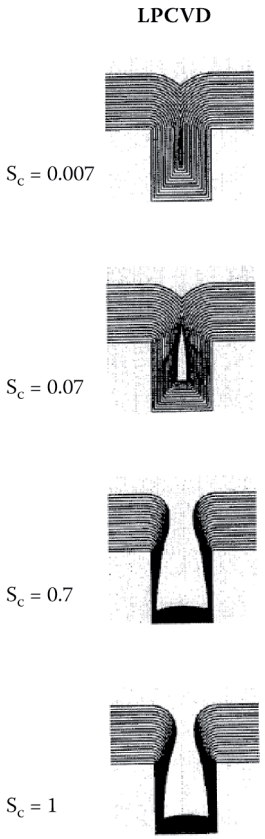

FIGURE 7.36 Effect of varying S_c on filling a gap between two metal lines. The simulation model used here is SPEEDIE, the Stanford etching and deposition profile simulator.

the Stanford etching and deposition profile simulator. Scaling of interconnects in future ICs will require more metal layers with reduced interconnect pitch. The height of the metals also has to be increased. The larger aspect ratio between the metal lines will increase dramatically the problem of step coverage. For a small gap or opening in a film, the aspect ratio is the ratio of its depth to width. Filling high-aspect-ratio gaps (>3:1) is critical for advanced wafer fabrication. It is anticipated that the thickness of deposited films in the IC industry will reach the order of 10 nm rather than a few micrometers, and thickness uniformity will be harder to maintain.

Although LPCVD reactors have lower deposition rates than APCVD reactors, it is found that this is more than compensated for by the high wafer capacity and coating uniformity. The future trend is toward single-wafer processing systems instead of the batch processes. This is because of the increasing wafer sizes (8 in. or more), and the development in technology to achieve better film uniformity in modern single-wafer reactors. The tendency is toward large single wafers that are transferred from station to station in so-called *cluster tools*.

Besides SPEEDIE, simulation models for nonplanar CVD were presented, for example, by Coronell et al.[29] The latter model again provides a picture of the evolution of the depositing film profile. The parameters investigated include the sticking coefficient, the surface mobility of the adsorbed reactants, the Knudsen number (the ratio of the mean free path to the feature size), the feature aspect ratio, and feature geometry.

Overview of CVD Process Types

In Table 7.14[23,30] we review some important CVD processes, listing applications and operational pressures and temperatures for the different types.

Atmospheric Pressure CVD

Atmospheric pressure to slightly reduced pressure CVD (±100–10 kPa) is used primarily to grow epitaxial (i.e., single-crystalline) films of Si and to deposit, at high rates, SiO_2, for example, from the reaction of SiH_4 and oxygen, at low temperatures of 300–450°C [low-temperature oxide (LTO)].[23] The epitaxy processes [also vapor phase epitaxy (VPE)] involve high growth temperatures (>850°C for Si). As we saw above, an APCVD reactor operates in the mass-transport regime so that wafer access, in contrast to the LPCVD process, becomes more important and temperature control less so. APCVD is susceptible to gas-phase reactions, and step coverage is often poor. High gas dilutions help avoid gas-phase nucleation. APCVD, reactor walls typically are cooled in a so-called *cold wall reactor type* (where only the susceptor holding the substrates is heated) to minimize particulate and impurity problems caused by deposition on them. In the early days of semiconductor processing, atmospheric pressure reactors were used mostly to deposit silicon and dielectric films. The advantage of deposition at atmospheric pressure is the simplicity of the reactor design and the high deposition rates (700 Å/min for SiO_2). The wafers are put on a hot susceptor, and reactant gases flow over the susceptor. The susceptor is heated by using high-intensity lamps, radiofrequency (RF) induction, or DC electric current (resistive) heating. These atmospheric pressure reactors have low throughput, require excessive wafer handling during wafer loading and unloading, and have poor thickness uniformity (>10%) across the wafer. To overcome some of these disadvantages, continuous throughput atmospheric pressure reactors were developed as shown in Figure 7.37. In these reactors, the wafers are carried through the reactor on a conveyor belt and are heated by convection. Also, there is a more uniform flow of the reactant gases across the wafer surface. These reactors have high throughput, good uniformity, and the ability to handle large-diameter wafers. The main disadvantages of this type of reactor are that they required frequent cleaning and that particles formed on the reactant dispenser head wind up on the wafers, which impaired process yield and device reliability.

Example 7.2: Epitaxial Si

As a first example of an APCVD application, consider silicon epitaxy at 1200°C (see also Figure 7.31B):

$$SiCl_4\,(gas) + 2H_2 \rightarrow Si\,(solid) + 4HCl\,(gas)$$

Reaction 7.2

Table 7.14 Review of CVD Processes

Process	Advantages	Disadvantages	Applications	Remark	Pressure/ Temperature
APCVD	Simple, high deposition rate (700 Å/min for SiO_2), low temperature	Poorer step coverage, particle contamination	Doped and undoped, low temperature, thick oxides (mainly dielectrics)	Mass transport-controlled	100–10 kPa 250–450°C
LPCVD	Excellent purity and uniformity, conformable step coverage, large wafer capacity	High temperature and lower deposition rate	Doped and undoped, high-temperature oxides, silicon nitride, polysilicon, W, WSi_2	Surface reaction-controlled	100 Pa 550–650°C
VLPCVD			Single-crystalline Si and compound semiconductor superlattices	Surface reaction-controlled	1.3 Pa
MOCVD	Excellent for epi on large surface areas	Safety concerns (highly toxic), very expensive source material	Compound semiconductors for solar cells, laser, photocathodes, LEDs, HEMTs, and quantum wells; also W and Cu	High volume, large surface area production	
PECVD	Lower substrate temperatures, fast, good adhesion, good step coverage, low pinhole density	Chemical (e.g., hydrogen) and particulate contamination, plasma damage	Low-temperature insulators over metals, passivation (nitride)	Tends to have more pinholes than LPCVD	2–5 Torr (pressure higher than in sputter deposition, more gas-phase collisions, less ion bombardment on surface) more collision in gas phase, less ion bombardment on substrate –200–400°C
Atomic layer deposition (ALD)	ALD is the deposition method with the greatest potential for producing very thin, conformal films with control of the thickness and composition of the films possible at the atomic level.	A major limitation of ALD is its slowness; usually only a fraction of a monolayer is deposited in one cycle.	A major driving force for the interest in ALD is for scaling down microelectronic devices.	Many technologically important materials such as Si and Ge, several multi-component oxides and certain metals cannot currently be deposited by ALD in a cost-effective way.	RT to 400°C
Spray pyrolysis	Inexpensive	Difficult to control, not compatible with IC	Gas sensors, solar cells, ITO, large area		Atmospheric 100–180°C

An intermediate species, $SiCl_2$, is necessary for silicon formation, and at less than 1000°C no $SiCl_2$ forms when starting from $SiCl_4$. Lower-temperature epitaxy can be performed by starting with SiH_2Cl_2 or $SiHCl_3$, which both decompose more readily to $SiCl_2$. When discussing Figure 7.31Bb, we pointed out that using pure silane (in the lowest temperature range) results in gas-phase decomposition of silane, resulting in particles (homogeneous reaction), and silane also must be avoided. Dichlorosilane (SiH_2Cl_2) is the most common and allows growth at ~800–1,050°C.

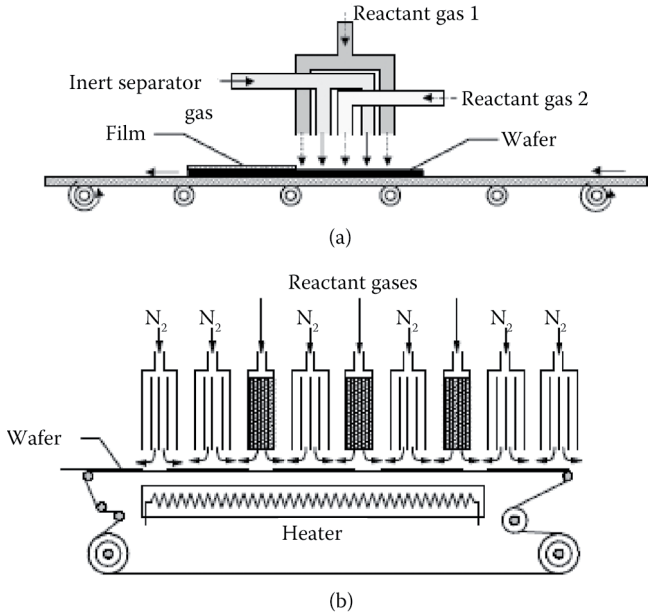

FIGURE 7.37 Simple continuous-feed atmospheric pressure reactor (APCVD): (a) Gas-injection type; (b) plenum type.

In Figure 7.38, we show the growth rate versus temperature for that reaction; the plot delineates a CVD polysilicon deposition region and an epitaxial monocrystalline silicon deposition region.[27] Nominal growth rates for single-crystal Si varies from 0.2–1.5 μm/min, depending on the source gas and the growth temperature. Impurity atoms can be introduced in the gas stream to grow doped epitaxial layers (Figure 7.39) (e.g., arsine-doped epitaxial silicon).

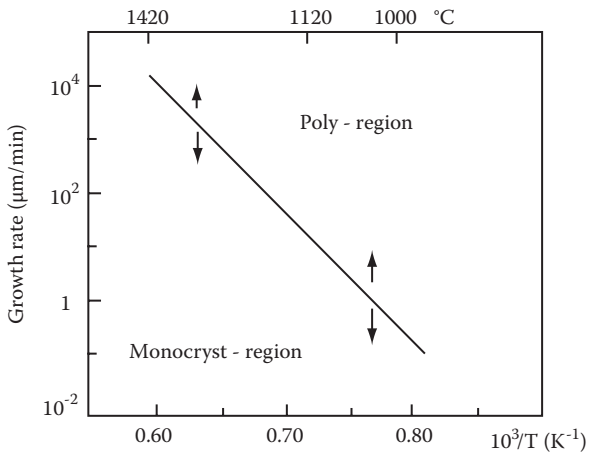

FIGURE 7.38 Growth rate versus temperature. Epitaxy to CVD transition in CVD polysilicon deposition and epitaxial monocrystalline Si deposition. (From Wolf, S., and R. N. Tauber. 1987. *Silicon processing for the VLSI era*. Sunset Beach, CA: Lattice Press. With permission.[27])

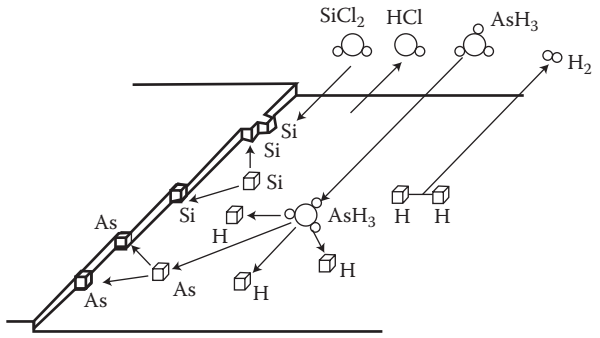

FIGURE 7.39 Arsine-doped epitaxial silicon.

Example 7.3: Oxide APCVD with Tetraethylorthosilicate

In low-temperature oxidation (LTO), silicon dioxide is deposited on the wafer out of the vapor phase from the reaction of silane (SiH_4) with oxygen at relative low temperatures (400–450°C) and low pressure (200–400 mTorr). Silane spontaneously combusts in the presence of oxygen (in other words, silane is pyrophoric), and to avoid a large depletion of the gases at the entrance of the furnace tube, the gases are introduced in the furnace through injectors along the length of the tube. The silane/oxygen gas mixture has been applied in atmospheric pressure CVD (APCVD) and plasma-enhanced CVD (PECVD) conditions. The main advantage of silane/oxygen is the low deposition temperature; the main disadvantage is the nonconformal step coverage.

Because silane is not safe, now tetraethylorthosilicate (TEOS) with oxygen or ozone is commonly used. TEOS is a liquid at room temperature, with a vapor pressure of about 1.5 Torr. TEOS slowly hydrolyzes into silicon dioxide and ethanol when in contact with ambient moisture, but its flammability and toxicity are similar to that of an alcohol. Ozone is more reactive than oxygen; hence the process can be carried out at low temperature without plasma. In general, TEOS brings about a better starting chemistry than the traditional silane-based CVD technologies. Use of TEOS oxide, to replace SiH_4-based oxide in spin-on-glass and photoresist planarization schemes, now has become commonplace for devices with small features. TEOS is especially suited for filling high-aspect-ratio gaps. Trench fill by APCVD of TEOS is illustrated in Figure 7.40.

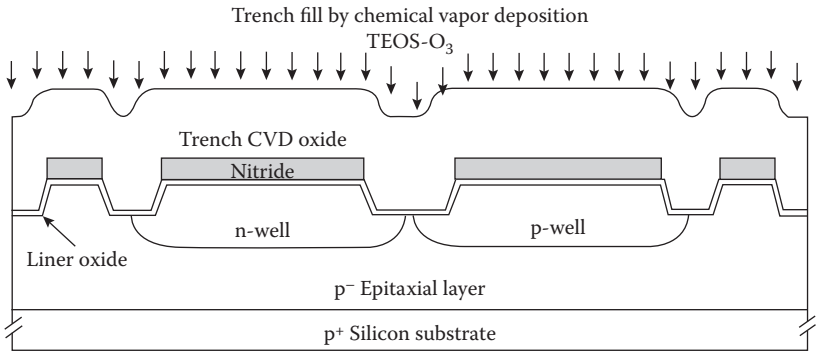

FIGURE 7.40 Trench fill by atmospheric pressure chemical vapor deposition of TEOS.

In APCVD both undoped glass and borophosphosilicate glass have been deposited from TEOS. The process involves the reaction of ozone with TEOS at a pressure of 600 Torr and at a temperature less than 400°C:

$$Si(C_2H_5O)_4 + 8O_3 \rightarrow SiO_2 + 10H_2O + 8CO_2$$

Reaction 7.3

While offering the same good step coverage over submicrometer gaps, the films from the thermal reaction of ozone and TEOS exhibit relatively neutral stress and have a higher film density compared with low-pressure processes. This increased density gives the oxide greater moisture resistance, lower wet etch rate, and smaller thermal shrinkage. Compared with a lower-pressure process, the film density is increased from 2.09–2.15 g/cm^3; the wet etch rate decreased by more than 40%; and the thickness shrinkage changed from 12 to 4% after a 30-min anneal in dry N_2 at 1000°C.[33]

Example 7.4: Carbon Nanotubes Grown by APCVD

Carbon nanotubes are produced in atmospheric pressure CVD (APCVD) by catalytic disproportionation of CO or CH_4 on catalyst particles (e.g., Fe in the form of iron pentacarbonyl). A typical CVD setup consists of a target substrate held in a quartz tube placed inside of a furnace. Typical parameters for carbon nanotube deposition include a pressure of 1 atm and a temperature of 700–900°C. Possible substrates include silicon, mica, quartz, or alumina, and the carbon supply is either CH_4 or CO gas. Common catalysts are nickel, iron, or cobalt. In a typical procedure, catalyst is sputtered, layered, or specifically placed onto the substrate. A carbon-containing gas is then passed over the substrate inside the furnace, and growth is initiated on the catalyst particles. Adding 25% hydrogen increases the SWNT yield. Advantages of the APCVD method for making carbon nanotubes include increased length and purity of the carbon nanotubes, large-scale production capability, increased control, and lower temperatures.

In an intriguing development, fast-heating CVD now offers the ability to grow millimeter-long carbon nanotubes while maintaining control over orientation of the carbon nanotubes. The fast heating minimizes the growing tubes' interaction with the substrate; this is called the *kite mechanism*. In this process, a catalyst is applied by photolithography to a silicon wafer. Using this process, Huang et al.[34] grew a square 2D network of SWNTs guided by flow of carrier gas (Fe/Mo catalyst and CO_2 gas) (Figure 7.41).

Low-Pressure CVD

Low-pressure CVD (LPCVD) at less than 10 Pa allows large numbers of wafers to be coated simultaneously without detrimental effects to film uniformity. This is the result of the large diffusion coefficient at low pressures leading to a growth limited by the rate of surface reactions rather than by the rate of mass transfer to the substrate. The surface reaction rate is very sensitive to temperature, but temperature is relatively easy to control. Typically, reactants can be used without dilution; therefore, growth rates are only an order of magnitude less than operation at atmospheric pressure allows. LPCVD in some cases can overcome the uniformity, step coverage, and particulate contamination limitations of early APCVD systems. One of the difficulties in the cold

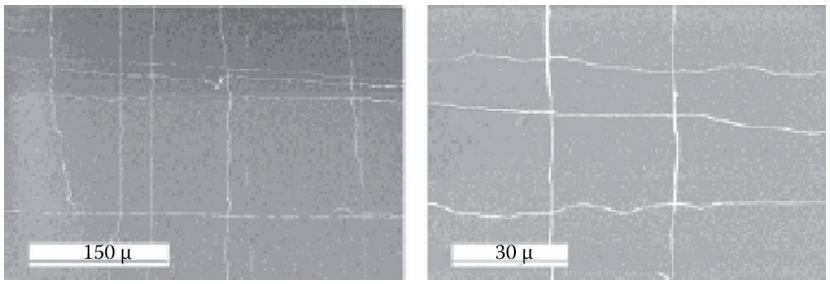

FIGURE 7.41 Square 2D network of SWNTs guided by flow of carrier gas (Fe/Mo catalyst and CO_2 gas). (Huang, S., X. Cai, and J. Liu. 2003. Growth of millimeter-long and horizontally aligned single-walled carbon nanotubes on flat substrates. *J Am Chem Soc* 125:5636–37.[34])

wall systems (where only the susceptor holding the wafer is heated) described earlier is maintaining a uniform temperature across the wafer surface. This can be overcome by putting the entire reaction chamber in a furnace maintained at a uniform temperature, as in the case of standard resistance-heated hot wall tubular furnaces. A large number of wafers can be stacked closely in these furnaces, and good uniformity across the wafer and wafer-to-wafer film thickness can be achieved if they are operated at very low pressures and in the surface reaction-limited regime. Figure 7.42 gives the schematics of a hot-wall, low-pressure CVD reactor used to deposit thin films of materials such as polycrystalline silicon, silicon dioxide, and silicon nitride. The reactor consists of a quartz tube heated by a resistance-heated furnace to maintain a uniform temperature along the reactor. Gases are introduced in one end and pumped out from the other end of the reactor. The operating pressures range from 0.25–2 Torr; temperatures range from 300–900°C; and gas flow rates range from 100–1000 sccm. A large number of wafers (~100) are stacked vertically, perpendicular to the gas flow, in a quartz holder. The inlet gases may undergo homogeneous gas-phase reactions to produce the deposition precursors, which are transported to the wafer surface by gas-phase diffusion. Excellent film uniformities (better than 5%) are obtained in these reactors. Although these reactors have lower deposition rates, it is found that this is more than compensated for by the high wafer capacity. In a hot-wall LPCVD reactor, not only the wafers get coated but also the reaction chamber walls get coated. Such systems require frequent cleaning to avoid serious particulate contamination (in situ cleaning using NF_3 or ClF_3). They find wide application because of their economy, throughput, and uniformity.

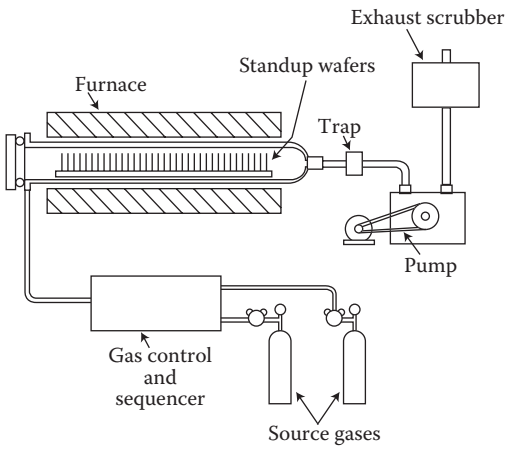

FIGURE 7.42 Low-pressure chemical vapor deposition hot wall reactor.

LPCVD polysilicon is used for structural layers in surface micromachines, and LPCVD SiO_2 and phosphosilicate glass (PSG) are used as sacrificial layers (see below). Two disadvantages of LPCVD are the low deposition rate and the relatively high operating temperatures.

Very low-pressure processes (about 1 Pa) have been used for the growth of single-crystalline Si at relatively low temperatures. Very low-pressure operation is also advantageous for the growth of III–V compound superlattices by reducing flow recirculations and improving interface abruptness.[23]

Example 7.5: Polysilicon Surface Micromachining Using LPCVD

Surface micromachining, we will see below, is based mostly on CMOS manufacturing. Alternating structural and sacrificial layers are deposited, patterned, and etched. Sacrificial

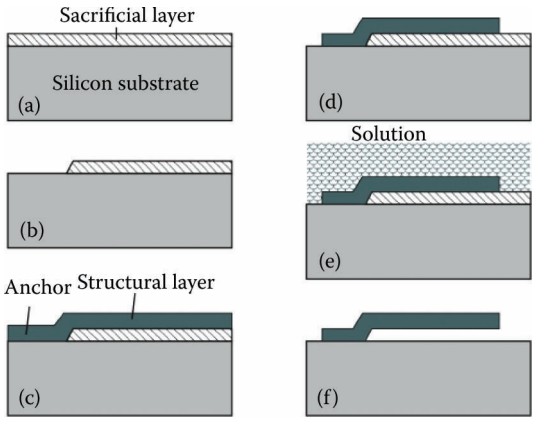

FIGURE 7.43 Basic surface micromachining process sequence. (a) Spacer layer deposition (the thin dielectric insulator layer is not shown). (b) Base patterning with mask 1. (c) Microstructure layer deposition. (d) Pattern microstructure with mask 2. (e–f) Selective etching of spacer layer.

layers are dissolved away at the end to free the structural layers so that they can be free to move as demonstrated in Figure 7.43. Materials are more or less restricted to CMOS-type materials (polycrystalline silicon, silicon oxide, silicon nitride, boron phosphosilicate glass [BPSG], phosphosilicate glass [PSG]). Structures have low aspect ratios and are sometimes referred to as 2.5D (quite planar). Polycrystalline silicon (called *polysilicon* to distinguish it from silicon having a single-crystal structure) has a number of uses in IC fabrication, including conducting materials for leads, gate electrodes in metal oxide semiconductor devices, and contact material in shallow junction devices. It is also the main structural material in surface micromachines. CVD to coat polysilicon onto a wafer involves reduction of silane at temperatures around 600°C, as expressed by the following reaction:

$$SiH_4 \rightarrow Si + 2H_2 \qquad \text{Reaction 7.4}$$

The surface micromachining process sequence depicted in Figure 7.43 is for the creation of a simple freestanding polysilicon anchor. A sacrificial layer, also called a *spacer layer* or *base*, is deposited on a silicon substrate (Figure 7.43a). CVD can be used to deposit layers of doped SiO_2, such as phosphorus-doped silicon dioxide (called *P-glass* or *PSG*). Phosphosilicate glass (PSG) deposited by LPCVD stands out as the best material for the sacrificial layer because it etches even more rapidly in HF than SiO_2. To obtain a uniform etch rate, the PSG film must be densified by heating the wafer to 950–1100°C in a furnace or a rapid thermal annealer (RTA). With a first mask, the base is patterned as shown in Figure 7.43b. A window is opened up in the sacrificial layer, and a microstructural thin film, consisting of polysilicon, is conformably deposited over the patterned sacrificial layer (Figure 7.43c). Furnace annealing of the polysilicon film at 1050°C in nitrogen for 1 h reduces stress stemming from thermal expansion coefficient mismatch and nucleation and growth of the film. Rapid thermal annealing has been found effective for reducing stress in polysilicon as well. With a second mask, the microstructure layer is patterned, usually by dry etching in $CF_4 + O_2$ or $CF_3Cl + Cl_2$ plasma (Figure 7.43d). Finally, selective wet etching of the sacrificial layer, e.g., in 49% HF, leaves a freestanding micromechanical structure (Figure 7.43e and f). The surface micromachining technique is applicable to combinations of thin films and lateral dimensions where the sacrificial layer can be etched without significant etching or attack of the microstructure, the dielectric, or the substrate. Typically, a surface micromachining stack may contain a total of four to five structural and sacrificial layers, but more are possible; the polysilicon surface machining process at Sandia's SUMMiT, for example, stacks up to five polysilicon and five oxide layers (see page 462).

Plasma-Enhanced CVD

One of the most important limitations of LPCVD is that it requires high deposition temperatures, which may be incompatible with other process steps, e.g., the deposition on an aluminum film. In plasma-enhanced CVD (PECVD), homogenous gas-phase reactions are initiated by collisions of neutrals with nonequilibrium energetic electrons produced by RF plasma instead of by thermal energy. Thus, the deposition precursors can be produced at much lower temperatures by these homogenous reactions. Furthermore, ion bombardment makes the surface more reactive by creating more dangling bonds (active sites) and/or supplying instantaneous energy at the surface for the heterogeneous reaction to take place. In general, PECVD can be carried out at a much lower temperature than LPCVD.

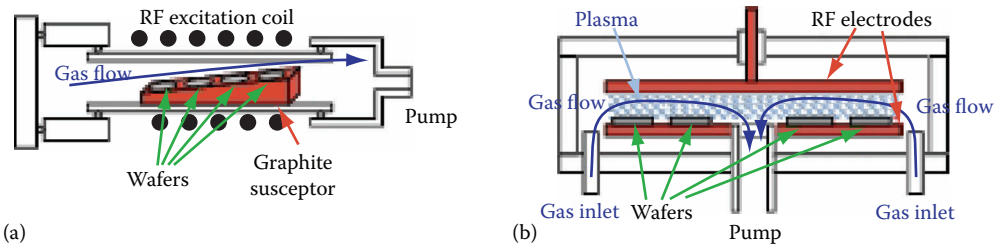

FIGURE 7.44 (a) Horizontal tube reactor. (b) Schematic of a cold wall, parallel-plate plasma deposition reactor, which is very similar to an etching reactor.

Moreover, the deposition rate is found to be higher in PECVD than in LPCVD. There are a number of different reactor configurations used for PECVD, but the physical principle is the same in all cases. Two basic PECVD setups are illustrated in Figure 7.44. In these setups, RF-induced plasma transfers energy into the reactant gases, allowing the substrate to remain at lower temperatures than in APCVD and LPCVD processes. We will only detail the cold-wall, parallel-plate plasma deposition reactor, which is very similar to an etching reactor.

With a simple parallel-plate reactor (Figure 7.44b), substrates can be placed horizontally or, if the pressure is low enough, vertically. The vertical position is used to increase throughput. No loss of film-thickness uniformity occurs in the latter case because the PECVD method is surface reaction limited. Adequate substrate temperature control ensures uniformity. The chamber consists of two electrodes, one of which is grounded, and the other is powered by an RF source. Wafers are placed on the grounded electrode and are subjected to a less-energetic bombardment than wafers placed on the powered electrode. The wafers are heated from below to the desired temperature by resistive heaters or high-intensity lamps. The reactant gases are introduced at the outer periphery, and they flow radially toward the center from where they are pumped out. Plasma is generated between the electrodes by the RF voltage applied across the electrodes. The electrode spacing is about 5–10 cm, and the operating temperature and pressure are ~400°C and 0.1–5 Torr, respectively. Homogenous reaction between the reactant gases is initiated by the electrons produced in the plasma. The ions are accelerated toward the electrodes as a result of the self-bias voltage between the plasma and the electrode. These energetic ions bombard the surface, making it more reactive, leading to higher deposition rates.

In most PECVD systems, the reactor configuration is changed so that the potential of both the powered and the grounded electrode, relative to the plasma, become equal.[27] Compared with sputter deposition, PECVD offers several advantages. The lower power densities, higher pressures, and somewhat higher substrate temperatures (e.g., >200°C) all lead to less-severe radiation damage than in sputter deposition. Moreover, for radiation-sensitive substrates such as compound semiconductors, afterglow or downstream deposition systems can be used where the radicals are formed in the glow discharge and then transported out of the region to a downstream deposition system. Thus, selective activation of reactants becomes possible without damaging the surface of the substrate.[35] PECVD films are not stoichiometric because the deposition reactions vary widely, and particle bombardment during growth of a multicomponent system changes the composition according to the ratios of sputtering yields of the component materials (nonthermal equilibrium). Because of the rapid deposition without the temperatures required for surface migration, film tends to be porous (possess holes like a sponge), leading to lower density than thermally grown films. Film stoichiometry and density can be monitored by a combination of etch rate comparisons to thermally grown films and ellipsometry to determine the index of refraction of the films.

Despite this negative consequence of particle bombardment, in general, the more ion bombardment, the better the film quality. Microstructure, stress, density, and other film properties show marked response, mostly for the better, to ion bombardment during deposition. Good adhesion, low

pinhole density, good step coverage, adequate electrical properties, and compatibility with fine linewidth pattern transfer processes have led to wide use of PECVD in very large-scale integration (VLSI). PECVD enables dielectric films such as oxides, nitrides, and oxynitrides to be deposited on wafers with small feature sizes and line widths at low temperatures and on devices unable to withstand the high temperatures of a thermally activated reaction. Planarization represents only one of the many applications of this versatile technology. Another application is deposition of amorphous silicon thin films, as used in flat-panel displays, eyeglasses, and photovoltaic panels. The most significant application is probably the deposition of SiO_2 or Si_3N_4 over metal lines.[35]

Summarizing, in PECVD, low RF excitation frequency, low reactor pressures, and low deposition rate at high temperature contribute to:

1. Lower processing temperature (250–450°C)
2. Excellent gap-fill for high-aspect-ratio gaps (with high-density plasma)
3. Good film adhesion to the wafer
4. High deposition rates
5. High film density as a result of low pinholes and voids
6. Low film stress as a result of lower processing temperature

Example 7.6: Si_3N_4 by PECVD

Silicon nitride is used as a passivation layer (protecting against sodium diffusion and moisture). Si_3N_4 has a low oxidation rate compared with silicon; therefore, a nitride mask can be used to prevent oxidation in coated areas on the silicon surface. Plasma nitride films are almost universally used for final passivation layers in IC fabrication, often in conjunction with a deposited oxide or PSG layer. A conventional CVD process for coating Si_3N_4 onto a silicon wafer involves reaction of silane and ammonia (NH_3) at around 800°C as follows:

$$3SiH_4 + 4NH_3 \rightarrow Si_3N_4 + 12H_2 \quad \text{Reaction 7.5}$$

Plasma-enhanced CVD is also used for basically the same coating reaction, the advantage being that it can be performed at a much lower temperature, around 300°C, compatible with aluminum metallization. In the latter application, stress control is important to avoid film cracking and degradation of metal reliability. Transparency in the UV must also be ensured in UV-erasable EPROM (erasable programmable read only memory) applications. PECVD silicon nitride is also often used for passivation of GaAs MESFETs [MESFET stands for metal semiconductor field effect transistor. Instead of using a p-n junction for a gate, a Schottky (metal-semiconductor) junction is used] to avoid oxidation of the exposed GaAs surface.

Properties of silicon nitride made by LPCVD versus PECVD are compared in Table 7.15.

Table 7.15 Comparison of LPCVD and PECVD Silicon Nitride

Property	LPCVD	PECVD
Deposition temperature (°C)	700–800	300–400
Composition	Si_3N_4	$Si_xN_yH_z$
Step coverage	Conformal	Fair
Stress at 23°C on silicon (dyn/cm^{-2})	$1.2–1.8 \times 10^{10}$ (tensile)	$1–8 \times 10^9$ (tensile or compressive)

Example 7.7: Polysilicon by PECVD

We remarked earlier on the quest for low-temperature polysilicon deposition processes, driven by the need for compatibility with prefabricated aluminum-metallized CMOS circuitry. This makes the 320°C PECVD polysilicon interesting (as is the ~350°C sputter deposition method).

PECVD polysilicon films, deposited in a 50-kHz parallel-plate diode reactor, can be doped in situ and crystallized by RTA (1100°C, 100 s). It was shown that small-grained PECVD films annealed by RTA have good electrical properties and gauge factors between 20 and 30, similar to those reported for other alternative types of polycrystalline silicon.[35]

A low-temperature polysilicon PECVD process is not only compatible with conventional oxide sacrificial layers (as used in surface micromachining; see below) but also with certain organic sacrificial layers such as polyimides.

More information on CVD thin films and how they are influenced by the above

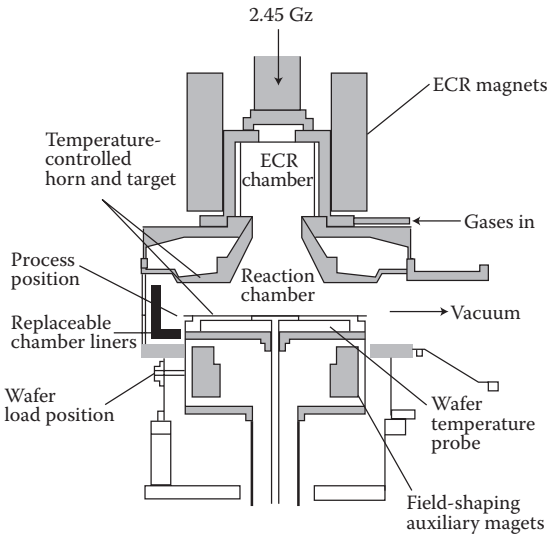

FIGURE 7.45 In ECRCVD, the plasma can deposit a film while simultaneously sputtering.

deposition parameters, as well as other parameters (e.g., moisture, flow rate, and gas composition), will be given in Volume III, Chapter 5 on selected MEMS materials.

High-Density Plasma CVD

High-density plasma sources such as inductively coupled plasma (ICP) and electron cyclotron resonance (ECR) stations (see Figure 3.36)—machines discussed in Chapter 3—can be used in high-density plasma CVD (HDPCVD) for both enhanced deposition and enhanced etching. Both systems work at low pressures (a few mTorr) and can independently control ion flux and ion energy. In ECRCVD, one uses ECR to generate a high-density plasma (HDP) that can deposit materials at high rates while pressures and temperatures remain low (Figure 7.45). ECRCVD technology provides a way to ensure durable ultrathin films. Alternating deposition and etch back is used for very effective planarization of topography. In submicrometer device fabrication, interlevel dielectric gap filling of high-aspect-ratio topography generally requires the use of multistep deposition/etch or spin-on dielectric processing to produce void-free, filled structures. With HDPCVD processing, high-aspect-ratio (up to 4:1) sub-half-micrometer structures can be filled and locally planarized in a *single* processing step. For gap filling, HDPCVD processing consists of a simultaneous deposition/etching process in which films over topographical features are sputtered off by reactive ions and radicals during deposition while deposition refills the newly created voids (see Example 7.8). The deposition/sputtering rate ratio (D/S) is an important measure of the gap-filling capability of the processes. For further reading, see Nguyen and references therein.[36] Alternative planarization techniques are reviewed in Chapter 1.

A typical ECRCVD machine is the Tek-Vac DRIE-1100-LL-ECR (http://www.tekvac.com/prd-ecr-1.htm) designed for both high-density plasma CVD and reactive ion etching of submicrometer integrated circuits (ICs), optical devices, and RF microwave electron devices. This type of equipment is used for CVD of diamond, diamond-like carbon, SiC, Si_3N_4, BN, and other refractory or high dielectric materials. The equipment provides high-density plasma with low damage and high etching rates and is well suited for etching devices sensitive to high energy electron damage, such as low-noise amplifiers. Various materials include aluminum, copper, gallium nitride, gallium arsenide, and HeCdTe, and semiconductor dielectrics have been etched this way. The method provides high uniformity of deposition and etching across large area substrates.

Example 7.8: Gap Filling by ECRCVD

ECRCVD simultaneously deposits and etches films to prevent bread-loaf and key-hole effects typical for PECVD processes, as shown in Figure 7.46. As shown in Figure 7.46b, ion-induced deposition is filling the gap between two metal lines. Argon ions then sputter-etch the excess film at the gap entrance, resulting in a beveled appearance of the film (Figure 7.46c). The etched material is redeposited, and the process is repeated, resulting in an equal "bottom-up" profile (Figure 7.46d).

Metalorganic CVD

Many materials that one wishes to deposit have too low a vapor pressure and thus are difficult to transport via gases. One solution is to chemically attach the material (e.g., Ga, Al, Cu) to an organic compound that has a high vapor pressure. Organic

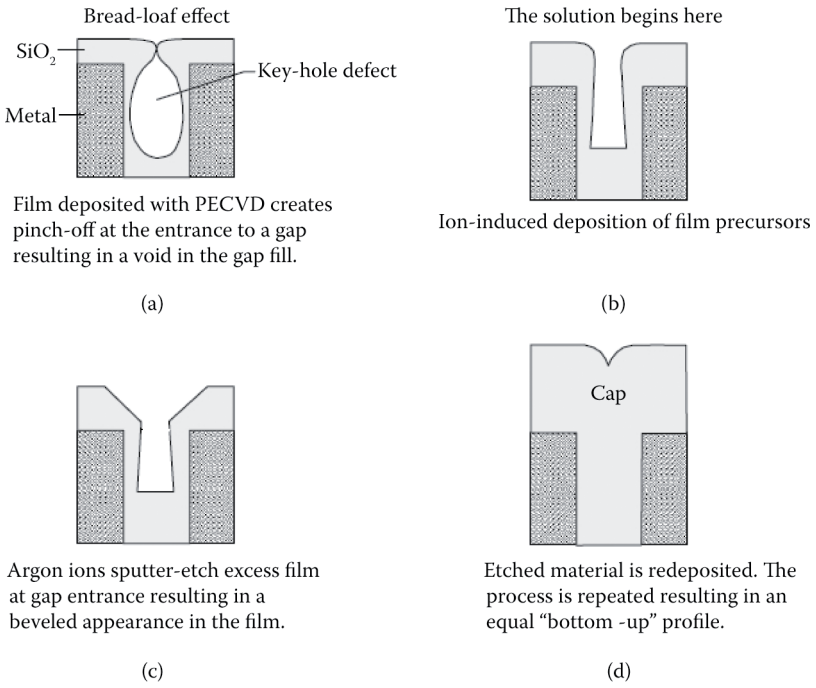

FIGURE 7.46 ECRCVD planarization.

compounds often have very high vapor pressure. The organic-metal bond is very weak and can be broken via thermal means on a heated wafer, depositing the metal with the high vapor pressure organic being pumped away. Care must be taken to ensure little of the organic byproducts are incorporated. Carbon contamination and unintentional hydrogen incorporation are sometimes a problem. Crystal growth by metalorganic CVD (MOCVD) began in the late 1960s. Metalorganic CVD, sometimes called *organometallic vapor phase epitaxy*, relies on the flow of gases (hydrides such as arsine and phosphine and organometallics such as trimethyl gallium and trimethyl aluminum) past heated samples placed in the gas stream. Typically, the reactive metal alkyls [e.g., $Ga(CH_3)_3$] react with a hydride of the nonmetal component (e.g., AsH_3) to produce the pure films (e.g., GaAs) and some byproducts (e.g., CH_4). For example:

$$(CH_3)_3Ga\ (g) + AsH_3\ (g) \rightarrow GaAs(s) + 3CH_4\ (g)$$

Reaction 7.6

The biggest advantage of MOCVD is the low growth temperature (cold wall reactor); the biggest disadvantage is the high cost of the very pure chemicals. MOCVD provides thickness control within one atomic layer and has become the preferred epitaxial process, a cost-effective manufacturing process for a variety of compound semiconductor devices. Foremost, MOCVD plays a key role in the manufacture of many optoelectronic devices with III–V compounds for solar cells, lasers, photocathodes, light-emitting diodes (LEDs), high electron mobility transistors (HEMTs), and quantum wells.[37] By using MOCVD, it is easier to scale it up to larger growth areas than it is to scale up liquid-phase epitaxy (LPE) (see below), and the uniformity and surface morphology of MOCVD grown lasers are superior to those attainable with LPE.

Atomic Layer Deposition

Atomic layer deposition (ALD) is a method of applying thin films to various substrates with atomic scale precision and constitutes one of the most promising "new" nanotechnology fabrication techniques. Dr. Tuomo Suntola and coworkers in Finland introduced ALD in 1974 to improve the quality of ZnS films used in electroluminescent displays.* It turns

* Picosun in Espoo, Finland, develops and manufactures ALD reactors for microelectronics and nanotechnology. With the help of Dr. Tuomo Suntola, Picosun has succeeded in developing inexpensive yet highly efficient ALD tools for research and development.

Table 7.16 List of ALD Applications

- High-k dielectrics (Al_2O_3, HfO_2, ZrO_2, Ta_2O_5, La_2O_3, etc.) for transistor gates and DRAM capacitors in Si, heterostructures, compound semiconductors, MESFETs, III–V semiconductor materials, organic transistors, graphene, graphite, nanotubes, nanowires, and molecular electronics
- Conductive gate electrodes (Ir, Pt, Ru, TiN, etc.)
- Metal interconnects and liners (Cu, WN, TaN, WNC, Ru, Ir, etc.); metallic diffusion barrier layers for copper interconnects and semiconductor vias for transistor gate and memory cell applications, DRAM capacitors, and passivation layers
- Catalytic materials (Pt, Ir, Co, TiO_2, V_2O_5); coatings inside filters, membranes, catalysts (thin economical Pt for automobile catalytic converters), fuel cells, ion exchange coatings
- Nanostructures (all materials); conformal deposition around and inside nanostructures and MEMS
- Biomedical coatings: (TiN, ZrN, CrN, TiAlN, AlTiN, etc.); biocompatible materials for in vivo medical devices and instruments
- Piezoelectric layers (ZnO, AlN, ZnS, etc.)
- Transparent electrical conductors (ZnO:Al, ITO)
- UV blocking layers (ZnO, TiO_2)
- OLED passivation (Al_2O_3)
- Solid lubricant layers (WS2)
- Photonic crystals (ZnO, ZnS:Mn, TiO_2, Ta_2N_5); coatings inside porous alumina, inverted opals
- Antireflection and optical filters (Al_2O_3, ZnS, SnO_2, Ta_2O_5); Fabry-Perot, flip-flop optical filters
- Electroluminescent devices (SrS:Cu, ZnS:Mn, ZnS:Tb, SrS:Ce)
- Processing layers (Al_2O_3, ZrO_2); etch barriers, ion diffusion barriers, fill layers for magnetic read heads
- Optical applications (AlTiO, SnO_2, ZnO); photonics, nanophotonics, solar cells, integrated optics, optical coatings, lasers, variable dielectric constant nanolaminates
- Sensors (SnO_2, Ta_2O_5, etc.); gas sensors, pH sensors
- Wear and corrosion inhibiting layers (Al_2O_3, ZrO_2)

out that ALD also produces outstanding high-k* dielectrics, metal electrodes, barriers, and spacers (see list of applications in Table 7.16). Objects of almost any size and shape can be coated, even atomic force microscope (AFM) tips. The method is similar in chemistry to CVD, except that the ALD reaction breaks up the CVD reaction into two half-reactions, keeping the precursor reagents separate during their reaction at the surface. As opposed to conventional CVD where one has continuous deposition and concurrent flow of precursors, ALD is based on the sequential deposition of individual monolayers at the surface in a well-controlled manner: the growth surface is alternately exposed to only one of two complementary chemical environments, i.e., individual precursors are supplied to the reactor one at a time. The precursors need to be thermally stable and should chemisorb fast and react aggressively with each other. Between exposure steps, an inert gas purge or a pump-down step is used to remove any residual chemically active source gas or byproducts before another precursor is introduced into the reactor. The overall ALD process then consists of a repetition of a number of growth cycles. Each cycle is made up of a typical sequence: 1) flow of precursor 1, 2) purge, 3) flow of precursor 2 and 4) purge. During a precursor exposure step, precursor molecules react with the surface until all available surface sites are saturated. Precursor chemistries and process conditions are chosen such that no further reaction takes place once the surface is completely saturated. This surface saturation guarantees the self-limiting nature of ALD. Precursors are preferably overdosed so that process results become independent of potential slight variations in the amount of precursor supplied to the surface. Thus, surface chemistry governs film growth rather than a precise control of tool-specific process parameters such as precursor flow and partial pressure. A known and constant thickness is deposited per growth cycle. Typically, deposition rates on the order of 0.1–1.0 Å/cycle are obtained, with cycle times ranging from 1–10 s. Cycle time critically depends on saturation behavior, chamber volume, and reactor design. The film is grown in a layer-by-layer mode, and the total film thickness is given by the number of cycles. Exceptional across-wafer thickness uniformity and excellent step coverage on high-aspect-ratio features can be achieved with ALD, making this technique one of the most exciting nanotechnology methods. In Figure 7.47 we illustrate a typical ALD setup, and in Figure 7.48 the ALD cycle for Al_2O_3 deposition is demonstrated.

* Many materials are currently under consideration as potential candidates for gate dielectrics for sub-0.1-μm CMOS technology. Silicon dioxide with a dielectric constant of 3.9 will be replaced by so-called *high-k materials*. Candidates for gate dielectrics include the oxides of yttrium, lanthanum, zirconium, and hafnium, which have much higher dielectric constants than SiO_2.

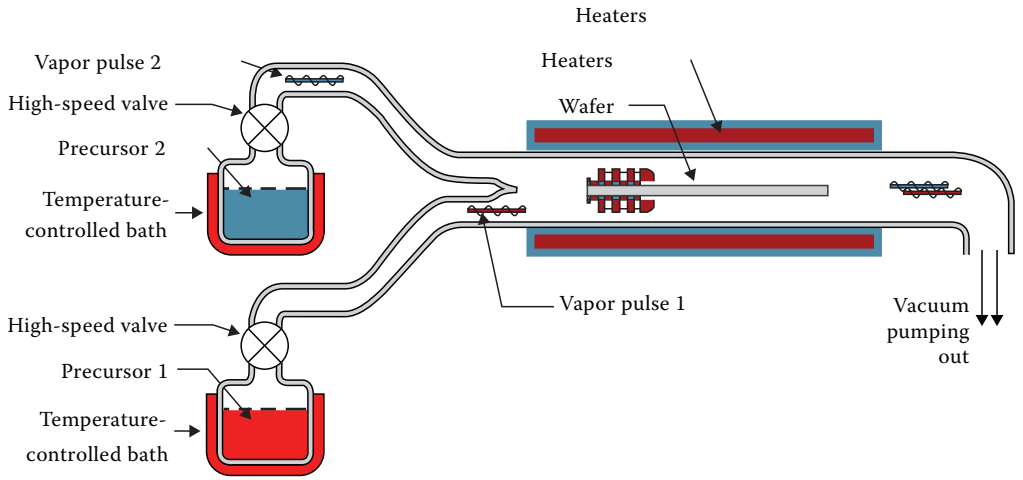

FIGURE 7.47 Typical atomic layer deposition (ALD) setup. (From *Atomic layer deposition.* Cambridge NanoTech Inc., April 24, 2006. http://www.cambridgenanotech.com.[231])

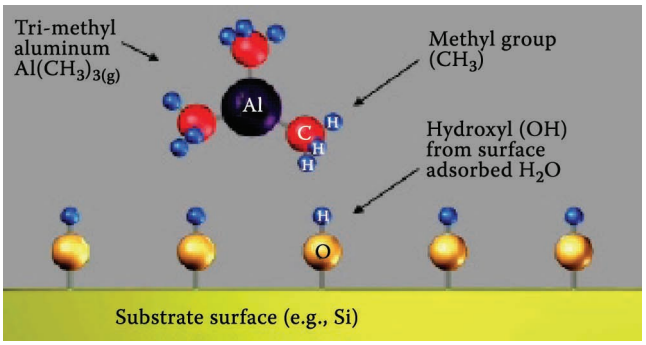
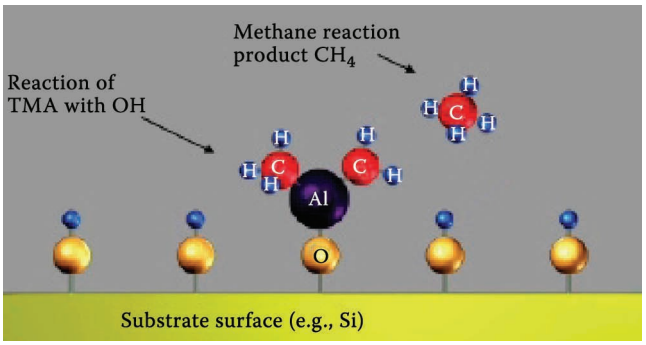
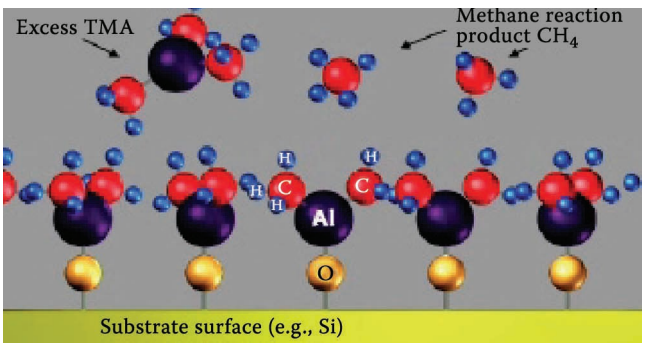


1. Flow of precursor 1: In air, water vapor is adsorbed on most surfaces, forming a hydroxyl group. In the case of Si this forms Si-OH. After placing the substrate in the reactor, trimethyl aluminum (TMA) is pulsed into the reaction chamber.



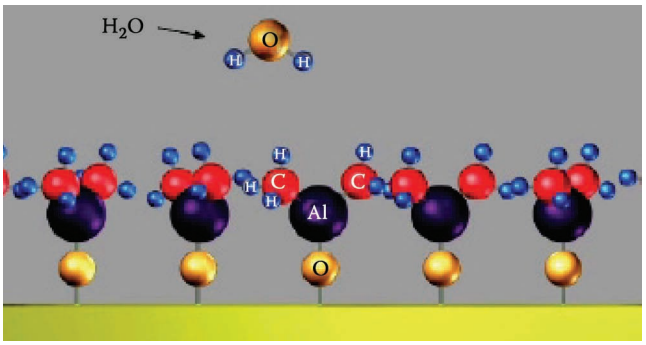
TMA reacts with the adsorbed hydroxyl groups, producing methane as a reaction product.

$$Al(CH_3)_3(g) + :Si-O-H(s) \rightarrow :Si-O-Al(CH_3)_2(s) + CH_4(g) \qquad \text{Reaction 7.7}$$

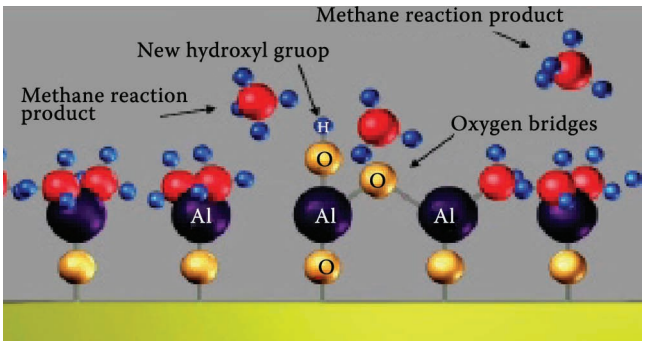


2. Purge cycle: TMA reacts with the adsorbed hydroxyl groups until the surface is passivated. TMA does not react with itself, limiting the reaction to one monolayer. This leads to the perfect uniformity and conformality of the ADL process. In the purge pulse, excess TMA and the methane reaction product are pumped away.

FIGURE 7.48 The atomic layer deposition (ALD) process illustrated for the Al_2O_3 process. (From *Atomic layer deposition.* Cambridge NanoTech Inc., April 24, 2006. http://www.cambridgenanotech.com.[231])

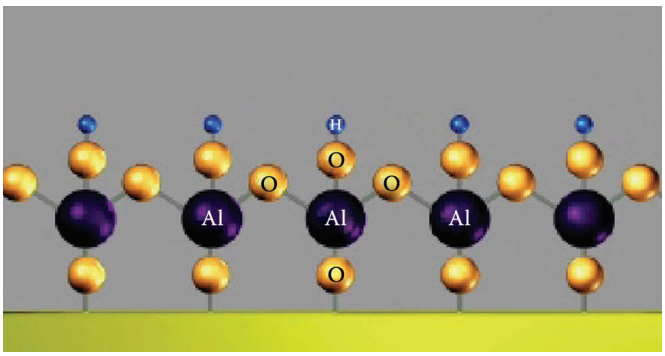


3. Flow of precursor 2: After all the TMA and methane have been pumped away, water is pulsed into the reactor chamber.

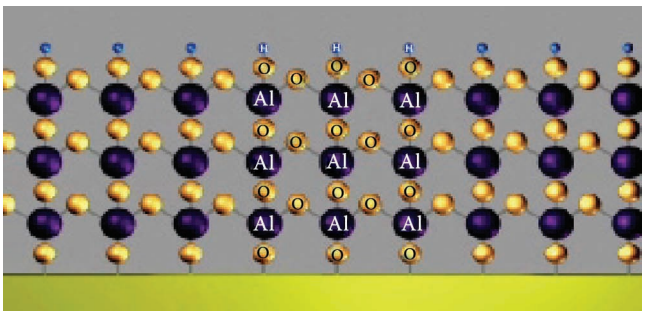


Water reacts with the dangling methyl groups on the new surface, forming aluminum-oxygen (Al-O) bridges and hydroxyl surface groups waiting for a new TMA pulse.

$$2H_2O(g) + :Si{-}O{-}Al(CH_3)_2(s) \rightarrow :Si{-}O{-}Al(OH)_2(s) + 2CH_4(g) \qquad \text{Reaction 7.8}$$



4. New purge cycle: The reaction product methane is pumped away. Excess water does not react with the hydroxyl surface groups, again causing perfect passivation limited to one monolayer.



One TMA pulse, one purge, and one water pulse form one cycle. Here three cycles are shown, with approximately 1 Å/cycle. Each cycle, including pulsing and purging, takes about 3 s.

FIGURE 7.48 (*Continued*)

Table 7.17 Comparison of ALD with CVD

ALD	CVD
Highly reactive precursors	Less reactive precursors
Slower deposition	Faster deposition
Precursors react separately on the substrate	Precursors react at the same time on the substrate
Low-temperature deposition possible	Higher deposition temperature
Precursors must not decompose at process temperature	Precursors can decompose at process temperature
Uniformity ensured by the saturation mechanism	Uniformity requires uniform flux of reactant and temperature
Stoichiometric films with large area uniformity and 3D conformality	
Gentle deposition process for sensitive substrates	
Thickness control by counting the number of reaction cycles	Thickness control by precise process control and monitoring
Surplus precursor dosing acceptable	Precursor dosing important

The list of applications for ALD keeps expanding, as evident from Table 7.16. In Table 7.17 we compare ALD with CVD.

Epitaxy

Introduction

Epitaxial techniques arrange atoms in single-crystal fashion on a crystalline substrate acting as a seed crystal so that the lattice of the newly grown film duplicates that of the substrate. The lattice constant of the epitaxially grown layer needs to be close to the lattice constant of the substrate wafer. Otherwise, the bonds cannot stretch far enough, and dislocations will result.

Si epitaxy is used for high-purity layer growth and can form very thick doped structures (30–100 μm) not possible with implantation or diffusion. Such thick, pure layers are often used in power devices with thinner, 1–5-μm structures, commonly used for CMOS and bipolar technology. In surface micromachining, where polycrystalline silicon functional layers are built up on a substrate rather than etched in the bulk of a single-crystal substrate as in bulk micromachining, epi-grown SOI wafers are a very attractive alternative. Surface micromachines built from layers of epi silicon and isolated from the substrate by a SiO_2 layer combine the most attractive features of surface micromachining (i.e., CMOS compatibility and freedom in types of structural shapes) with the superior single-crystal properties of the epilayer. For ICs, SOI is compatible with existing wafer processes, provides 50% faster circuit speed than bulk silicon, allows easier scaling to finer line widths, and can reduce the number of required mask levels for a given design by ~30%. SOI may very well represent the wave of the future in the IC industry rather than GaAs.[38] Silicon micromachining has typically followed in the footsteps of the IC industry; therefore, the prevalence of SOI in IC is a good indicator of coming trends in micromachining. SOI simplifies building micromachines by reducing the number of masks, reducing packaging concerns, and making integration of electronics easier. In the IC industry, many device parameters such as transistor breakdown voltage, junction capacitance, transistor gain, and AC performance depend on the epilayer thickness, thus necessitating precise control of it. This precise control also enables more reproducible and predictable mechanical micromachines.

Liquid- and Solid-Phase Epitaxy

In the section on PVD techniques we discussed molecular beam epitaxy (MBE) as the most advanced. In the CVD section we encountered two types of vapor phase epitaxy (VPE) techniques, APCVD and MOCVD. For silicon processing, VPE has met with the widest acceptance because excellent control of impurity concentration and crystalline perfection can be achieved. In growing an epilayer with VPE, the processing is accomplished under closely controlled conditions at higher temperatures than conventional CVD of Si, using diluted reacting gases to slow the process so that an epitaxial layer can be successfully formed. Here, we briefly discuss liquid- and solid-phase epitaxy. For depositing multilayer structures

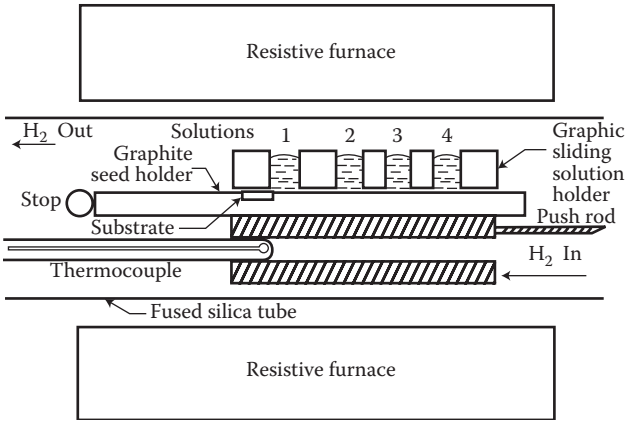


FIGURE 7.49 Liquid-phase epitaxy setup. (From Brodie, I., and J. J. Muray. 1982. *The physics of microfabrication.* New York: Plenum Press. With permission.[1])

of different materials on the same substrate, liquid phase epitaxy (LPE) is used. LPE films grow from a liquid solution very near the equilibrium state, making the technique reproducible and resulting in films with low concentrations of growth-induced defects. A schematic for a typical LPE setup is presented in Figure 7.49.[1] In operation, a graphite slider plate moves relative to a multiple-well assembly to bring the substrate in a recess in the slider plate in contact with the different solutions. LPE has found its widest application in producing epitaxial layers of III–V compounds (e.g., InP, GaAs) for lasers and photodetectors. Anderson reviews the technique well.[39]

Solid-phase epitaxy describes the crystalline regrowth of amorphous layers that extend continuously to the underlying single-crystal substrate. At temperatures between 500 and 600°C, in the case of silicon, a recrystallization process occurs on the underlying crystalline substrate, and regrowth proceeds toward the surface. Regrowth is faster on (100) than on (111) Si, and impurities such as B, P, and As enhance the regrowth, whereas O, C, N, and Ar retard it.[27]

Selective Epitaxy

The incorporation of selective epi in the micromachining arsenal is making more versatile microstructures possible. Under the correct growth conditions and/or surface treatment, it is possible to initiate Si growth in selected areas.[27,40] Selective epitaxial growth allows the formation of closely spaced silicon features isolated by SiO_2 (see Figure 7.50). Besides increased density over other insulation techniques (important mainly for the IC industry), structures as shown in Figure 7.50a and b, might enable a host of interesting mechanical microstructures. For example, imagine that the SiO_2 in Figure 7.50b is selectively etched away, resulting in an epi anchor with suspended polybeams. In selective epitaxy of the type shown in Figure 7.50a, silicon atoms possessing high surface mobility migrate to sites on the single crystal where nucleation is favored. In the ideal case, all the epi grows exclusively in the oxide openings. Silicon mobility improves in the presence of halides. The higher the number of chlorine atoms in the silicon source, the better the degree of selectivity (e.g., $SiHCl_3$ is a better source than SiH_2Cl_2). The selective deposition shown in Figure 7.50b is accomplished by simultaneous deposition of epitaxial silicon in the oxide openings and polysilicon on the oxide surfaces. The angle between the epi and the poly in Figure 7.50b depends on the crystallographic orientation of the

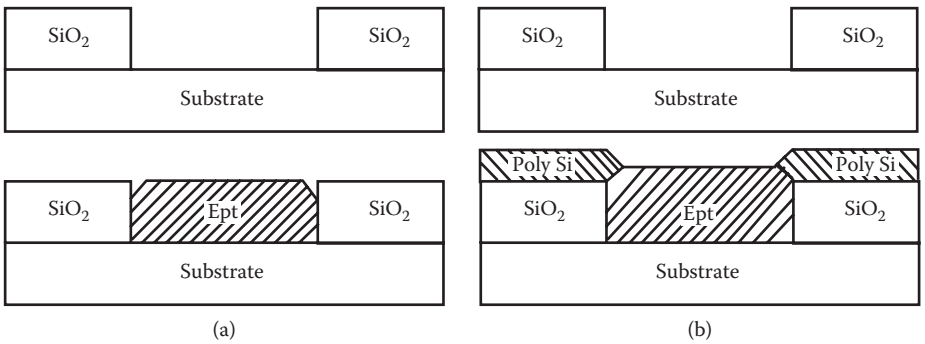

FIGURE 7.50 Selective deposition of epitaxial silicon. (a) Selective deposition of epi Si on Si in SiO_2 windows. (b) Simultaneous deposition of epi Si on Si, and polysilicon on SiO_2. (From Wolf, S., and R. N. Tauber. 1987. *Silicon processing for the VLSI era*. Sunset Beach, CA: Lattice Press.[27])

substrate. The angle is 90° for <110> orientations, 72° toward the polysilicon for <100> orientations, or tapered toward the single-crystal silicon at 70° for the <111> orientation.[27] These figures represent interesting angles from which to construct micromechanical structures. This selective deposition process also lends itself to CVD, for example, for selective deposition of W.

Epilayer Thickness

Epitaxial layer thickness is a critical parameter both in IC applications and micromachines and therefore must be accurately measured and controlled. Many devices, from discrete transistors and 16-megabyte dynamic random access memory (DRAM) to membrane-based micromechanical structures, use silicon epitaxial layer wafers as their starting material. The thickness of an epitaxial layer forms an integral part in the design of many micromachined devices. For example, in a piezoresistive pressure sensor, epilayer thickness control ultimately determines the pressure sensitivity control.

Epilayer thickness can be measured from infrared reflectance, angle lap and stain, tapered groove, weighing, capacitance-voltage measurements, and profilometry. The most widely used, nondestructive method of measuring epi thickness is with infrared instruments. Fourier transform infrared offers automated epilayer thickness measurements.[41]

CVD Equipment

For a detailed historical timeline of vacuum coating and vacuum/plasma technology, visit http://www.svc.org/H/H_HistoricalTime.html, posted on the Internet by the Society of Vacuum Coaters.

Typical sources for CVD equipment are CVD Equipment Corporation (http://www.cvdequipment.com) and IonBond Inc. (http://www.ionbond.com). Commercial epitaxial services offer layers ranging from 0.5–150 μm and N, P, N^+, and P^+ type with uniformity better than ±5%.

Planar (http://www.planar.com) and Cambridge NanoTech (http://www.cambridgenanotech.com) manufacture atomic layer deposition (ALD) systems for many coating applications. Vacuum equipment to clean, deposit, and etch is combined more and more in so-called *cluster tools* (Figure 7.51).[42]

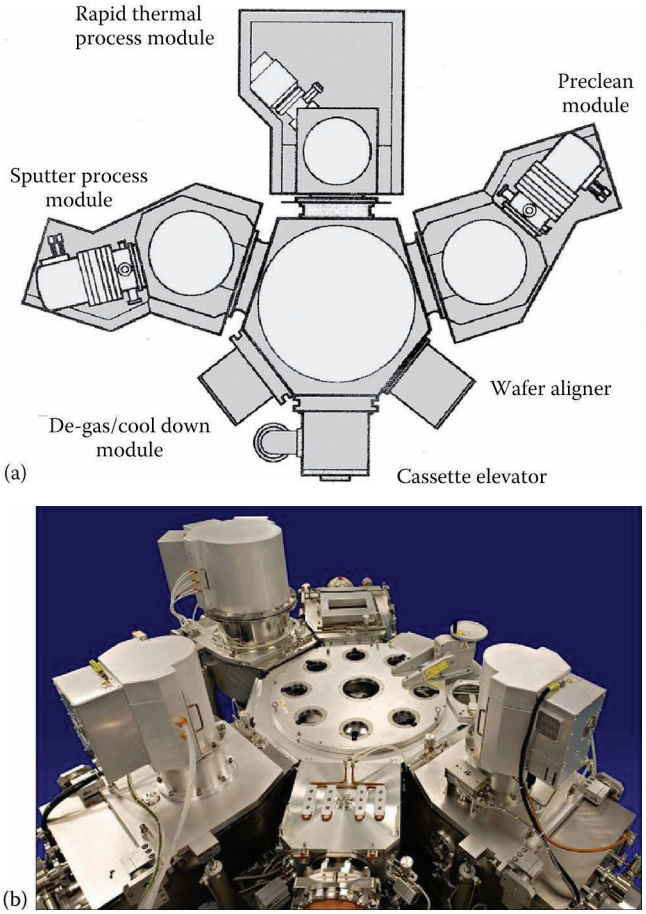

FIGURE 7.51 Cluster tools. (a) Schematic. (b) Example from Ovonyx (http://www.ovonyx.com/corporate).

Selection criteria for the additive processes reviewed in this chapter depend on a variety of considerations, such as:

1. Limitations imposed by the substrate or the mask material: T_{max} (maximum temperature), surface morphology, substrate structure and geometry, and so on
2. Apparatus requirement and availability
3. Limitations imposed by the material to be deposited: chemistry, purity, thickness, T_{max}, morphology, crystal structure, and so on
4. Rate of deposition to obtain the desired film quality
5. Adhesion of deposit to the substrate; necessity of adhesion layer or buffer layer
6. Total running time, including setup time and postcoating processes
7. Cost
8. Ease of automation
9. Safety and ecological considerations

Mechanical Properties of Thin Films

Introduction

The study of the mechanical behavior of thin films started in the 1950s. This early work was initiated to better understand the stresses and failures in integrated circuit (IC) structures. The MEMS field, especially surface micromachining, provided an additional impetus in the late 1980s, and the investigations were extended to more general applications of thin films. In this section, advances in the understanding of mechanical properties of thin films are reviewed with special focus on the mechanical behavior of polycrystalline thin films for MEMS and NEMS applications.

Thin films in surface micromachines must satisfy a large set of rigorous chemical, structural, mechanical, and electrical requirements. Excellent adhesion, low residual stress, low pinhole density, good mechanical strength, and chemical resistance all may be required simultaneously. For many microelectronic thin films, the material properties depend strongly on the details of the deposition process and the growth conditions, and some properties may depend on postdeposition thermal processing, referred to as *annealing*. Furthermore, the details of thin-film nucleation and/or growth may depend on the specific substrate or on the specific surface orientation of the substrate. Although the properties of a bulk material might be well characterized, its thin-film form may have properties substantially different from those of the bulk. For example, thin films generally display smaller grain size than bulk materials. An overwhelming reason for the many differences stem from the properties of thin films, which exhibit a higher surface-to-volume ratio than large chunks of material and are strongly influenced by the surface properties.

Examples where thin films are directly "mechanically challenged" include the myriad of structural and moving parts in MEMS devices, such as the membranes in pressure sensors, hinges in micromirror arrays, wear-resistance coatings on cutting tools, and protective coatings for magnetic disks. In many other applications, thin films are selected primarily because of their unique electronic, magnetic, optical, or thermal properties; however, the mechanical characteristics of the materials of choice in such applications are not unimportant because thin films are often subjected to large mechanical stresses during both the manufacturing process and normal operation of the end-use devices.

Some terminology characterizing thin films and their deposition is introduced in Table 7.18.

Because thin films were originally not intended for load-bearing applications, their mechanical properties were ignored for a long time. As we indicated earlier, it was the IC and MEMS world that

Table 7.18 Thin-Film Terms Used in Characterizing Deposition

Term	Remark
Film	Bond energy <10 kcal/mol
Chemisorbed film	Bond energy >20 kcal/mol
Nucleation	Adatoms forming stable clusters
Condensation	Initial formation of nuclei
Island formation	Nuclei grow in three dimensions, especially along the substrate surface
Coalescence	Nuclei contact each other and larger, rounded shapes form
Secondary nucleation	Areas between islands are filled in by secondary nucleation, resulting in a continuous film
Grain size of thin film	Generally smaller than for bulk materials and function of deposition and annealing conditions (higher T, larger grains)
Surface roughness	Lower at high temperatures except when crystallization starts; at low temperature the roughness is higher for thicker films, also oblique deposition and contamination increases roughness
Epitaxial and amorphous films	Very low surface roughness
Density	More porous deposits are less dense; density reveals a lot about the film structure
Crystallographic structure	Adatom mobility: amorphous, polycrystalline, single crystal or fiber texture, or preferred orientation

precipitated a strong appreciation for the need of an understanding of the mechanical properties as essential for improving the reliability and lifetime of thin films, even in nonstructural applications.[43] Generally, mechanical stresses in thin films can be divided into intrinsic or growth stresses that develop during the deposition process and extrinsic stresses that are induced by external physical effects. The extrinsic stresses are induced by various physical effects after the film is grown.

Thin-film materials are fabricated using very different processing methods than those for bulk materials, such as the various CVD and PVD deposition techniques studied in the current chapter. These processing methods often result in development of intrinsic mechanical stresses in the films. We saw earlier that metal films sputtered at room temperature typically consist of very fine grains, whereas evaporated films are often highly textured with larger grain sizes than sputtered films. It was also pointed out that mobility of the atoms of the deposited material significantly affects the microstructure formation in both deposition and postdeposition processes. The microstructure evolution during the growth process typically involves 1) nucleation of crystallite islands from the condensed material atoms at many sites on the substrate surface, 2) growth of individual crystallite islands until they coalescence with other islands, and 3) coarsening of grains during thickening of the film. For bulk materials, the crystal grain growth occurs at the expense of small grains through the motion of grain boundaries, driven by the reduction in the total grain boundary energy. In thin films the situation is a bit more complex because free surfaces and interfaces also play an important role in the microstructure development. Mismatch strains often develop between the film and the substrate, and this leads to higher strain energy in the film. Grain growth and crystallographic texture development in thin films are driven by the reduction of the total energy, including the grain boundary energy, the surface and interface energy, and the strain energy. This is a thermally activated kinetic process, and for films grown at room temperature, grain growth and texture development are often slow because of lack of thermal activation, resulting in a metastable structure with very fine grains (see section on sputtered films). The microstructure of thin films can be further modified through a postdeposition process, such as annealing. During annealing, grains grow and crystallographic textures develop to minimize the total energy at a rate determined by the annealing temperature. When a grain grows to a size on the order of the film's thickness, the grain boundaries start intersecting the film surface, forming grooves at the surface. These grooves suppress further growth of the grain. As a result, a columnar grain structure with grain boundaries traversing the film thickness results. Thus, the grain size in the plane of the film is on the order of the film thickness.

There have been many mechanisms proposed for the development of growth stresses, which depend sensitively on the material systems, deposition technique, and process parameters. Mechanics at small length scales in micro- and nanotechnology is a challenge for those who recognize its existence and want to optimize the mechanical performance of micro- and nanosystems and a threat for those who ignore it. We will see in Volume III, Chapter 6 on metrology and analytical techniques that surface micromachined devices contribute strongly to the understanding of mechanical properties of thin films.

Strength of Thin Films

Most thin film properties can be simply explained through extrapolation of bulk behavior, but other properties depend on mechanisms that remain unexplained. The strength of thin films is such an example. A substantial body of work has shown that thin metal films can support much higher stresses than the same material in bulk form. This strengthening has generally been attributed to dimensional and microstructural constraints on dislocation activity in these films. Dimensional constraints are imposed by the interfaces and the small dimensions typically encountered in thin films, whereas microstructural constraints arise from the very fine grains that often typify thin films. In bulk materials, microstructural constraints dominate the plastic behavior of the material. However, when material dimensions are comparable to microstructural length scales—as is typically the case for thin films—free surfaces and interfaces play an important role as well. For example, dislocations can exit the material through free

surfaces, whereas interfaces may prevent them from doing so. Consequently, strong interfaces lead to a higher cumulative dislocation density in the film and result in a higher flow stress and a greater strain-hardening rate. In addition to dimensional constraints, the microstructure of thin films also affects their mechanical properties. Because thin films are fabricated using different techniques than those for bulk materials, the microstructure of thin films is often very different from that of bulk materials.

Let us remember what controls the strength of a material. Based on their bond strength most materials should be much stronger than they are in practice. For example, the strength for an ionic bond should be about 10^6 psi, but a more typical strength for an ionic material is 40 10^3 psi. The reason, as we saw in Volume I, Chapter 2, is that materials do not usually fail by breaking bonds. Real materials have lots of dislocations; therefore, the strength of the material depends on the force required to make the dislocation move, not the bonding energy. When dislocations move, slip occurs and the direction of the movement is the same as the Burgers vector (= the deformation direction, e.g., for an edge dislocation it is perpendicular to the dislocation line, and for a screw dislocation it is parallel to the line of the dislocation). When dislocations run into each other a traffic jam effect results; thus, more dislocations increase the strength of a material. Dislocations may be pinned by solutes, interstitials, and precipitates. An example of a solute is Zn atoms in a Cu matrix: the bigger Zn atoms make the slip plane "rougher," and thus increase the resistance to dislocation motion. Precipitates (small particles) also can promote strengthening by impeding dislocation motion. Applying a force to the material increases the number of dislocations, and this is called *strain hardening* or *cold work*. Work hardening accounts for the higher strength of cold rolled steel. Grain boundaries act to impede dislocation motion because the slip systems in adjoining grains will usually not line up; increases in yield strength arising from this mechanism are called *boundary strengthening*. In a small grain, a dislocation gets to the boundary and stops. In a large grain, the dislocation can travel farther. Therefore, a small grain size equates to more strength. Hall and Petch, working independently around 1950, found that the yield strength of a polycrystalline material follows the following dependence:

$$\sigma_Y = \sigma_0 + \frac{K}{\sqrt{d}}$$

(Volume I, Equation 2.70)

where σ_0 is the lattice friction stress needed to move dislocations and K is a constant (e.g., the elastic limit of copper doubles when the grain size decreases from 100 μm to 25 μm). This relation is essentially empirical, but it can be rationalized by viewing the second term as related to the stress needed to activate a new mobile dislocation in an unfavorably oriented grain. The Hall-Petch relation is illustrated in Figure 7.52 for steel at room temperature. The grain size is often given in ASTM grain size number (n)—a measure of the size of the grains in a crystalline material obtained by counting the number of grains per square inch at a magnification × 100. Instead of yield strength one might also plot the hardness (H) of the material in Figure 7.52. Indentation (hardness) testing is very common for bulk materials where the direct relationship between bulk hardness and yield strength is well known. Pressing a hard, specially shaped point into the surface and observing the indentation can measure hardness. This type of measurement is of little use for measuring thin films less than 5 × 10^4 Å. Consequently, very little is known

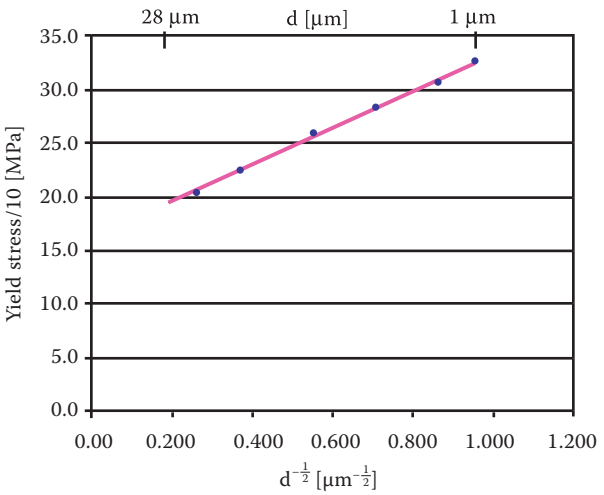

FIGURE 7.52 The Hall-Petch equation—the relationship between yield strength and grain size—in steel at room temperature.

about the hardness of thin films. Recently, specialized instruments have been constructed (e.g., the nanoindenter) in which load and displacement data are collected while the indentation is introduced in a thin film. This eliminates the errors associated with later measurement of indentation size and provides continuous monitoring of load/displacement data similar to a standard tensile test. Load resolution may be 0.25 μN, displacement resolution 0.2–0.4 nm, and *x*-*y* sample position accuracy 0.5 μm. Empirical relations have correlated hardness with Young's modulus and with uniaxial strength of thin films. Hardness calculations must include both plastic and long-distance elastic deformation. If the indentation is deeper than 10% of the film, corrections for elastic hardness contribution of the substrate must also be included.[43] Mechanical properties such as hardness and modulus of elasticity can also be determined on the micro- to picoscales using an atomic force microscope (AFM).[44] Bushan[45] provides an excellent introduction to this field in the *Handbook of Micro/Nanotribology*.

The Hall-Petch relationship has been well established experimentally for grain sizes in the millimeter through submicrometer regimes. Consequently, it was thought that nanosized grains would produce materials with even greater mechanical integrity. The above relation indicates that simply by decreasing the grain size one can make a material arbitrarily strong! Of course, this is not sensible because a polycrystalline material with grain size of a single atom would just be amorphous or a single crystal. In other words, there must be a limit where Hall-Petch breaks down! It is easily recognized that the Hall-Petch behavior is expected to break down, for example, if the smallest dislocation loop no longer fits in a grain (Figure 7.53). For very small grain

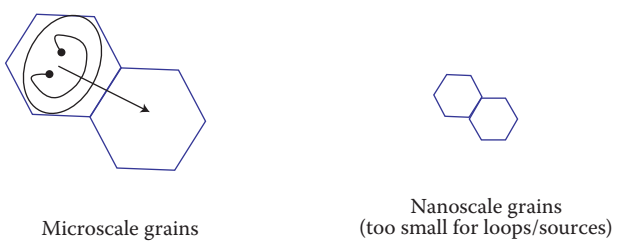

FIGURE 7.53 Hall-Petch behavior breaks down if the smallest dislocation loop no longer fits in a grain.

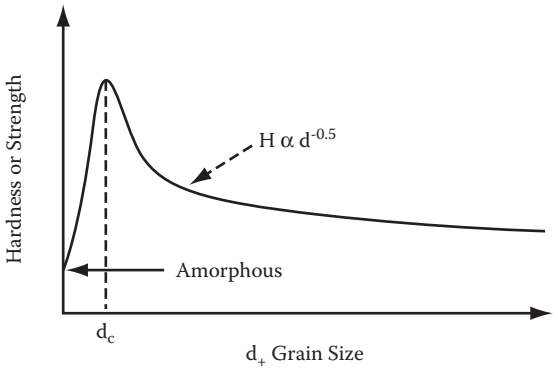

FIGURE 7.54 Hall-Petch and reverse Hall-Petch.

sizes one can perform atomistic simulations of the deformation, and these simulations suggest that for very small grain sizes there is a reverse Hall-Petch effect, i.e., the strength decreases with increasing grain size; in other words, an optimal grain size (d_c) exists as suggested by the plot in Figure 7.54. The classic Hall-Petch relationship is based on the idea that grain boundaries act as obstacles to dislocation movement and that dislocations require greater amounts of energy to overcome these barriers. Because dislocations are carriers of plastic deformation, this manifests itself macroscopically as an increase in material strength. The deformation mechanism for materials with very small grains (<20 nm) is different, and it has been suggested that plastic deformation in this case is no longer dominated by dislocation motion but by atomic sliding of grain boundaries.[46] For very small grain sizes, this sliding effect might conceivably constitute the dominant effect because of the larger ratio of grain boundary to crystal lattice, and this mode of deformation could then lead to the observed softening of a nanomaterial. Other explanations to rationalize the apparent softening of metals with nanosized grains include poor sample quality and the suppression of dislocation pileups.[47]

A reverse Hall-Petch behavior has been observed experimentally in nanocrystalline materials with sufficiently small grain sizes.[48] There are also observations of "kinked" Hall-Petch graphs, i.e., cases where the slope is reduced (but still positive) below a certain grain size. However, today there is still a lot of uncertainty about the exact interpretation of a reverse Hall-Petch effect. It is possible that many of the early measurements of a reverse Hall-Petch

effect were likely the result of unrecognized pores in the samples. The presence of voids in nanocrystalline metals would undoubtedly lead to their having weaker mechanical properties. It is not entirely clear what exactly the dependency of yield stress should be on grain sizes less than a diameter d of 20 nm. Nanocrystalline materials have been the subject of widespread research in recent decades; since the review by Gleiter[49] in 1989, thousands of papers have been published on the topic.

The yield strength of metallic films is affected by several microstructural dimensions: grain size, film thickness, free-standing or deposited on a substrate, and obstacle spacing (e.g., precipitate concentration). A common approach to the quantification of the role of different parts of the microstructure to the yield stress of a deposited film is to assume that their contributions have a power-law form and can be superimposed:

$$\sigma_Y = \sigma_0 + Kd^{-n} + K't^{-m} \qquad (7.22)$$

where the first term represents the bulk yield stress for a large-grained polycrystal, the second represents the contribution from the grain boundaries (with d the grain size), and the third represents the contribution from the film surface or interface with t, the film thickness. The first two terms together form the well-known Hall-Petch relation, in which, commonly, n = 0.5.[50] For thin films with very fine grains ($d \ll t$) or in multilayers with very thin constituent layers, the deposition of individual dislocation segments becomes more important than the formation of pileups, which makes n approach 1. In several studies of thin films deposited on a substrate, an increase of the yield strength with decreasing film thickness has been observed. For example, for thin films of copper, with thickness between 0.1 and 3 μm, vapor deposited on 12.7- or 7.6-μm-thick polyimide Kapton substrates, Yu et al.[50] find that the yield stress depends strongly on the film thickness and is fit by $\sigma_Y = 116 + 355t^{-0.473}$ where t is the thickness in meters and σ_Y is in MPa. The origin of the hardening induced by the finite size of the film is the deposition of dislocation segments at the film surface if oxidized or otherwise passivated and at the film substrate interface. The blocking of the dislocations at the film substrate interface leads to an inhomogeneous strain distribution, in which the plastic strain approaches zero near the interface.

For free-standing films, the effect of film thickness is reversed, with thinner films being weaker. It has been found that grain-size effects are diminished when Cu test sample size decreases to less than about 1 mm, an observation that has important consequences for micromanufacturing. When the grain size d varied between 18 μm and 200 μm, it was found that strength is reduced with an increase in d/t, not the Hall-Petch grain size d.[51] The tensile strength may apparently be described by a rule of mixtures between surface grains with a grain-size independent strength and interior grains that obey the Hall-Petch relation. As shown in Figure 7.55, the tensile strength of Al films decreases with decreasing part thickness in the range of 0.1–0.5 mm.[51]

From the above, size effects may strengthen or weaken the material, and interface strengthening or weakening will play a dominant role. Let us consider Si yield strength as an example. Because of the high activation energy for dislocation motion in silicon (2.2 eV), hardly any plastic flow occurs in single crystalline silicon for temperatures lower than 673°C. Grain boundaries in polysilicon further enhance this blocking of dislocation motion; hence polysilicon films can be treated as an ideal brittle material at room temperature.[52] From the above, we now understand why high yield strengths often are obtained in thin deposited films with values up to 200 times as large as those found in the corresponding bulk material.[53] In this light, the fact that fracture stress of polysilicon is between 2 and 10 times smaller than that of bulk single crystal is surprising. Greek et al.[54] explain this deviation by pointing at the high surface roughness of polysilicon films compared with single-crystal Si. They believe that a reduction in surface roughness would improve the tensile fracture strength considerably.

Adhesion

The importance of adhesion of various films to one another and to the substrate in overall IC performance and reliability cannot be stressed enough. Because

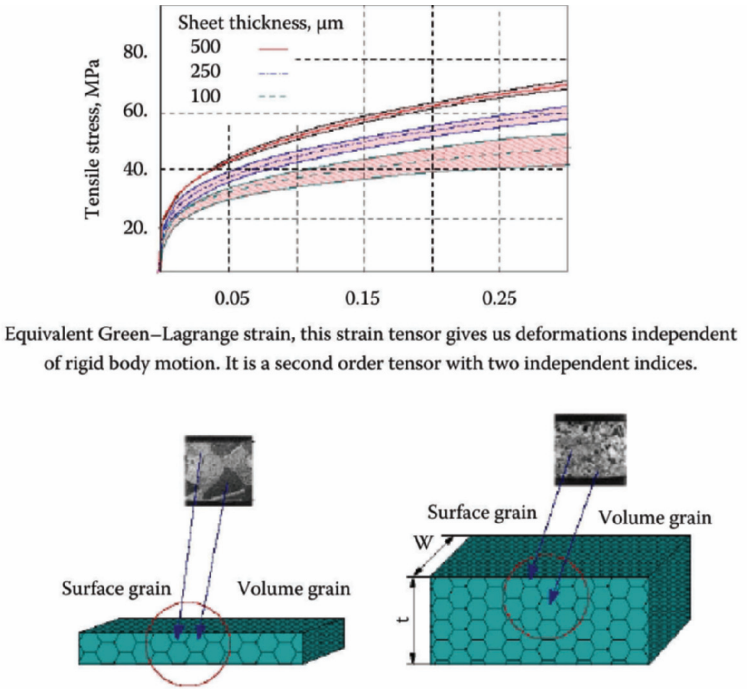

FIGURE 7.55 Thinner Al films mean weaker.[51]

mechanical pulling forces might be involved, adhesion is even more crucial in micromachining. If films lift from the substrate under a repetitive, applied mechanical force, the device will fail. Classical adhesion tests include the scotch tape test, abrasion method, scratching, deceleration (ultrasonic and ultracentrifuge techniques), bending, pulling, and so on (see also Volume III, Chapter 6 on metrology and analytical techniques).[55] Micromachined structures, because of their sensitivity to thin-film properties, enable some innovative new ways of in situ adhesion measurement. Figure 7.56 illustrates how a suspended membrane may be used for adhesion measurements. In Figure 7.56a, the membrane is suspended but still adherent to the substrate. Figure 7.56b shows the membrane after it has been peeled partially from its substrate by an applied load (gas pressure). Figure 7.56c illustrates the accompanying pressure-volume (*P-V*) cycle, in which the membrane is inflated, peeled, and then deflated. The shaded portion of Figure 7.56c illustrates the *P-V* work creating the new surface, which equals the average work of adhesion for the film-substrate interface times the area peeled during the test.[55]

Cleanliness of a substrate is a *conditio sine qua non* for good film adhesion. Roughness, providing more bonding surface area and mechanical interlocking, further improves it. Adhesion also improves with increasing adsorption energy of the deposit and/or increasing number of nucleation sites in the early growth stage of the film. Sticking energies between film and substrate range from less than 10 kcal/mol in physisorption to more than 20 kcal/mol for chemisorption. The weakest form of

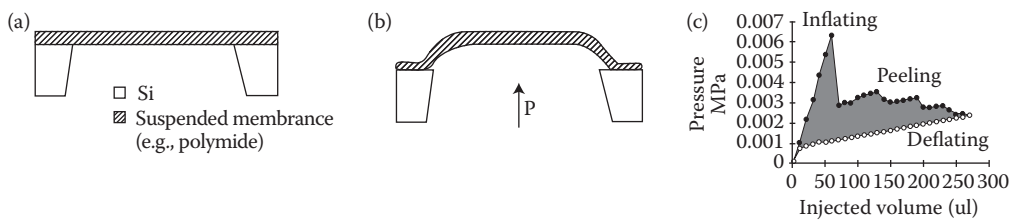

FIGURE 7.56 Micromachined structure to evaluate adhesion. (a) Suspended membrane. (b) Partially detached membrane-outward peel. (c) Pressure-volume curve during inflate-deflate cycle. (From Senturia, S. 1987. *Proceedings: IEEE micro robots and teleoperators workshop.* Hyannis, MA: IEEE. With permission.[55])

adhesion involves Van der Waals forces only (see also Table 7.17).

It is highly advantageous to include a layer of oxide-forming elements between a metal and a substrate. These adhesion layers, such as Cr, Ti, and Al, provide good anchors for subsequent metallization. Intermediate film formation allows for a continuous transition from one lattice to the other and results in the best adhesion. Adhesion also improves when formation of intermetallic metal alloys takes place.

Stress in Thin Films

Qualitative Description

Film cracking, delamination, and void formation may all be linked to film stress. Nearly all films foster a state of residual stress as a result of mismatch in the thermal expansion coefficient, nonuniform plastic deformation, lattice mismatch, substitutional or interstitial impurities, and growth processes. Figure 7.57 illustrates stress-causing factors categorized as either intrinsic or extrinsic.[55] The intrinsic stresses (also growth stresses) develop during the film nucleation. Extrinsic stresses are imposed by unintended external factors such as temperature gradients or sensor package-induced stresses. Thermal stresses, the most common type of extrinsic stresses, are well understood and often rather easy to calculate (see below on page 448). They arise either in a structure with inhomogeneous thermal expansion coefficients subjected to a uniform temperature change or in a homogeneous material exposed to a thermal gradient.[56] Intrinsic stresses in thin films often are larger than thermal stresses. They usually are a consequence of the nonequilibrium nature of the thin-film deposition process. For example, in chemical vapor deposition (CVD), depositing atoms (adatoms) may at first occupy positions other than the lowest energy configuration. With too high a deposition rate and/or too low adatom surface mobility, these first adatoms may become pinned by newly arriving adatoms, resulting in the development of intrinsic stress. Other types of intrinsic stresses illustrated in Figure 7.57 include transformation stresses occurring when part of a material undergoes a volume change during a phase transformation; misfit stresses arising in epitaxial

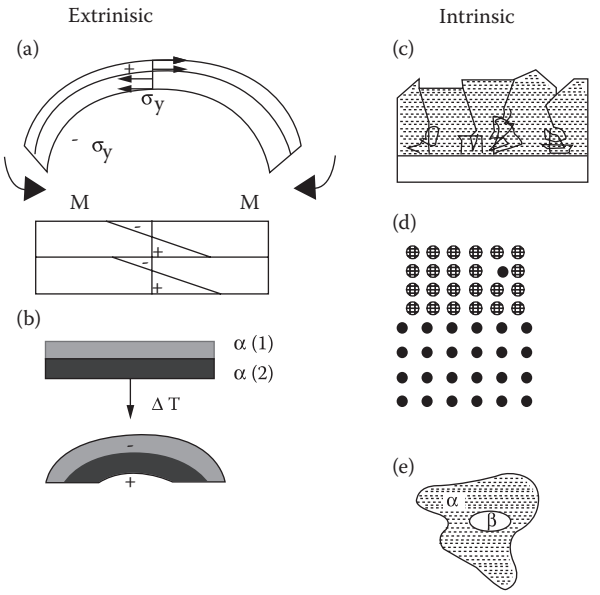

FIGURE 7.57 Examples of intrinsic and extrinsic residual stresses. (a) Nonuniform plastic deformation results in residual stresses on unloading. M = bonding moment. (b) Thermal expansion mismatch between two materials bonded together. α (1) and α (2) are thermal expansion coefficients. (c) Growth stresses evolve during film deposition. (d) Misfit stresses resulting from mismatches in lattice parameters in an epitaxial film and stresses from substitutional or interstitial impurities. (e) Volume changes accompanying phase transformations cause residual stresses. (From Krulevitch, P. A. 1994. *Micromechanical investigations of silicon and Ni–Ti–Cu thin films.* PhD thesis, University of California, Berkeley.[56])

films as a result of lattice mismatch between film and substrate; and impurities, either interstitial or substitutional, which cause intrinsic residual stresses as a result of the local expansion or contraction associated with point defects. Intrinsic stress in a thin film does usually not suffice to result in delamination unless the film is thick. For example, to overcome a low adsorption energy of 0.2 eV, a relatively high stress of about 5×10^9 dyn/cm^2 (10^7 dyn/cm^2 = 1 MPa) is required.[53] High stress can result in buckling or cracking of films.

The stress developing in a film during the initial phases of a deposition may be compressive (i.e., the film tends to expand parallel to the surface), causing buckling and blistering or delamination in extreme cases (especially with thick films). Alternatively, thin films may be in tensile stress (i.e., the film tends to contract), which may lead to cracking if forces high enough to exceed the fracture limit of the film

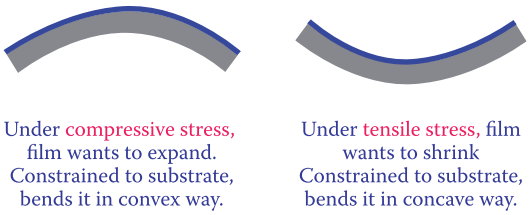

FIGURE 7.58 Tensile and compressive stress in thin films.

material are present (Figure 7.58). Subsequent rearrangement of the atoms, either during the remainder of the deposition or with additional thermal processing, can lead to further densification or expansion, decreasing remaining tensile or compressive stresses, respectively.

The mechanical response of thin-film structures is affected by the residual stress, even if the structures do not fail. For example, if the residual stress varies in the direction of film growth—in other words, if there is a stress gradient—the resulting built-in bending moment will warp released structures, such as cantilever beams (Figure 7.59). The presence of residual stress also alters the resonant frequency of thin-film, resonant microstructures (see Equation 7.29 below).[57] In addition, residual stress can lead to degradation of electrical characteristics and yield loss through defect generation.[56] For example, it was found that the resistivity of stressed metallic films is higher than that of their annealed counterparts. Residual stress has been used advantageously in a few cases, such as in self-adjusting microstructures,[58] and for altering the shape-set configuration in shape memory alloy films.[56]

In general, the stresses in thin films, by whatever means produced, are in the range of 10^8 to 5×10^{10} dyn/cm^2 and can be either tensile or compressive. For normal deposition temperatures (50 to a few hundred °C), the stress in metal films typically

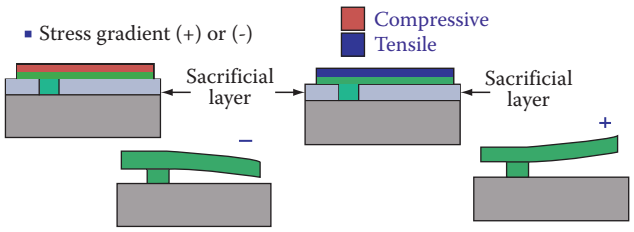

FIGURE 7.59 Stress gradients cause a bending moment in a cantilever upon release, i.e., removal of the sacrificial material.

ranges from 10^8–10^{10} dyn/cm^2 and is tensile, with the refractory metals (Mo, Ta, Nb, W, and Ta) at the upper end and the soft ones (Cu, Ag, Au, and Al) at the lower end. At low substrate temperatures, metal films tend to exhibit tensile stress. This often decreases in a linear fashion with increasing substrate temperature, finally going through zero or even becoming compressive. The changeover to compressive stress occurs at lower temperatures for lower melting point metals. The mobility of the adatoms is key to understanding the ranking for refractory and soft metals. A metal such as aluminum has a low melting temperature and a corresponding high diffusion rate even at room temperature; thus, usually it is fairly stress free. By comparison, tungsten has a relatively high melting point and a low diffusion rate, and tends to accumulate more stress when sputter deposited. With dielectric films, stresses often are compressive and have slightly lower values than commonly noted in metals.

Tensile films result, for example, when a process byproduct is present during deposition and later driven off as a gas. If the deposited atoms are not sufficiently mobile to fill in the holes left by these departing byproducts, the film will contract and go in tension. Nitrides deposited by plasma CVD are usually compressive because of the presence of hydrogen atoms in the lattice. By annealing, which drives out the hydrogen, the films can become highly tensile. Annealing also has a dramatic effect on most oxides. Oxides often are porous enough to absorb or give off a large amount of water. Full of water, they are compressive; devoid of water, they are tensile. Thermal SiO_2 is compressive even when dry. If atoms are jammed in place (such as with sputtering), the film tends to act compressively. The stress in a thin film also varies with depth.

When reviewing dry etching in Chapter 3 we discussed plasma chemistry and physics. The following listing further completes that information. The RF power of a plasma-enhanced CVD (PECVD) deposition influences stress, e.g., a thin film may start out tensile, decrease as the power increases, and finally become compressive with further RF power increase. CVD equipment manufacturers concentrate on building stress-control capabilities into new equipment by controlling plasma frequency.

Therefore, in what follows we pay specific attention to PECVD parameter settings influencing thin-film properties, important in building surface micromachined microstructures, i.e., film stress and density. Surface micromachining uses deposited thin films, such as polysilicon, silicon nitride, and silicon dioxide. One of the challenges of any surface-micromachined process is to control the intrinsic stresses in those deposited films. Plasma settings act as critical controlling parameters of intrinsic stress in CVD films. Recall that the plasmas of interest are low-pressure glow discharges consisting of ions, electrons, and neutral species. The neutral species, molecules, and radicals greatly outnumber the electrons and ions and are not influenced by external electrical fields. Just as etching occurs mainly through neutral species, deposition also almost exclusively involves neutrals. In etching, the ions impart anisotropy to the etching process, whereas in deposition they alter the properties of the deposited films. The different reactor parameter settings have the following influence on the CVD deposited films:

1. *Total reactor pressure*: Because gas density varies with pressure, the mean free path is longer at lower pressures. Consequently, ions accelerated toward the cathode at lower pressure can gain more energy before a collision takes place. Therefore, the effect of ion bombardment is more pronounced at lower pressures, and better quality CVD films ensue, characterized as films with a low wet etch rate (high film density) and low compressive stress. Experimental results show that as the reactor pressure is lowered, film stress goes from tensile to compressive and wet etch rates decrease. Often, stress dynamically changes when the film is exposed to the atmosphere and subsequent heating. In the case of oxide films, for example, tensile films take up water, swell, and become more compressive (the substrate bends down). Compressive oxide films have a greater moisture resistance. A nitride film, on the other hand, absorbs no water and shows no tendency toward compressive stress with time. In the latter case, the amount of Si-H bonds, controlled by annealing at 490°, seems to dominate the stress behavior.[59] Too high pressures promote gas-phase polymerization, increasing defect density in the deposited material. In the other extreme, too low pressures (alternatively, the reactant gas is too diluted) change the process from CVD-like to PVD-like, giving way to a columnar film morphology with more defects.
2. *Frequency of the RF excitation*: At low frequencies, ions experience the full amplitude of the RF voltage, whereas above the ion-transition frequency (>3 MHz), where ions cannot follow anymore, the ion energy is determined by the time average of the RF amplitude. Consequently, lower frequency shifts the ion energy upward. At the lower frequencies, wet etch rates decrease, and compressive film stress results. Again, higher-energy bombardment yields better films. Higher ion bombardment also improves the film quality on sidewalls. Multiple-frequency plasma equipment is emerging rapidly because it allows the user precise control over film properties (particularly stress) for a wide range of process conditions and can also improve step coverage.
3. *RF power effects*: An increase in RF power leads to more intense ion bombardment due to the increase in ion current. With a higher ion current, the film deposition rate goes up. To separate the effect of RF power on growth rate and film quality, the ratio of power density to deposition rate must be evaluated. This ratio represents a rough measure of ion bombardment per deposited molecule. In a plot of wet etch rate versus power density divided by the deposition rate, the maximum ion bombardment, corresponding to highest energy density, leads to the lowest wet etch rate.[60]
4. *Growth temperature*: The growth temperature has a strong influence on the structure of the film. At low temperatures (and high growth rates), the surface diffusion is slow relative to the arrival rate of film precursors. In this situation, the adsorbed precursor molecule is likely to interact with an impinging precursor molecule before it has a chance to diffuse away on the surface, and an amorphous film is formed. At high temperatures (and low growth rates),

the surface diffusion is fast relative to the incoming flux. The adsorbed species can diffuse to step growth sites, forming single crystalline materials.

Summarizing, low RF excitation frequency, low reactor pressures, and low deposition rate at high temperature contribute to improved film quality as evidenced by stress and (wet) etch rate measurements. More information on CVD thin films and how they are influenced by the above deposition parameters, as well as other parameters (e.g., moisture, flow rate, and gas composition) will be given in Volume III, Chapter 5 on selected MEMS and NEMS materials.

Stress in Thin Films on Thick Substrates—Quantitative Analysis

The total stress in a thin film typically is given by:

$$\sigma_{tot} = \sigma_{th} + \sigma_{int} + \sigma_{ext} \tag{7.23}$$

i.e., the sum of any intentional external applied stress (σ_{ext}), the thermal stress (σ_{th}, an unintended external stress), and different intrinsic components (σ_{int}). With constant stress through the film thickness, the stress components retain the form of:

$$\begin{aligned} \sigma_x &= \sigma_x(x,y) \\ \sigma_y &= \sigma_y(x,y) \\ \tau_{x,y} &= \tau_{x,y}(x,y) \\ \tau_{xz} &= \tau_{yz} = \sigma_z = 0 \end{aligned} \tag{7.24}$$

In other words, the three nonvanishing stress components are functions of x and y alone. No stress occurs in the direction normal to the substrate (z). With x,y as principal axes, the shear stress τ_{xy} also vanishes,[61] and Equation 7.24 reduces to the following strain-stress relationships:

$$\begin{aligned} \varepsilon_x &= \frac{\sigma_x}{E} - \frac{\nu\sigma_y}{E} \\ \varepsilon_y &= \frac{\sigma_y}{E} - \frac{\nu\sigma_x}{E} \\ \sigma_z &= 0 \end{aligned} \tag{7.25}$$

In the isotropic case, $\varepsilon = \varepsilon_x = \varepsilon_y$, so that $\sigma_x = \sigma_y = \sigma$, or:

$$\sigma = \left(\frac{E}{1-\nu}\right)\varepsilon \tag{7.26}$$

where the Young's modulus E of the film and the Poisson ratio of the film act independently of orientation. The quantity $E/1 - \nu$ often is called the *biaxial modulus*. Uniaxial testing of thin films is difficult, prompting the use of the biaxial modulus rather than Young's uniaxial modulus (see Volume III, Chapter 6 on metrology and analytical techniques). Plane stress, as described here, is only a good approximation when several thicknesses (e.g., three) away from the edge of the film.

Thermal Stress

The most commonly encountered example of thin film stress is the thermal mismatch stress due to the thermal expansion mismatch between a film and its substrate. The manufacturing process and normal operation of most thin film-based devices often involve large temperature cycles. Therefore, thermal mismatch stresses are inevitable, and they can be very high if the thermal mismatch is large and the elastic modulus of the film is large, such as is the case for Cu films used in integrated circuits (ICs). Thermal stresses develop in thin films when high-temperature deposition or annealing is involved, and they usually are unavoidable because of mismatch of thermal expansion coefficients between film and substrate. The problem of a thin film under residual thermal stress can be modeled by considering a thought experiment involving a stress-free film at high temperature on a thick substrate. Imagine detaching the film from the high-temperature substrate and cooling the system to room temperature. Usually, the substrate dimensions undergo minor shrinkage in the plane, whereas the film's dimensions may reduce significantly. To reapply the film to the substrate with complete coverage, the film needs stretching with a biaxial tensile load to a uniform radial strain, ε, followed by perfect bondage to the rigid substrate and load removal. The film stress is assumed to be the same in the stretched and freestanding film as

in the film bonded to the substrate, i.e., no relaxation occurs in the bonding process. To calculate the thermal residual stress from Equation 7.26, the elastic moduli of the film must be known, as well as the volume change associated with the residual stress, i.e., the thermal strain, ε_{th}, resulting from the difference in the coefficients of thermal expansion between the film and the substrate.

Let us now consider whether, qualitatively, the above assumptions apply to the measurement of thin films on Si wafers. Such films typically measure 1 μm thick and are deposited on 4-in. wafers, nominally 550 μm thick. In this case, the substrate measures nearly three orders of magnitude thicker than the film, and, because the bending stiffness is proportional to the thickness cubed, the substrate essentially is rigid relative to the film. The earlier assumptions clearly apply.

Figure 7.60 portrays a quantitative example where a polyimide film, strain-free at the deposition temperature (T_d) of 400°C, is cooled to room temperature T_r (25°C) on a Si substrate with a different coefficient of thermal expansion. The resulting strain is given by:

$$\varepsilon_{th} = \int [\alpha_f(T) - \alpha_s(T)]dT \qquad (7.27)$$

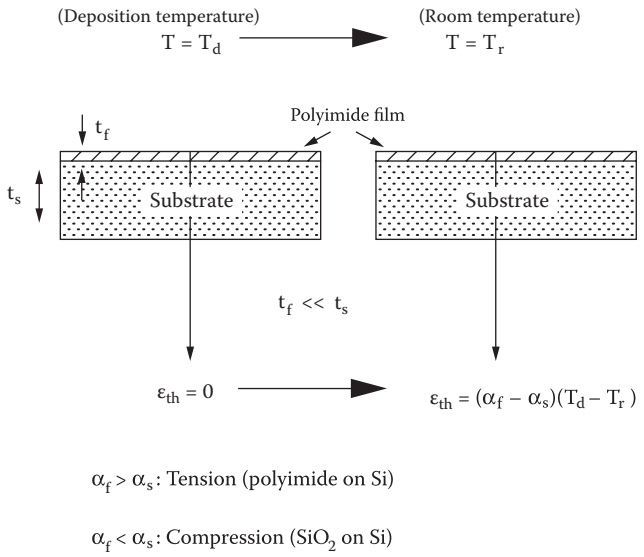

FIGURE 7.60 Thermal stress. Tension and compression are determined by the relative size of thermal expansion coefficients of film and substrate. Suppose a strain-free film at deposition temperature, T_d, is cooled to room temperature, T_r, on a substrate with a different coefficient of thermal expansion.

where α_f and α_s represent the coefficients of thermal expansion for the polyimide film and the Si substrate, respectively. The thermal strain can be of either sign; based on the relative values of α_f and α_s, positive is tensile, and negative is compressive. Polyimide features a thermal expansion ($\alpha_f = 70 \times 10^{-6}°C^{-1}$) larger than the thermal expansion coefficient of Si ($\alpha_s = 2.6 \times 10^{-6}°C^{-1}$); hence a tensile stress is expected. With SiO_2 grown or deposited on silicon at elevated temperatures, a compressive component [$\alpha_f(0.35 \times 10^{-6}°C^{-1}) < a_s(2.6 \times 10^{-6}°C^{-1})$] is expected. Assuming that the coefficients of thermal expansion are temperature independent, Equation 7.27 simplifies to:

$$\varepsilon_{th} = [\alpha_f - \alpha_s](T_d - T_r) \qquad (7.28)$$

The calculated thermal strain for polyimide on Si then measures 25×10^{-3} at room temperature. The biaxial modulus ($E/1 - \nu$), with E = 3 GPa and ν = 0.4, equals 5 GPa, and the residual stress σ, from Equation 7.26, is 125 MPa and tensile.

Intrinsic Stress

The intrinsic stress, σ_i, reflects the internal structure of a material and is less clearly understood than the thermal stress, which it often dominates.[62] Several phenomena may contribute to σ_i, making its analysis very complex. Intrinsic stress depends on thickness, deposition rate (locking in defects), deposition temperature, ambient pressure, method of film preparation, type of substrate used (lattice mismatch), incorporation of impurities during growth, and so on. Some semiquantitative descriptions of various intrinsic stress-causing factors follow:

- Doping ($\sigma_{int} > 0$ or $\sigma_{int} < 0$): When doping Si, the atomic or ionic radius of the dopant and the substitutional site determine the positive or negative intrinsic stress ($\sigma_{int} > 0$ or tensile and $\sigma_{int} <$ 0 or compressive). With boron-doped polysilicon, a small atom compared with Si, the film is expected to be tensile ($\sigma_{int} > 0$); with phosphorous doping, a large atom compared with Si, the film is expected to be compressive ($\sigma_{int} < 0$).
- Atomic peening ($\sigma_{int} < 0$): Ion bombardment by sputtered atoms and working gas densifies thin films, rendering them more compressive.

Magnetron sputtered films at low working pressure (<1 Pa) and low temperature often exhibit compressive stress. This topic was discussed in some detail higher above.

- Microvoids ($\sigma_{int} > 0$): Microvoids may arise when byproducts during deposition escape as gases and the lateral diffusion of atoms evolves too slowly to fill all the gaps, resulting in a tensile film.
- Gas entrapment ($\sigma_{int} < 0$): As an example we can cite the hydrogen trapped in Si_3N_4. Annealing removes the hydrogen, and a nitride film, compressive at first, may become tensile if the hydrogen content is sufficiently low.
- Shrinkage of polymers during cure ($\sigma_{int} > 0$): The shrinkage of polymers during curing may lead to severe tensile stress, as becomes clear in the case of polyimides. Special problems are associated with measuring the mechanical properties of polymers because they exhibit a time-dependent mechanical response (viscoelasticity), a potentially significant factor in the design of mechanical structures where polymers are subjected to sustained loads.[63]
- Grain boundaries (σ_{int} = ?): Based on intuition it is expected that the interatomic spacing in grain boundaries differs depending on the amount of strain, thus contributing to the intrinsic stress. However, the origin of, for example, the compressive stress in polysilicon and how it relates to the grain structure and interatomic spacing are not yet completely clear (see also below on coarse and fine-grated Si).

For further reading on thin-film stress, refer to Hoffman.[64,65] For a short tutorial, visit http://www.uccs.edu/~tchriste/courses/PHYS549/549lectures/mechchar.html.

Case Study: Polysilicon Deposition and Film Microstructure

Introduction Thin-film properties prove not only difficult to measure but also cumbersome to reproduce, given the many influencing parameters. Evaporation, sputtering, and molecular beam techniques can deposit dielectric and polysilicon films. In VLSI and surface micromachining, none of these techniques is as widely used as CVD. The major problems associated with the former methods are defects caused by excessive wafer handling, low throughput, poor step coverage, and nonuniform depositions. From the comparison of CVD techniques for typical IC and MEMS materials in Table 7.19, we can conclude that LPCVD, at medium temperatures, prevails above all others. VLSI devices and integrated surface micromachines require low processing temperatures to prevent movement of shallow junctions, uniform step coverage, few process-induced defects (mainly from particles generated during wafer handling and loading), and high wafer throughput to reduce cost. These requirements are best met by hot-wall, low-pressure depositions.[66] While depositing a material with LPCVD the following process parameters can be varied: deposition temperature, gas pressure, flow rate, and deposition time.

The IC industry applies LPCVD polysilicon in applications ranging from simple resistors, gates

Table 7.19 Comparison of Different Deposition Techniques

	Atmospheric CVD (APCVD)	Low T LPCVD	Medium T LPCVD	Plasma-Assisted CVD (PECVD)
Temp (°C)	300–500	300–500	500–900	100–350
Materials	SiO_2, P-glass	SiO_2, P-glass, BP-glass	Polysilicon, SiO_2, P-glass, BP-glass Si_3N_4, SiON	SiN, SiO_2, SiO_2, SiON
Uses	Passivation, insulation, spacer	Passivation, insulation, spacer	Passivation, gate metal, structural element, spacer	Passivation, insulation, structural elements
Throughput	High	High	High	Low

for MOS transistors, thin-film transistors (TFT) based on amorphous hydrogenated silicon (a-Si:H), DRAM cell plates, and trench fills, as well as in emitters in bipolar transistors and conductors for interconnects. For the last application, highly doped polysilicon is especially suited: it is easy to establish ohmic contact; it is light insensitive and corrosion resistant; and its rough surface promotes adhesion of subsequent layers. Doping elements such as arsenic, phosphorous, or boron reduce the resistivity of the polysilicon. Commercial LPCVD equipment is available to deposit polysilicon on wafers up to 8 in. in diameter. A typical batch is 100–200 wafers. The mechanical properties of polycrystalline silicon are very good:

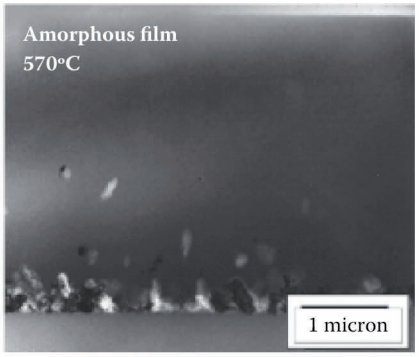
- Stronger than stainless steel: fracture strength of polysilicon ~ 2–3 GPa (steel ~ 0.2 GPa–1 GPa)
- Young's modulus E ~ 140–190 GPa
- Extremely flexible: maximum strain before fracture ~ 0.5%
- Does not fatigue readily
- Compatible with IC fabrication processes: process parameters are well known

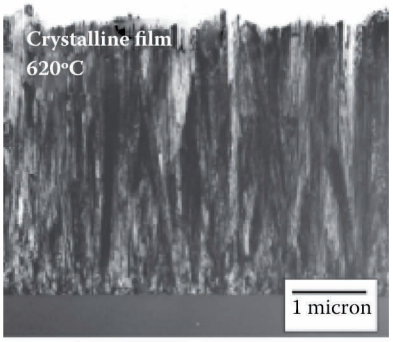
These properties explain how polysilicon also has emerged as the central structural/mechanical material in surface micromachining, and a closer look at the influence of deposition methodology on its material characteristics is warranted. In this case study we tackle polysilicon deposition by LPCVD and compare it with PECVD and sputtered polysilicon.

Undoped Polysilicon

The properties of low-pressure CVD (LPCVD) undoped polysilicon films are determined by the nucleation and growth of the silicon grains. In most cases, the Si wafers to deposit polysilicon on are placed vertically and closely spaced together in quartz boats. Stress depends on crystal structure. LPCVD Si films, grown slightly below the crystallization temperature (about 600°C for LPCVD), initially form an amorphous solid that subsequently may crystallize during the deposition process.[56,68] The CVD method results in amorphous films when the deposition temperatures are well below the melting temperature of Si (1410°C). The subsequent transition from amorphous to crystalline depends on atomic surface mobility and deposition rate. At low temperatures, surface mobility is low, and nucleation and growth are limited. Newly deposited atoms become trapped in random positions and, once buried, require a substantial amount of time to crystallize as solid-state diffusion is significantly lower than surface mobility. That is why, for low temperature deposition, amorphous layers only start to crystallize after sufficient time at temperature in the reactor. Working at temperatures between 580 and 591.5°C, Guckel et al.[68] produced mostly amorphous films. However, Krulevitch,[56] working at only slightly higher temperatures (605°C) and probably leaving the films longer in the LPCVD setup, produced crystallized films. On crossing the transition temperature between amorphous and crystalline growth (see Figures 7.61 and 7.38), crystalline growth immediately initiates at the substrate due to the increased surface mobility, which allows adatoms to find low-energy, crystalline positions from the start of the deposition process.

The deposition temperature at which the transition from amorphous to a crystalline structure occurs depends on many parameters, such as deposition rate, partial pressure of hydrogen, total pressure, presence of dopants, and presence of impurities (O, N, or C).[67] In the crystalline regime, numerous nucleation sites form, resulting in a transition zone of a multitude of small grains at the film/substrate interface to columnar crystallites on top, as shown in the schematic of a 620–650°C columnar film in Figure 7.62. In this figure, a transition zone of small, randomly oriented grains is sketched near the SiO_2 layer. The rate of crystallization is faster here than the deposition rate. Columnar grains ranging between 0.03 and 0.3 μm in diameter form on top of the small grains.[67] The columnar coarse grain structure arises from a process of growth competition among the small grains, during which those grains preferentially oriented for fast vertical growth survive at the expense of misoriented, slowly growing grains.[69,70] The lower the deposition temperature, the smaller the initial grain size will be. At 700°C, films also are columnar; however, the grains are cylindrical, extending through the thickness of the entire film, and there is no transition zone near the





Effect of temperature:

Amorphous to crystalline:	570°C
Equi-axed grains:	600°C
Columnar grains:	625°C

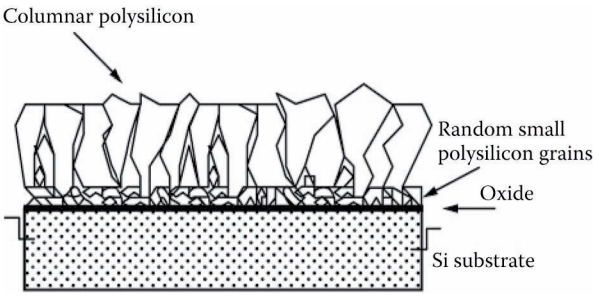

FIGURE 7.62 Schematic of compressive polysilicon formed at 620–650°C. The columnar coarse-grain structure arises from a process of grain growth competition among the small grains, during which those grains preferentially oriented for fast vertical growth survive at the expense of misoriented, slowly growing grains. (From Krulevitch, P. A. 1994. *Micromechanical investigations of silicon and Ni–Ti–Cu thin films.* PhD thesis, University of California, Berkeley.[56])

SiO_2 interface.[56] Temperature has to be very accurately controlled as grains grow with temperature, increasing surface roughness, causing loss of pattern resolution and stresses in MEMS.

Stress in polysilicon films was found to vary significantly with deposition temperature and silane pressure. Guckel et al.[68] found that their mainly amorphous films, deposited at temperatures less than 600°C, proved highly compressive with strain levels as high as –0.67%. At temperatures barely more than 600°C, Krulevitch reports tensile films, whereas for yet higher temperatures (≥620°C), the stress again turns compressive. Whereas films deposited at temperatures more than 630°C all turned out compressive, the magnitude of the compression decreased with increasing temperature. The stress gradient in the polysilicon films explains why compressive undoped and unannealed polysilicon beams tend to curl upward (positive stress gradient) when released from the substrate.[71]

Using high-resolution transmission electron microscopy, Guckel et al.[68] and Krulevitch[56] found a strong correlation between the material's microstructure and the exhibited stress. Guckel et al. found that in their mainly amorphous films, deposited at temperatures less than 600°C, a region near the substrate interface crystallized during growth with grains between 100 and 4000 Å. Krulevitch found that tensile, low-temperature films (605°C) have Si grains dispersed throughout the film thickness. These equiaxed crystals in an isotropic, higher-density film result in a tensile stress with a very small stress gradient. Krulevitch suggests that the compressive stress in the higher temperature compressive films (≥620°C) relates to the competitive growth mechanism of the columnar grains. As crystals grow vertically and in-plane they push on neighbors, resulting in compressive stress and a positive stress gradient. The same author concluded that thermal sources of stress are insignificant.

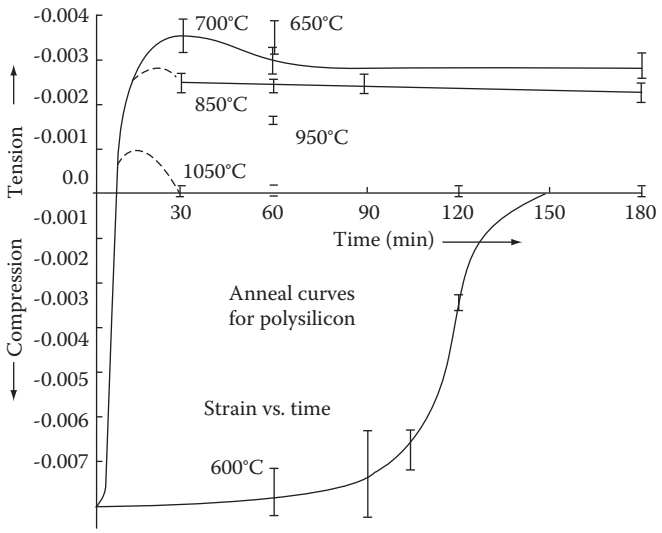

FIGURE 7.63 Anneal curves for polysilicon. Strain versus anneal time. Upper curves: low-temperature film. Lower curve: high-temperature film. (From Guckel, H., D. W. Burns, C. C. G. Visser, H. A. C. Tilmans, and D. Deroo. 1988. Fine-grained polysilicon films with built-in tensile strain. *IEEE Trans Electron Devices* 35:800–01. With permission.[74])

Importantly, Guckel et al. discovered that annealing in nitrogen or under vacuum converts the low-temperature films with compressive built-in strain (–0.007) to a tensile strain with controllable strain levels between 0 and +0.003 (see Figure 7.63). Annealing can reduce stresses by a factor of 10–100.

During anneal, no grain size increase was noticed (100–4000 Å), but a slight increase in surface roughness was measured. This type of polysilicon is referred to as *fine-grain polysilicon* (also Wisconsin poly-Si). Guckel et al. explain this strain field reversal as follows: as the amorphous region of the film crystallizes, it attempts to contract, but because of the substrate-constrained newly crystallized region, a tensile stress results. Higher temperature films, during an anneal, also become less strained, but the strain remains compressive (see lower curve in Figure 7.63). Moreover, in this case grain size increases, and the surface turns considerably rougher. The latter is called *coarse-grain polysilicon*. Fine-grain polysilicon, with its tensile strain, is preferable; however, it cannot be doped to as low a resistivity as coarse-grain polysilicon. Hence fine-grain polysilicon should be considered a structural material rather than an electronic material.

The above picture is further complicated by the controlling nature of the substrate. For example, depositing amorphous Si at even lower temperatures of 480°C from disilane (Si_2H_6) and crystallizing it by subsequent annealing at 600°C demonstrated a large dependency of crystallite size on the underlying SiO_2 surface condition. Treating the surface with HF:H_2O or NH_4OH:H_2O_2:H_2O leads to polysilicon films with a large grain size, two or three times as large as without SiO_2 treatment, believed to be the consequence of nucleation rate suppression.[72]

Abe and Reed made low-strain polysilicon thin film by DC-magnetron sputtering and postannealing. The films showed very small regional stress and very smooth texture. The deposition rate was 193 Å/min, and the substrate was neither cooled nor heated. The average roughness was found to be comparable with the surface roughness of polished, bare silicon substrates.[73]

Summarizing, stress in polysilicon depends on the material's microstructure, with tension arising from the amorphous to crystalline transformation during deposition and compression from the competitive grain growth mechanism.

Polysilicon deposited at 600–650°C has a {110}-preferred orientation. At higher temperatures, the {100} orientation dominates. Dopants, impurities, and temperature influence this preferred orientation.[67] Drosd and Washburn[75] introduced a model explaining the experimental observation that regrowth of amorphous Si is faster for {100} surfaces, followed by {110} and {111}, which are 2.3 and 20 times slower, respectively. Interestingly, the latter also pinpoints the order of fastest to slowest etching of the crystallographic planes in alkaline etchants. As discussed in Chapter 4, Elwenspoek et al.[76] used this observation of symmetry between etching and growing of Si planes as an important insight to develop a new theory explaining anisotropy in etching. In Table 7.20 we compare the discussed coarse- and fine-grain polysilicon forms.

Doped Polysilicon

To produce micromachines, doped polysilicon is used far more frequently than undoped polysilicon. Dopants decrease the resistivity to produce conductors and control stress. Polysilicon can be doped by diffusion, implantation, or the addition of dopant gases during deposition (in situ doping).

Table 7.20 Comparison of Coarse-Grain and Fine-Grain Polysilicon

	Coarse-Grain Polysilicon	Fine-Grain Polysilicon
Temperature of deposition (°C)	620–650	570–591.5
Surface roughness	Rough >50 Å	Smooth <15 Å
Grain size	Undoped: 160–320 Å as deposited In situ P-doped: 240–400 Å	Very small grains
As deposited strain	–0.002 (compressive)	–0.007 (compressive)
Effect of high temperature anneal	Grains size increases Residual strain decreases but remains compressive Reduced bending moment	Grain size increases to 100 Å;[74] others have found 700–900 Å large variation in strain: from compressive to tensile
Dry and wet etch rate	Higher for doped material, depends on dopant concentration	Higher for doped material, depends on dopant concentration
Texture	<110> as deposited <311> in situ P-doped	No texture as deposited, depends on dopant concentration, <111> after 900–1,000°C anneal[77]

Doping polysilicon films in situ reduces the number of processing steps required for producing doped microdevices by eliminating the need for a subsequent high-temperature step associated with a diffusion or ion-implantation anneal and also provides more uniform doping throughout the film thickness. In situ doping of polysilicon is accomplished by maintaining a constant PH_3 to SiH_4 gas flow ratio of about 1 vol% in a hot-wall LPCVD setup. At this ratio, the phosphorous content in the film appears above the saturation limit, and the excess dopant segregates at the grain boundaries.[67] Phosphorus diffuses significantly faster in polysilicon than in single-crystalline silicon. The diffusion takes place primarily along the grain boundaries. The diffusivity in thin films of polysilicon (i.e., small equiaxed grains) is about 1 10^{-12} cm^2/s. The dopant concentration of in situ doped films is normally very high ($\sim 10^{20}$ cm^{-3}). At more than about 1 10^{21} cm^{-3}, the film resistivity reaches a plateau of 4×10^{-4} $\Omega \cdot cm$ because of the low mobility of electrons or holes. The maximum mobility for the highest phosphorus-doped polysilicon is about 30 cm^2/Vs.[78]

In situ phosphorus-doped polysilicon undergoes the same amorphous to crystalline growth transformation observed in the undoped film, with the material's microstructure depending on deposition temperature and deposition pressure. The temperature of transformation is lower for the doped films than for the undoped polysilicon and occurs between 580 and 620°C.[79,80] Thus, phosphorus doping enhances crystallization in amorphous silicon,[81] and because of passivation of the polysilicon surface by the phosphine gas, reduces the polysilicon deposition rate.[79] Decreases in deposition rate by as much as a factor of 25 have been reported.[82] Slower deposition rates allow more time for adatoms to find crystalline sites, resulting in crystalline growth at lower temperatures. From Table 7.20, we read that the grain size of phosphorus-doped polysilicon tends to be larger (240–400 Å) than for the undoped material and that {311} planes show up as a texture facet in the doped material. In contrast to in situ phosphine and arsine doping, which both decrease the deposition rate, diborane doping of polysilicon to make it p^+ accelerates the deposition rate.[67]

At lower deposition temperatures and higher pressures, the microstructure again consists of amorphous and crystalline regions, whereas at higher temperatures and lower pressures columnar films result and as deposited films exhibit compressive residual stress. The columnar films have a stress gradient that increases toward the film surface, as opposed to the gradient found in undoped columnar polysilicon. This gradient in stress most likely is to the result of nonuniform distribution of phosphorus throughout the film. Annealing at 950°C for 1 h results in the same stress and stress gradient for initially columnar and initially amorphous/crystalline films [i.e., $\sigma_f = -45$ MPa and $\Gamma = +0.2$ mm^{-1} (a linear stress gradient with physical dimensions 1/length), respectively].[56]

As in the case of undoped polysilicon, phosphorus-doped polysilicon films with smooth surfaces (fine grain) are obtained by depositing in situ doped films in the amorphous state and then

annealing.[77,83] Phosphorus-doped polysilicon oxidizes faster than undoped polysilicon. The rate of oxidation is determined by the dopant concentration at the polysilicon surface.[67] The addition of oxygen to polysilicon increases the film's resistivity, and the resulting coating, semi-insulating polysilicon (SIPOS) acts as a passivating coating for high-voltage devices in the IC industry. SISPOS has not yet emerged in surface micromachining.

Four drawbacks of in situ phosphorus doping are the complexity of the deposition process, slower deposition rates,[84] reduced film thickness uniformity,[82] and the cleaning of the reactor, which is more demanding for the doped process.

Diffusion is often a more effective method for doping of polysilicon than in situ doping, especially for very heavy dopings (e.g., polysilicon resistivities down to the 10^{-4} $\Omega \cdot$cm) of thick (e.g., 2 μm) films. However, diffusion is a high-temperature (e.g., 900–1,000°C) process. If the diffusion step is performed for long durations (a few hours) to achieve uniform doping throughout film thickness a few micrometers thick, it will destroy electronics that are fabricated on the wafer before polysilicon surface micromachining. If performed for too short a time, dopant distribution through the film thickness will not be sufficiently uniform, resulting in difficulties with mechanical property variations through the film thickness.

Ion implantation can also be used for doping polysilicon. The implantation energy is typically adjusted so that the peak of the concentration profile is at the center of the film thickness. However, the resistivity of implanted polysilicon films is not as low as that possible by diffusion.

As with undoped polysilicon, the intrinsic stresses in as-deposited doped polysilicon films are large (>500 MPa) and can result in warping or curling of released micromechanical structures. The values for the fracture stress of boron-, arsenic-, and phosphorus-doped polysilicon are 2.77 ± 0.08 GPa, 2.70 ± 0.09 GPa, and 2.11 ± 0.1 GPa, respectively, compared with 2.84 ± 0.09 GPa for undoped polysilicon. The lower value for phosphorus-doped material has been attributed to high surface roughness and with the large number of defects associated with extensive grain growth in highly phosphorus-doped films.[85] Maluf[86] reports that the operation of polysilicon at elevated temperatures is subject to long-term instabilities, drift, and hysteresis as a result of slow stress-annealing effects.

Several sensors using polysilicon piezoresistive sense elements have been demonstrated. The piezoresistive coefficient is an average over all the orientations in polycrystalline silicon. The gauge factor ranges between 20 and 40, which is about a factor of five smaller than in single-crystal Si, and quickly decreases as the doping exceeds 10^{19} cm^{-3}. At doping levels of 10^{20} cm^{-3}, the temperature coefficient of resistance of polysilicon is approximately 0.04% per °C compared with 0.14% per °C for crystalline Si. This is an advantage for the use of polysilicon, even though the gauge factor is low at these high doping levels.

PECVD and Sputtered Polysilicon

The quest for low-temperature polysilicon deposition processes is driven by the need for compatibility with prefabricated aluminum-metallized CMOS circuitry. This makes the 320°C PECVD and ~350°C sputter deposition methods of polysilicon especially interesting, although both methods result in amorphous films.

PECVD films, deposited in a 50-kHz parallel-plate diode reactor, can be doped in situ and crystallized by rapid thermal annealing (RTA; 1100°C, 100 s). It was shown that small-grained PECVD films annealed by RTA have good electrical properties and gauge factors between 20 and 30, similar to those reported for LPCVD polycrystalline silicon (see above).[87]

Honer et al.[88] introduced sputtered polysilicon to the MEMS community. Sputtered silicon can be used to fabricate polysilicon microstructures atop standard, aluminum metallized CMOS at temperatures less than 350°C. Films with stress values less than 100 MPa are routinely obtained.

An important benefit of both these low-temperature processes is that they are not only compatible with conventional oxide sacrificial layers but also with certain organic sacrificial layers (e.g., polyimide). Organic layers can be removed in a dry oxygen plasma etch, thus avoiding the stiction and selectivity problems associated with wet etch releases and at

the same time alleviating the concerns over chemical attack on structural elements by HF.

A drawback for the sputtered boron-doped Si films is that to increase their conductivity (to 25 mho/□), they need to be clad in symmetric, 50-nm-thick layers of titanium-tungsten.

Kamins[78] provides a detailed study of polysilicon physical properties. Another good resource on polysilicon morphology and doping can be found at http://www.iue.tuwien.ac.at/22.0.html. Sharpe and Edwards[89] at Johns Hopkins have perhaps provided the most detailed polysilicon mechanical property studies.

Thin Film Characterization

In Volume III, Chapter 6 on metrology, we detail thin film characterization. For material structure we rely on scanning electron microscopy (SEM), transmission electron microscopy (TEM), scanning probe microscopies (STM, AFM), and x-ray diffraction (XRD). For chemical composition we use auger electron spectroscopy (AES), energy dispersive analysis of x-rays (EDAX or EDS), x-ray photoelectron spectroscopy (XPS), secondary ion mass spectrometry (SIMS), and Rutherford backscattering (RBS). Mechanical properties of thin films are studied using residual stress measurement and micro-/nanoindentation. Electrical properties are derived from resistance (four-point probe) and capacitance measurements. For optical properties we rely on ellipsometry, and for film thickness we rely on stylus profilometer and ellipsometry.

We also introduce a wide variety of surface micromachined devices that are used in characterization of thin films.

Surface Micromachining

Introduction

Bulk micromachining means that 3D features are etched into the bulk of crystalline and noncrystalline materials (see Chapter 4). In contrast, surface-micromachined features are built up, layer by layer, on the surface of a substrate (e.g., a single-crystal silicon wafer). Dry etching defines the surface features in the x, y plane, and wet etching releases them from the plane by undercutting. In surface micromachining,

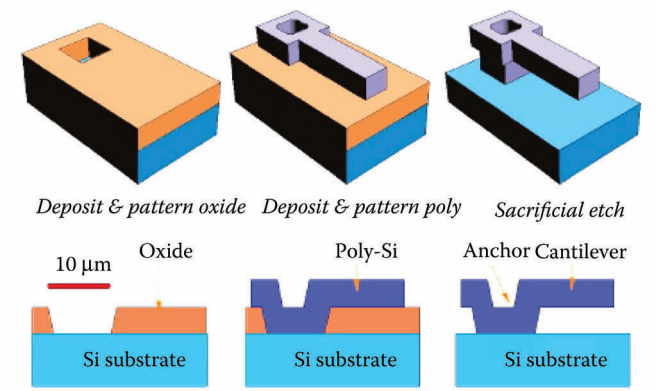

FIGURE 7.64 Surface micromachining of a polysilicon anchor.

shapes in the x, y plane are unrestricted by the crystallography of the substrate (see Figure 7.1). In Figure 7.64 a polysilicon anchor is made using typical surface micromachining techniques.
